TUNNEL VENTILATION DURING CONSTRUCTION

IMPORTANCE OF CAREFUL ATTENTION—QUANTITY OF AIR REQUIRED — MODERN METHODS OF REFRIGERATION AND VENTILATION IN LONG AND DEEPLY OVERLAID TUNNELS.

By E. LAUCHLI,
Civil and Hydraulic Engineer.

THE successful completion of over half a dozen long tunnels within the past 15 years has thrown much light on the ventilation and refrigeration of such tunnels during and after construction, and the progress of medical science, together with that of sanitary and mechanical appliances, has made possible for men to work, not only a few days, as, for instance, under the regime of the Cæsars, but for a lifetime, in tunnels subjected to high rock-temperature, deadly gases, and a high degree of humidity. The research work of the United States Bureau of Mines, in connection with the sampling and testing of mine and tunnel air, also that of inflammable gases and explosives, has added valuable information to that obtained from the driving of the long European tunnels.

Vitiation of the Atmosphere of Tunnels.—When exhaled by the human body, air contains about 4.4 parts of carbon dioxide and 15.4 parts of oxygen, as against 0.03 and 20.7 parts, respectively, when pure; thus, air exhaled by men, and incidentally by animals, is vitiated by a lack of oxygen and by an increase of carbon dioxide. A certain amount of water vapor is also expelled by exhaling and by the body, the amount depending on the percentage of humidity in the surrounding air. The amount of carbon dioxide excreted by the human body varies according to the degree of bodily activity; it has been estimated by various authorities that a man of average size gives out .6 to .7 cu. ft. of carbon dioxide per hour, but a man working hard gives out about 1.2 cu. ft. per hour. For certain practical purposes in connection with the subject treated in this paper, it is assumed that a tunnel-man, working under average conditions, excretes 1 cu. ft. of CO_2 per hour; practically similar conditions prevail with animals, and it has been determined that the amount of CO_2 excreted by a horse or mule is about 8.5 cu. ft. per hour.

Carbon dioxide to the extent of 2 per M. is not injurious to human beings or animals; as a matter of fact, human beings oftentimes spend several hours daily in rooms containing a larger proportion of CO_2 without experiencing discomfort. Railroad and street cars contain as much as 3 per M. of CO_2; cafes and theatres from 3 to 5 per M.; class-rooms up to 10 per M. Generally, however, little or no muscular efforts are exercised by people present in the above places; furthermore, their stay is relatively of short duration. In the Simplon tunnel, the amount of CO_2 varied from 0.5 to 7.5 per M. on the south side, and from 0.7 to 4.8 on the north side. Driving of the St. Gothard tunnel often proceeded with as much as 10 per M. of carbon dioxide.

The effects of carbon dioxide on men, animals and lights is quoted by different authorities to be as follows: Up to a content of 2 per M. of CO_2 in air, men and animals are capable of accomplishing hard and continuous work; with 10 per M. of CO_2, men are still able to work under normal conditions. without resenting ill effects; in a proportion of 50 per M., human beings are affected and lights burn poorly. Great danger for human beings when air contains 80 per M. of CO_2, and animals die when inhaling air with 130 per M. of CO_2.

The presence of gases has occurred not only in coal mines or coal-bearing strata; traces have been observed, and even large quantities of gases have been encountered in limestone, sandstone and shale formation, both in dry and wet tunnels. These gases, consisting chiefly of methane and hydrogen, are produced either by carboniferous, sulphuric or ore deposits, or by the chemical action of water, air, or both. Vegetable detritus and remains of dead animals lying on the ground surface, are carried by water together with air, into cracks or faults of the earth, where a chemical action takes place, and, according to the density of these gases and also of the structural formation of the ground, they either rise to the ground surface or penetrate deeper in the ground; whence their appearance in tunnels under construction.

In tunnel work, the daily consumption of some 800 to 1,000 lbs. of dynamite contributes largely to the vitiation of the air, especially in headings, where 50 to 80 lbs. of explosives are consumed per round, 6 to 8 blasts being fired in 24 hours. The effect on human beings of the gases of dynamite, consisting chiefly of carbon dioxide, carbon monoxide, nitrogen, and a smaller percentage of hydrogen and methane, is too well known to dwell upon here; poisoning, if not total asphyxiation, caused by inhaling some of the gases referred to above, has occurred only too frequently in ill-ventilated tunnels, and the engineer is confronted here with the complex problem of the preservation of life with a minimum consumption of time and power.

It is generally accepted that the explosion of 1 lb. of dynamite produces 3.4 to 3.6 cu. ft. of carbon dioxide. The burning temperature of nitro-glycerine has been found to be about 5,400° F., and it is estimated that the heat given out by the consumption of 1 oz. of dynamite was about 135,000 B.T.U.; yet, from observations made

in tunnels of small cross-section and in headings, where the consumption of explosives was high, it has been found that their influence on the air temperature was very small; due undoubtedly to the rapidity with which their combustion takes place, and owing to the low specific heat of their gases.

The methods that serve the purpose of increasing the speed of driving long tunnels, involve a large amount of materials to be drilled, blasted and removed, thus producing much dust, which naturally also adds to the discomfort of tunnel-men. In driving the Loetschberg tunnel, as many as 560 lin. ft. of holes were drilled in

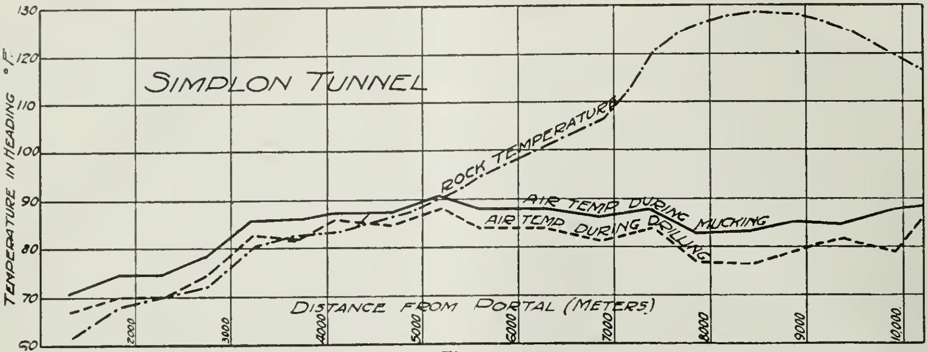

Fig. 1.

The removing and hauling of excavated and other materials necessitate the use of a large number of work trains. In the Simplon tunnel, for instance, 24 trains were usually run per day; in the Loetschberg tunnel, the traffic was still more intense, there being one train every

24 hours in the heading (limestone formation), thus causing some .75 cu. ft. of rock to be pulverized every hour, and when, in addition to this, some 500 to 600 yds. of materials were excavated daily, a large amount of dust was forcibly carried away by the powerful ventila-

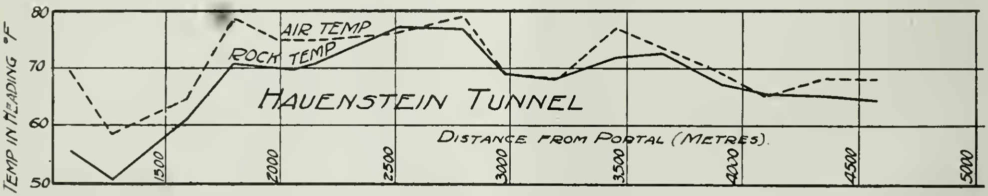

Fig. 2.

45 minutes; that is, 30 to 34 trains per day. Under similar conditions it becomes evident that the use of steam locomotives becomes prohibitive, for, besides being of no assistance to ventilation, like compressed-air locomotives, which in some cases exhaust from 2 to 5 per cent. of the total volume of the air introduced in a tunnel, they generate heat, gases and steam. The gases consist chiefly of carbon dioxide, nitrogen, some carbon monoxide and sulphur fumes. Gasolene locomotives have

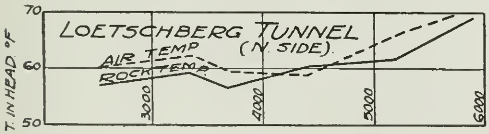

Fig. 3.

been used quite extensively, and when run properly they do not present such inconveniences as do steam locomotives. Under normal conditions, the gases exhausted consist of nitrogen, carbon dioxide and water vapor. When run in such a way as to cause incomplete combustion, the gases exhausted contain an appreciable amount of carbon monoxide, and in several instances this inconvenience has justified their abandonment.

tion. The introduction of water-core drills, together with the practice of sprinkling the muck before handling it, is a marked improvement in tunnel work. Certain materials, when drilled and blasted, give out less dust than others. For instance, mica-shist, and in general tough rocks, produce less dust than more brittle ones, like granites or limestones. The practice of allaying dust is

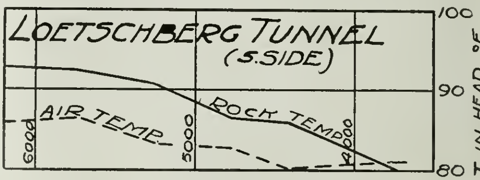

Fig. 4.

to be recommended, not only for the sake of the tunnel-men's health, but also to reduce the wear of tools and machinery.

The presence of candles, oil and acetylene lamps in a tunnel affect also to a large extent the degree of purity and the temperature of the air. In long tunnels as many as 300 to 500 lamps are used daily, and a consumption of 400 to 500 lbs. of oil or calcium carbide is not un-

usual. It is estimated that the amount of CO_2 produced by oil and acetylene lamps is about .8 and .53 cu. ft. per hour, respectively. The use of acetylene lamps is increasing rapidly in connection with tunnel work, and they are to be preferred to oil lamps, for, in addition to giving out less CO_2, the heat produced is about 7,500 B.T.U. per hour, more or less, according to the size and make; that is, about one-half only of that given out by oil lamps.

Heat Radiation of Human Beings and Animals, and Humidity of Atmosphere.—It is well known that the human body, also that of an animal, gives out a certain amount of heat by exhalation and by radiation, the amount depending upon atmospheric conditions and also on the degree of bodily activity; more heat is generated by a man accomplishing hard work than by a man at rest. As the result of various observations, it has been determined that with an air temperature of 70 to 80° F. the amount of heat given out by the human body is 10,000 B.T.U. per hour; that of a horse of average size, 95,000 B.T.U. per hour.

The proportion of humidity in the atmosphere plays also an important part in connection with the vitiation and temperature of the air in which tunnel-men are called upon to work. Human beings feel best when, at an average normal temperature, the percentage of humidity is 50 to 60 per cent. Everyone has observed that, when perspiration does not take place freely, a feeling of uneasiness is experienced; the greater the humidity, the greater the discomfort. It has been determined that the amount of water perspired by a man, at 84° F. and a percentage of humidity of 6, was 4 oz.; with the same temperature and 81 per cent. humidity, the weight of water perspired was only .85 oz. Men worked in the St. Gothard tunnel at a temperature of 86° F. and with 100 per cent. humidity; in the Simplon tunnel the percentage of humidity varied from 70 to 98; in the Loetschberg tunnel the humidity was high, reaching 100 per cent.

Miscellaneous Agencies Affecting the Purity of Tunnel Atmosphere.—In addition to carbon dioxide expelled when exhaling, foul or bad odors are excreted by the stomach or the body of men and animals, due either to improper digestion or uncleanliness. Unsanitary conditions, inadequate toilet facilities and poorly-drained tunnel stables for horses are all agencies contributing to the vitiation of the air in tunnels. Where a large quantity of timber is used, decaying or rotting of same, together with other agencies of lesser importance, all add to the evils above referred to.

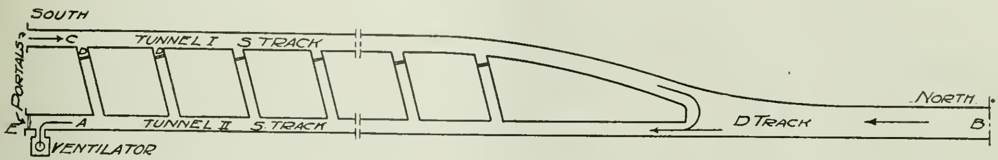

Fig. 5.

The quantity of carbon dioxide allowed or advocated nowadays in working chambers or zones of long tunnels varies from 1 to 2 per M., according to the conditions prevailing; under normal conditions, i.e., when the rock temperature and the consumption of explosives lie within reasonable limits, the last-named figure can be used, but when the rock temperature reaches 90° F. or more, and when 60 to 70 lbs. of explosives are consumed per blast, in heading work, it is advisable to keep the proportion of CO_2 within 1.5 per M. In the presence of methane or other explosive gases, it becomes necessary to keep the proportion of CO_2 within 1 per M.

Methods of Ventilation.—In driving long tunnels, little reliance can be placed on natural ventilation, for, even with a powerful artificial ventilation, the seasonal air temperature variations are but little perceptible in a tunnel, save within a relatively short distance from the portal. In the St. Gothard tunnel, for instance, no fluctuation in the air temperature was noticeable 3,500 ft. away from the north portal; in the Simplon tunnel, seasonal variations of the air were quite perceptible for a distance of 2,000 ft.; but 6,000 ft. away from the portal the temperature fluctuations were hardly perceptible. This tends to show that little attention can be paid to external high and low air temperature, and that weight should rather be given to the average yearly air temperature.

Although the basic method of ventilating short tunnels varies greatly, it is rather surprising to note that the plenum method has been used almost exclusively in driving some 10 tunnels from 2 to 12 miles long; this is due chiefly to the fact that conditions not met with in driving short tunnels are encountered in driving long ones. For instance, the driving methods used in connection with the last-named tunnels necessitated that fresh air should be distributed along various working sections of the tunnel, and in order to cool the air in the bore within a practicable limit, fresh air had to be supplied to the heading or other points within a very short time after leaving the fan or blower, so as not to be subjected to heating when coming in contact with the walls of bore, oftentimes warmer by many degrees than the air supply. The necessity also of using, for mechanical, construction and economical reasons, a primary ventilating system, consisting of fans located at the tunnel portal, and of blowers and injectors for the ventilation of the heading, are some of the reasons for giving preference to the plenum method of ventilation during construction. Yet, a combination of the plenum and

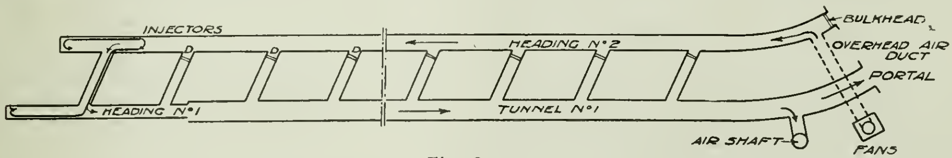

Fig. 6.

vacuum methods has been used in a few isolated cases, or when the portal ventilators were to be part of the system to be used in connection with the permanent ventilation after construction.

Quantity of Air Necessary for Ventilation During Construction.—This is by no means a matter of guess, as is often believed and done; erroneous assumptions have led to a lack of adequate ventilation in a few instances and to a waste of power in others. The amount of air necessary to overcome the evils caused by the agencies referred to in the first part of this paper can

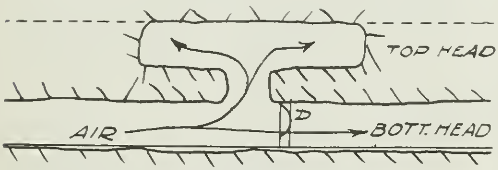

Fig. 7.

be based: (1) On the amount of carbon dioxide excreted or produced by men, animals and lights. (2) On the amount of CO_2 produced by the consumption of explosives. (3) On the heat generated by the presence of men, animals and lights. (4) On the heat occasioned by the temperature of the rock penetrated. (5) On the gases liable to be encountered during the driving period. (6) On miscellaneous agencies affecting the condition of air.

Then in formula 1, A equals 13,582 cu. ft., B = .002, C = 2,400,000 cu. ft., D = .0004, and Q is found to be 6,087,500 cu. ft. per 24 hrs., or 4,320 cu. ft. per min.

Should now the rock temperature be high, and the consumption of explosives very considerable, B should be made .00175, or even .0015. Using these figures in the above example would make Q equal to 5,330 and 6,840 cu. ft., respectively.

Formula 1, if used to determine the amount of air necessary for heading ventilation, would give results altogether too low to meet the requirements of heading work. In driving long tunnels, the field of operation is spread over a large zone, extending over a distance of several thousand feet, and blasting occurs at several points, as against one face only in heading work; also, the mining crews, timbermen, masons, etc., are distributed in small groups of ten to 50 men, in a room of large cubic contents. In a heading, altogether different conditions prevail. Here we have some 20 or 25 men with lights, cramped in a room 60 to 80 sq. ft. in cross-section and 100 to 150 ft. long; the consumption of explosives varies from 50 to 90 lbs. per blast, according to the material penetrated, and when 6 to 8 blasts are fired daily, as little time as possible can be lost after firing so as to enable the mining crews to resume their work. According to the efficiency of heading ventilation, the time lost or spent idly by the men, waiting for fumes to clear off after a blast, varies from 15 min. to one hour, 30 to 40 minutes being a fair average. In such cases, the amount of air necessary for adequate ventilation cannot be based on the amount of carbon dioxide excreted or

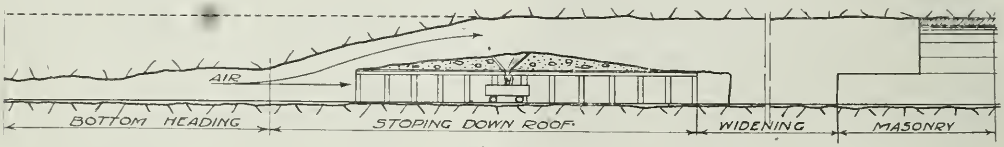

Fig. 8.

The vitiation of tunnel air referred to in items 1 to 4, inclusive, can be estimated with reasonable accuracy for all practical purposes, but the conditions brought on by agencies such as are referred to in items 5 and 6 can only be provided for by making a reasonable allowance for contingencies, and the judgment of the engineer, together with that of the geologist, should govern in this matter.

For nearly all practical purposes the amount of air necessary for the ventilation of a long tunnel during construction, exclusively of that for the ventilation of the heading, can be expressed by the formula:—

$$Q = \frac{A\,(1 - B)}{B - D} - C \quad . \; . \; . \; . \; . \; . \quad (1)$$

Where Q = amount of air, in cu. ft. introduced into the tunnel in 24 hrs.;
A = total amount of carbon dioxide, in cu. ft., given out in 24 hrs, by men, animals, lights and explosives;
B = amount of carbon dioxide allowed in tunnel air;
C = cubic contents (in cu. ft.) of the tunnel section in which crews are working;
D = cubic contents (in cu. ft.) of carbon dioxide in one cu. ft. of air, generally taken as .0004 cu. ft.

Example: In a tunnel driven under fair conditions, 3 shifts of 300 men, each with acetylene lamps and 4 horses, are employed, and 500 lbs. of explosives are consumed per 24 hrs. The tunnel crews are spaced over a length of 6,000 ft., and the tunnel has a cross-sectional area of 400 sq. ft. Carbon dioxide is not to exceed 2 parts in 1,000.

produced by men, animals and lights, but chiefly upon the consumption of explosives in one blast; also on the rock temperature and the gases encountered, if any.

The following formula, if used with judgment, will be found of assistance in determining the amount of air to be forced into a heading:—

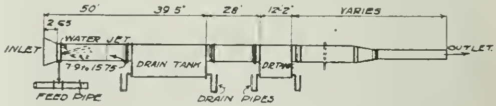

Fig. 9.

$$Q = \frac{\dfrac{A\,(1 - B)}{B - D} - C}{T} \quad . \; . \; . \; . \; . \; . \; . \quad (2)$$

Where Q = amount of air, in cu. ft., introduced in the heading per minute;
A = amount of carbon dioxide, in cu. ft., produced by the consumption of explosives in one blast.
B = amount of carbon dioxide specified for the air in the heading at the end of time, T.
C = contents of heading in cu. ft.
D = .0004.
T = time from explosion of round until resumption of work in heading (in minutes).

Example: In a heading 7 x 10 ft. in cross-section, and 300 ft. long, the consumption of dynamite per blast is 60 lbs.

• The men are to work in an atmosphere containing not more than .002 of carbon dioxide, twenty minutes after firing a blast.

Then in formula 2, A equals 210, B = .002, C = 21,000, D = .0004, T = 20, and Q is found to be equal to 5,500 cu. ft. According to the conditions prevailing, Q can be made larger or smaller by giving B or T different values.

The total quantity of air to be forced into the tunnel is the sum of the value for Q as given by formulæ 1 and 2, or in the example selected = 4,230 + 5,500 cu. ft. = 9,730 cu. ft. An allowance of 20 to 30 per cent. should be made for contingencies.

The amount of air to be forced by, and the capacity of the ventilators depends to a large extent on the type of drills used in driving a bore. The Mont Cenis and St. Gothard tunnels were driven solely with the assistance of the ventilation produced by the exhaust of air-drills; the ventilation thus available was poor, however, and insufficient in many instances; yet these bores were completed without other means of ventilation. The rock temperature in these tunnels was not very excessive, and the driving progress very slow. On the other hand, the capacity of the ventilating plant of the Simplon tunnel was remarkable for its magnitude, necessitated by a high rock temperature and by the total absence of air-drills, water-drills being used in the heading, and hand ones in the enlargement. The use of air-drills, and practically the complete abandonment of hand drilling in connection with the driving of recent long tunnels, besides enabling more progress to be made at a lesser cost, has become a valuable auxiliary to tunnel ventilation. In the Loetschberg tunnel, from 4 to 6 large Ingersoll Rand drills and as many as 15 hammer air-drills were used. In the Hauenstein tunnel there was as many as 40 drills at one end of the bore.

Fig. 10.

Fig. 11.

Table 1 gives the amount of air introduced into the south side of the Loetschberg tunnel by the ventilating system, together with that of drills and locomotives; thus 7 to 22 per cent. of the total amount of air introduced into the tunnel was exhausted from the drills, while that introduced by the air locomotives was as high as 5.4 per cent. of the total. As a matter of fact, later on, 50 per cent. of the air introduced into the bore was exhausted from the drills. This fact is to be kept in sight, for it demonstrates in a most convincing way that, instead of using a large amount of power for the ventilation alone, it is more economical to use power that will operate drills first, and then be still of utility for ventilating purposes.

From others and the writer's observations, it has been found that, for low rock temperatures, up to, say, about 90° F., the air temperature in a tunnel or heading is 5 to 7° higher than the rock temperature, and also that the air temperature reached a maximum during mucking (see Figs. 1, 2, 3, 4). At this very moment, that is just after firing a blast, the drillers are busy setting up their drills, the muckers are loading the blasted material into cars as rapidly as possible, thus the necessity of doing away with the fumes of explosives in a minimum lapse of time.

Refrigeration of Tunnels during Construction.—It is beyond the scope of this paper to go into lengthy details pertaining to the refrigeration of long tunnels during construction; however, let it be pointed out briefly that the cooling of air by air is only possible or economical within a certain limit. In the Simplon tunnel, for instance, this limit was reached when the air temperature in the tunnel was 100° F. In order to cool the tunnel by the introduction of fresh air, when the rock temperature is high, it would be necessary to force in a large amount of cool air from outside; but, as the size of ventilating pipes or conduits is limited to certain practical dimensions, depending on the room available, the velocity of the air conveyed by these would soon reach too high a velocity; the friction would increase rapidly, thus generate heat, and the air would reach its destination at too high a temperature to be effective for refrigerating purposes. Should the fresh air supply be a few degrees warmer than the rock temperature when reaching the heading, it would have little cooling effect, if any, on the air temperature. Fortunately, in most cases, the ventilating air has a lower temperature than that of the rock. With a high rock temperature of, say, 100° or more, other means of refrigeration have to be resorted to. As it is not proposed to describe here the methods that have been or are being used to ventilate long tunnels in each case, the reader is referred to Table 2, giving the characteristic features pertaining to the ventilation of 12 tunnels 12,000 to 65,000 ft. long; yet it is interesting to review the methods advocated or used at various epochs of modern construction.

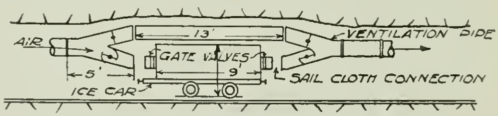

Fig. 12.

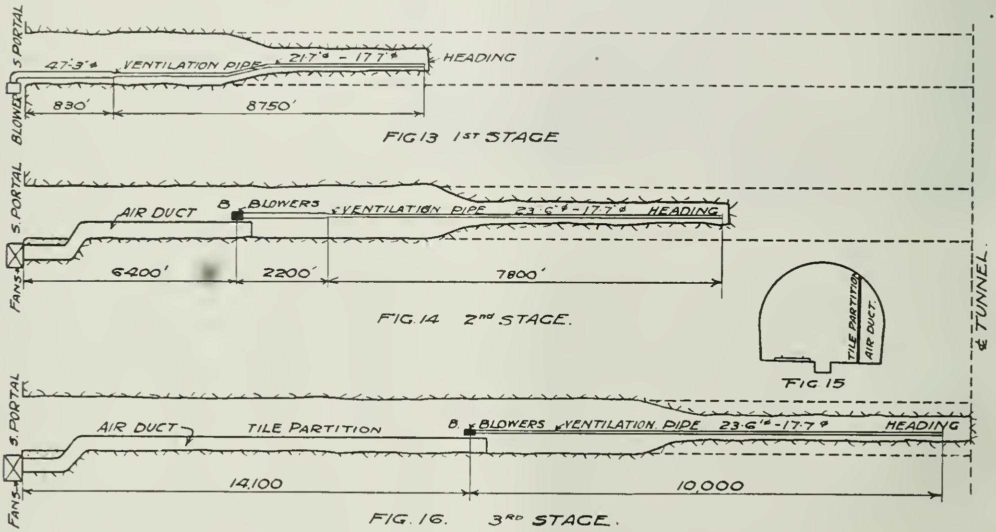
The experience gained in driving the Mont Cenis and St. Gothard tunnels had demonstrated clearly the inconvenience caused by inadequate ventilation, and when the driving of the Arlberg tunnel was started, an elaborate ventilating plant was provided at each portal. On the east side of the bore, where air-drills were used, the capacity of the plant was 5,300 cu. ft. per minute, and on the west side, where water drills were used, 6,350 cu. ft. Iron pipes served as means of air conveyance. Later on, the capacity of both systems was increased to 12,600 cu. ft. per min.

In 1891, when the Simplon tunnel project was considered anew, it was estimated that, having regard to the high rock temperature to be expected (107° F.), an adequate system of ventilation would be required, and the following plan of construction was advocated (Fig. 5). From the north portal to about half-way between portals the tunnel was to have a cross-section accommodating two tracks; the bore would then branch off in two single-

track tunnels extending to the south portal and connected at intervals with cross galleries. During construction, on the south side, a ventilating plant at the portal of Tunnel 2 was to exhaust the vitiated atmosphere of Tunnel 1 through the cross galleries; Tunnel No. 2 was to be closed at the portal by a bulkhead, E. Thus, fresh air would rush in at C during construction, and also at B after completion of the tunnel. During the driving period the cross galleries, except that nearest to the heading, were to be closed by bulkheads, D. On the north side, the ventilation was to be provided by forcing in air from the portal through a 31.5-in. diam. pipe. It was estimated that, theoretically, 56 cu. ft. of air per sec, and per h.p. could be forced in through the ventilating pipe, and 9.5 cu. ft. per sec. and per h.p. through the double tunnel system on the south side. Thus, for equal power consumption, the intensity of the ventilation would be 17 times greater with the double heading system than with the ventilating pipe. Later transverse gallery next to the heading's face. Power-driven blowers were used also to some extent, but with little success. The intake end of the injectors was located in heading No. 2, and one pipe conveyed air to each heading. Each injector consisted of a nozzle through which 3.8 cu. ft. of water was discharged per min. at 1,100 lbs. pressure and 280 ft. vel. per sec. About 2,100 cu. ft. of air was thus forced per minute, at 5.6 oz. pressure, through 300 ft. of 15.7 and 8-in. diam. pipe. As many as four injectors were installed on one conduit, 1,300 ft. long.

Owing to the increase in temperature, the primary and secondary ventilating systems soon became inadequate, and the following methods of refrigeration were resorted to: In heading No. 2, 21 water sprays (Fig. 10) were installed, forming a water curtain 65 ft. deep, through which passed the air, forced in by the portal fans. The air thus cooled off, but containing much humidity, was forced through wire screens located in



Figs. 13, 14, 15 and 16.

on it was decided to drive two single-track bores between the end portals.

Ventilation and Refrigeration of the Simplon Tunnel as Actually Built.—The primary ventilating plant consisted of 2 fans, 12.3 ft. in diam., each driven by a 200 h.p. hydraulic turbine, located at the portals (Fig. 6). When running in parallel, the capacity of the fans was 105,900 cu. ft. per min. at 5.7 oz. water pressure. Air was forced into heading No. 2 and exhausted through Tunnel No. 1, being conveyed from one bore to the other through the gallery nearest to the heading's face, and the others closed by a bulkhead, D.

In order to ventilate the top heading, a sailcloth curtain (Fig. 7) was provided at each upraise to deflect the air current upwards. In the very hot sections, however, the ventilation of the top heading became so inadequate that, instead of driving a top heading, it became necessary to stope down the rock, overlaying the bottom heading, on a timber platform (Fig. 8). This method of ventilation was found to be more effective, the air being thus given a better circulation through both the top and bottom headings. The secondary ventilation consisted of water injectors (Fig. 9) installed at the front of the sprays. This system, although very effective, was a serious hindrance to traffic, and it was superseded by that illustrated in Fig. 11. The above appliances enabled air to be cooled by about 17° F., the temperature of water used for spraying purposes varying from 39 to 62° F., according to the season.

In order to cool the air conveyed by the ventilating pipes in the headings, ice cars were branched on the ventilation pipes (Fig. 12) and air forced through these. Each car contained 513 vertical tubes 1½ in. diam., 31 in. long, presenting to the ventilating air a surface of 540 sq. ft. This cooling system necessitated twelve ice cars per day; after five months' use it was abandoned altogether, being too costly and very cumbersome. In addition to the above refrigerating systems, perforated pipes located at intervals in the tunnel or headings served the purpose of sprinkling the walls of the bore with cold water.

From observation it has been determined that in heading No. 1, for instance, when the rock temperature was highest (130° F.), the cooling effect due to air and water supplied for this purpose was as follows: During drilling 11.6 B.T.U. were absorbed per sq. ft. of rock

surface and per hour, and during mucking 6.4 B.T.U. per sq. ft. per hour.

Ventilation of the Loetschberg Tunnel.—The system of ventilation used on the south side of this bore will be described only, that on the north side being similar, although somewhat less elaborate.

pipes varying in dia. from 47.3 to 17.7 in. At intervals, water injectors were provided on the pipe, and, as work progressed, the masonry duct and the secondary ventilating plant, the latter being carried on trucks (Fig. 17), were moved forward. According to the rock temperature, as many as 3 electrically-driven blowers were pro-

During the first construction period, that is, until the tunnel had reached a length of about 11,500 ft., the ventilating plant consisted of 2 Capell blowers (Fig. 13), located at the portal, and having a total capacity of 4,200 cu. ft. per min. at 10.8 oz pressure. Air was forced through wrought-iron pipes, 47.3 in. diam. at the blower outlet and 17.7 in. in the heading. When the pipes had

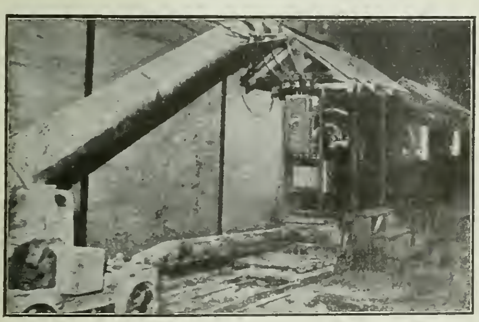

Fig. 17.

reached a length of 7,300 ft., two water injectors were installed on the pipes, this system being used until the tunnel reached a length of 11,500 ft., and as many as 4 injectors were used on the air conduit. Soon after the ventilating plant, which was to be used during the operation of the tunnel, was put in operation; it consisted of two fans, 11.5 ft. diam., driven by 175 h.p. electric motors, and having a total capacity of 106,000 cu. ft. per min. at 5.7 oz. pressure. Air was conveyed in the tunnel through a duct of 68 sq. ft. area (Figs. 14, 15 and 16), consisting of blowers "B" of 100 cu. ft. capacity per sec., taking air from the main ventilating duct and forcing it through the heading at 3.8 oz. pressure through

vided on the ventilating pipe. When available, large quantities of snow were also introduced into the tunnel. During construction, the primary ventilation was found to be of too high a capacity, and the air supply was reduced to 10,000 cu. ft. per minute.

Conclusions.—For tunnels 25,000 to 35,000 ft. long, a ventilating system consisting of fans at the portals, forcing in a large quantity of air at low pressure, and of power-driven blowers and water injectors, for the ventilation of the heading, will be found amply adequate in most instances; for, let it be pointed out here, that there exist a relation between the length and the mass, or height of material overlaying a bore; one can hardly conceive a short tunnel very deeply overlaid.

For double-track tunnels, 40,000 to 50,000 ft. long, when the rock temperature is not expected to exceed 100° F. by many degrees, a duct system similar to that used in the Loetschberg tunnel will prove ample and feasible in most cases. For longer tunnels, where a high

rock temperature may be encountered, the double-bore system, consisting either of 2 single-track tunnels, or of a double-track tunnel with an auxiliary bore of smaller dimension, driven parallel to and connected at intervals by cross galleries with the main bore, may have to be resorted to.

LAYING OUT SIDE HILL ROADS.

THE following method of laying out contour grades for side hill roads is from a paper written by Capt. A. C. Gardner, Chief Surveyor, Land Titles Office of Saskatchewan for the Regina Engineering Society. At the outset he emphasizes the desirability of the engineer appointed to such work being thoroughly practical, and claims the following as valuable assets: a good knowledge of the country, as to climatic conditions, nature and extent of the different seasons and general requirements, also a well developed faculty for recognizing suitable road locations.

A few years ago, in addition to probable amount of traffic, the most serious question was to obtain a satisfactory road at much below minimum cost of suitable construction and the views of the engineer had in many cases to be sacrificed, in order not to exceed the amount allowed. At the same time some kind of an outlet for traffic had to be provided, and that in many cases quickly. This state of affairs was unfortunate, as a certain amount of discredit has been reflected upon the engineers who had to lay out roads of this nature, and who are entirely blameless as to excessive grades and poor locations. The engineer has generally a choice of locations, the first considerations in choice being the most direct, easiest grade, minimum cost of construction and up-keep. This choice can readily be determined with a climometer and the assistance of one or two men. Whether starting from the valley or upland, very often a good idea of feasibility of location can be determined in the following manner, viz.: Starting at the approximate point of commencement and sighting on some conspicuous point at the approximate outlet, the angle of elevation is read and knowing the distance approximately between the two points it is a simple mathematical problem to work out what the probable grade would be and if results are at all satisfactory much time has been gained. These rough shots are worth trying if they can be taken. In any event, having decided where the engineer will try and get his location the practice would be to put on an angle of elevation or depression (as the case may be) which gives about two-thirds of the maximum grade intended for the road, the rodman is then instructed to take up points from one to three hundred feet apart and at all prominent points encountered along the preliminary grade line, rough stakes are driven temporarily to mark the points above mentioned. Whilst engaged in this work careful notes should be taken as to the suitability of location, where the grades can be altered to advantage, location of springs, number of culverts required for proper and effective drainage, suitability of road for traffic at all seasons of the year, whether the road would be easy of construction or otherwise, and many other points of more or less importance. The author usually accomplished the reconnaissance work in from a few hours to one or two days, depending on the length of road and the difficulties to be overcome. In some cases, having run the preliminary grade and finding the outlet unsuitable, he would choose a suitable outlet, and starting there, run in a reverse direction, generally meeting the first grade at some point on the way up or down (as the case might be). Having decided upon the location by the above means, the author next had his men cut the necessary number of stakes. These were about 1½ inches in diameter and 18 inches long, and blazed on both sides (material usually easily obtainable at or near location of this kind). In the meantime he would probably walk over the location several times, taking notes as to final location. A little difficulty is encountered at first in setting up an instrument on hillside work and some care is required to avoid disturbing the adjustments of same after it is set up, but this is soon overcome by practice.

Method and Practice of Staking Final Location.—First have the rodman cut a rod about 1 inch in diameter, cut square across at both ends and peeled or blazed, the length of rod equal to the height of axis of telescope from the ground (the instrument being set at height suitable to the observer) usually from 4½ to 5 feet. The instrument is then set up at point of commencement and the height of same guaged by rod., i.e., rod on ground and top reaching axis of telescope, the instrument is levelled and angle of elevation (or as the case may be) to give the required grade set off on vertical circle and telescope clamped. About thirty-four and one-half minutes gives a one per cent. grade. The rodman then starts off with a bundle of stakes holding one crosswise on top of his rod and moves up or down the hill till the observer sees the stakes cut by the horizontal hair. Stakes are numbered consecutively and driven by another man following along the line. This man also keeps the rodman supplied with stakes. The interval between stakes is from 15 to 20 feet where hillside is uniform and at closer intervals where pronounced irregularities are encountered. So long as the line of sight is direct and grade uniform, the line can be staked for a considerable distance from one station, when the line begins to swing appreciably either towards the observer, or the reverse, or where it is desired to change the grade, the next station is taken up over the last stake set and instrument set up in the manner previously described; all sharp and short turns are run in either level, but in any case not exceeding a one per cent. grade. A slack grade is always put on at the outlet of the road, particularly if the bulk of heavy traffic is going up hill. Where a uniform grade could be obtained for any considerable distance, the author usually broke same in several places unless the ground admitted of a very slack grade in the first instance. At all runways or wherever he intended placing a culvert, a long stake would be placed about the centre of the proposed road, the rod was held on top of same and stake driven until the top became grade, the stake was then marked "culvert" and dimensions stated on one side, and on opposite side of stake was written "grade; fill to top of stake." It is often necessary to go back over portions of the staked line improving the grade wherever possible. The grade can easily be determined at any point where it is desired to commence a change by setting up over stake at this point and then directing the rodman to go backwards and forwards about five or six stakes. The telescope is then directed on cross stake on top of rod and clamped. Angle is then read on vertical circle, and as a further check the rodman then moves forward holding rod at foot of each stake set. If the horizontal wire cuts stake held on top of rod in each case you have the grade from angle given on vertical circle in the first instance. The changing of grade does not occupy much time once the line is established. Having staked the grade the writer would then engage a farmer and have him plough a furrow along the line of stakes where the hillside was open, using one of the men to either hold the plough or drive the horses, and

going along with them would see that the line of stakes was closely adhered to and a suitable furrow made. This left an almost permanent grade line, even if the stakes were knocked down or fell out. The furrow was not necessarily through the bush, as a clear-cut line was always made which could be easily picked up for a considerable time afterwards, and stakes were not liable to be disturbed.

To ensure a satisfactory road being built, it is advisable (if possible) for the engineer to have the road foreman with him when he stakes the grade or before he leaves the ground, and by going over the line with him and pointing out how he will be able to strengthen the road and round out the bends, also how to work from the staked line or furrow (and if a practical man) he will in a few hours thoroughly understand what is required and how to carry out the work.

In making the survey of the road the writer usually ran the line so that the road foreman, in order to keep within the limits of roadway, practically had to follow, not only closely to grade, but also required to straighten road and round out bends. It is, of course, advisable for the engineer to be on the ground at least a portion of the time during construction. The author was seldom able to do this, but by taking the above precautions most of the roads he laid out were satisfactorily constructed.

The longest and most satisfactory side hill which he laid out by the methods above described is about 2¾ miles in length. Maximum grade 5½ per cent. with an average grade of about three per cent. or slightly under. All the curves are practically level and several of the shorter turns are level. There is one small timber bridge which eases out a very sharp bend and avoids a large spring, situate about one-quarter of the way down hill. The road was constructed under the supervision of a Mr. J. Bird, road foreman and contractor.

At the time, construction of this road was considered expensive. It did not, however, cost any more, if as much, per mile, as some of the roads constructed on the uplands where many ponds or sloughs were encountered.

It would be out of place in this paper to discuss the usual methods of staking out side hill roads beyond stating that in comparison, it is practical, economical, rapid and easily picked up at some future time as this location remains much longer defined on the ground, and if marked in the manner described it is apparent to anyone what the grade will be (i.e., easy or otherwise). Considerable time in the past often elapsed between location and construction. To somewhat support this statement, the following is an extract from the report, 1909-10, of the late Mr. E. W. Walker, District Surveyor and Engineer, Department of Public Works, Province of Saskatchewan. (Mr. Walker, in speaking of methods, means the usual method of staking centre line and putting in slope stakes).

"The shortcomings of these methods, as I see them now, are that this work is often done so long before the road foreman and grading crew begin operations, that the stakes with their markings, as planted by the engineer, have disappeared, and the engineer is called upon to replace and re-mark these before the work of grading can be commenced properly, and it therefore tempts the road foreman to go ahead with the grading, disregarding the stakes if he has to replace and re-mark them from the engineer's diagram which, in many cases, he doubtless does not fully understand or appreciate."

According to a recent statistical report laid before the aldermen of Montreal, within the last four years, the city of Montreal has spent approximately $100,000,000.

TOWN PLANNING.

In a paper entitled "Housing and Town Planning," read by Christopher J. Yorath, A. M. Inst. C.E., M. R. S. I., city commissioner of Saskatoon, at the Calgary convention of the Alberta Town Planning Association, June 16, 17 and 18, the two chief problems with which civic improvement organizations have to contend were severally dealt with. Concerning bad housing, the primary causes were given as follows:

(1) Lack of proper legislation;
(2) Lack of sympathy between landlord and tenant;
(3) Insufficient education; and
(4) Overcrowding due to want of proper transit facilities and the number of houses allowed to be built on an acre of land.

The author dealt at length with these evils and went on to show how the questions which usually face the problem of housing reform are dealt with in Great Britain. He summarized the position of housing as it is at the present day as follows:

1. Unhealthy areas and dwellings exist which can and must be dealt with by the local authority.

2. Houses unfit for human habitation must be made fit for human habitation at the cost of the landlord, if necessary the local authority carrying out the work.

3. The provision, where insufficient, of more dwellings for the working classes, either by the local authority or through building societies.

Town Planning.*—In the building of every city there should be some object in view, some aim towards which those who are responsible for its foundations and growth are consciously aiming. Unfortunately, in the majority of cases the aim has been an unconscious one with the result that cities have grown up in a haphazard manner and many a beautiful spot turned into an ugly accumulation of bricks and mortar. Until recent years, it was thought that the checkboard system of planning was all that could be desired, but anyone who has studied the subject of town planning will realize at once that it is a failure and has necessitated even in what are known as the New World Cities, large expenditure to rectify some of its many defects. How can a system be called a plan which does not take into consideration local characteristics such as the undulation of the ground, a winding river, thickly wooded spots and other amenities.

It invariably happens that town planning is not thought of or put into operation until a certain amount of development has taken place. In Great Britain this does not interfere to any great extent with the planning for the future, as the undeveloped land is not staked out into lots and held by numerous landholders, but is usually in possession of a few; whereas in Canada, owing to the checkboard system and the selling of outlying plots far in advance of the time when the land is ripe for development, the proper planning of the future is rendered far more difficult and in many cases the difficulties will be so great as likely to make a scheme impracticable without special legislation.

A city attractive by its beauty, by its artistic symmetry and design and by the amenities and conveniences which it offers, will gain a reputation and an individuality of which not only its council and its landowners but also its citizens may be proud.

The aim of every city should be the one implied by the term "Garden City," beautiful, well planted and finely

*[This section of Commissioner Yorath's paper is given practically in full.—Editor.]

laid out, known and characterized by the charm and amenities which it can accord to those who seek a residence or dwelling removed from the turmoil, stress, and discomforts of a manufacturing district.

The various systems of planning which have been adopted in the past are rectangular, radial, and circumferential and curvilineal, but the latest schemes for town planning are generally a combination of all three, which allows for the best fulfilment of town planning ideals.

Essentials in Making a Town Plan.—The most essential points for consideration in the drawing up of a town plan are:—

(1) A general survey of past growth, present conditions and future possibilities.

(2) The preparation of a map of the city and its environment showing the configuration and undulations of the site, etc.

(3) The entrances to the city by water and land.

(4) The direction of main, radial and circumferential avenues and boulevards.

(5) Transportation.

(6) The layout and construction of avenues, drives and boulevards.

(7) The appearance and furnishings of the streets.

(8) The provision of parks, open spaces and recreation grounds.

(9) The administrative or civic centre.

(10) The defining of areas from a residential, industrial and commercial standpoint.

(11) The architecture of buildings, the space about same, the limitation of houses per acre, and the height and character of same.

(12) The design of water, sewerage and tramway systems.

Survey of Past, Present and Future Growth of City.—Before commencing a town plan it is necessary that the town planner should make a complete survey of the site and make himself thoroughly acquainted with local conditions. He should consider the rate of development of the city in the past and whether conditions will be such that its rate of development will be as great or greater in the future and what the main factors governing its growth and expansion will be.

In framing the town plan for Saskatoon, the writer had consideration for the following:—

(*a*) That the population had increased from 113 in 1903 to 30,000 in 1913.

(*b*) That it is the geographical centre of the fertile portion of the province of Saskatchewan.

(*c*) That it is served by the three principal Canadian railways and has a distribution area of 48,000 square miles.

(*d*) That a large terminal elevator is being constructed by the Dominion Government, and the city is likely to be the large wheat collecting centre for the Hudson Bay route.

(*e*) That owing to its being in a position to obtain cheap power from the large gas fields in Western Saskatchewan, it is likely to increase in importance as a large manufacturing and distributing centre.

(*f*) That, having the University and Agricultural Experimental Farm, it will be the educational centre of the province.

Having regard to all these circumstances, it was decided to plan the future growth of the city for a population of 250,000, with facilities for further extension without impairing the general design.

Map of City and Its Environments.—Many of the once beautiful sites which some of our cities now occupy have been wantonly spoiled by the worst form of vandalism and the lack of a proper system of planning instead of providing a setting and vista by which the beauty of monumental and public buildings may be shown.

The second step preparatory to the drawing up of a town planning scheme is to make a contour map of the site with contours showing the rise or fall of the ground every five to ten feet. The map should be drawn to a scale of not less than 400 ft. to an inch, and in addition should show existing trees, places of historic or local interest, railways, existing residences, public and industrial buildings, waterways, etc. The map should also show any towns or villages in the vicinity of the city, which may possibly become in the future, part of the city, together with the most important main roads or trails leading to or from the city.

This map will enable the town planner to lay down the main radial and circumferential avenues so that the important transit routes are linked up one with the other in such a manner as will avoid traffic congestion in the centre of the city. It will also enable him to preserve places of beauty, the water front, and to establish the most important buildings in commanding positions; to design his storm and sanitary sewers so as to obtain the maximum amount of gravity flow and to arrange his water supply in the most suitable zones so that the whole system of public utilities can be built up in units, which will ultimately become parts of a completed whole.

In Canada the preparation of this plan is more costly and entails a far greater amount of work than the preparation of a similar plan in Great Britain, as in the latter country the Ordnance Survey, which is carried out by the government, is complete in every detail, even to the showing of lamp posts on the streets.

The Entrances to the City by Water and Land.—After having secured a plan of the town or city as it actually is, the town planner should become thoroughly acquainted with its approach by land and water, so that he can lay the foundation of his scheme from these points in such a way that the visitor as he approaches the city will be immediately impressed by its civic dignity and beauty.

The water entrance may be from the sea; by river; or by lake and gives innumerable opportunities (owing to its varied characteristics) of special treatment, and cannot be too carefully studied before finally settling upon the scheme which will for all time be the chief characteristic by which the city is known.

How often is the water front spoiled by being entirely occupied by quays, warehouses and railways, when with a little judicious planning the whole could have been so planned as to make a commanding entrance. Space can be provided for all without disfiguring the natural beauty of the site; the quays can be made to follow the graceful curves of the shore and spacious esplanades provided to break the monotony of continuous lines of warehouses. If the ground should slope towards the water front much can be done by terracing, boulevarding and parkways which will add dignity and beauty to the site. By grouping the principal buildings and providing spacious and well-planted boulevards leading to and from the main front, a facade will be provided which will at once impress upon the mind the civic splendor and harmony in style.

Again, the graceful winding river so often found running through the heart of a city should be jealously guarded as the most beautiful asset which a city can

possess. Its banks can be made beautiful by the planting of trees, if they are not already wooded, and parks, terraces and boulevards provided which will be the most cherished belongings of the community. Sometimes the banks are flat, with large stretches of mud and the stream is very sluggish. This defect can often be remedied by formation of embankments and the land reclaimed formed into river-side parks.

Saskatoon has the South Saskatchewan River running through its centre with well-wooded and gradual sloped banks. In the town planning scheme which has been prepared by the writer, provision has been made along both sides of the river to form drives and boulevards, so that eventually when the scheme is completed a continuous drive of over 14 miles in length will be provided.

Again, the entrance to the city over the river by means of bridges should be considered from the architectural and scenic point of view. The whole beauty of the river may be spoiled by the construction of inartistic bridges, whereas they should be made to harmonize with their general surroundings. Every bridge over a river should be made a monument to the town.

Main, Radial, Circumferential Avenues and Boulevards.—The planning of the main, radial and circumferential avenues forms the skeleton upon which the town plan is built up, the minor and residential streets filling in the detail.

The main avenues, including the encircling boulevards and radial avenues bear the heavy traffic as they are usually the shortest means of transit between important points such as railway depots, quays, industrial and manufacturing districts. These avenues usually contain a street railway and should be made of sufficient width not only to take heavy traffic but also that they may be made attractive by means of boulevards.

In many of these avenues the street railway is laid in the centre of a boulevard with shaded walks on either side. By this method of construction a considerable sum of money is saved as compared with the system of paving the whole width of the track, and in addition a very much quicker means of transit is obtained as the railway is not hampered by the ordinary traffic of the street.

In planning out the widths of main roads it is difficult to estimate what the future will demand, but in any case it will be better to err on the wide side rather than the narrow.

The various types of streets usually required in a city are:—

(*a*) Main traffic avenues with tramways and boulevards (width from 100 to 200 feet).

(*b*) Secondary traffic avenues without provision for tramways (80 to 150 feet).

(*c*) Semi-residential avenues with provision for side and centre boulevards (width from 80 to 120 feet).

(*d*) Semi-residential avenues without provision for tramways but with side and centre boulevards (width from 80 to 100 feet).

(*e*) Residential avenues without provision for tramways but with side and centre boulevards (60 to 80 feet).

(*f*) Secondary residential avenues (width from 40 to 60 feet).

Transportation.—The most rapid and direct means of transport from and to important parts of the city is one of the chief considerations in the framing of a town plan, and emphasizes the necessity of developing the city's transportation facilities as a whole, and not as is often the case, the independent development of railway, water and interurban transportation. This latter method often entails very large expenditure in linking up the different systems in order to increase the efficiency of transportation. It is now realized in all large cities that enormous sums of money can be saved by commerce and industry if rapid means of transit are provided; and in many cities underground subways and elevated railways have been constructed in order to relieve congestion and provide this very essential requirement to aid the economic expansion of trade.

The Appearance and Furnishings of the Streets.—While it is essential and necessary in a town planning scheme to make provision for wide streets and to control the architecture of buildings, it is also important to remember that all objects in the streets, utilitarian or otherwise, are things to be seen, part of an organic whole, each having its respective part and place.

The furnishings of a street usually consist of street lighting posts, direction posts, telegraph and telephone poles, street railway poles and overhead wires, police patrol and fire alarm systems, letter boxes, public conveniences, advertisements, placards, etc.

It can easily be conceived and readily understood that if all these poles and erections on the street are neglected and allowed to be erected haphazard and without regard to artistic taste that no matter how much care may be taken in the upkeep of boulevards, and the control of architectural design that the general appearance and harmony will be spoiled.

The civic authorities and town planners should therefore give as much consideration to the details of street furnishings as to the development of the town plan if they wish to obtain the best results. The street lighting posts should be properly designed and appropriate in style; the street railway posts should also be artistically designed with ornamental base, etc. In many cities on the continent of Europe these posts, in the summer, are very much improved in appearance by flowers and drooping creepers hung from a basket fixed round the post.

Wherever possible, telephone and electric wires should be placed underground, as not only are the poles and wires a great disfigurement, but the poles occupy valuable space and they are a considerable source of danger to the public.

Parks, Open Spaces and Recreation Grounds.—In locating open spaces and parks, special consideration should be given to the preservation of places of natural beauty, such as wood, waterways, etc., and by the adoption of a town plan a young city can make provision for parks, etc., at very much less cost than would be the case in later years when building development has not only spoiled many beauty spots, but increased the value of land to a prohibitive price.

It is important that there should be ample reservations of open spaces, public parks and pleasure grounds, as without these "lungs" the health of a city must be very much impaired.

Although an endeavor has been made from time to time to fix a ratio of park area with population, up to the present there is no accepted ratio, as local conditions vary to such a large extent. In the United States it has been found that in cities with populations over 100,000 the number of persons per acre of park varies from 11,000 to 27,000.

With the checkboard system of planning, a large amount of valuable ground is often wasted in the unnecessary provision of paved streets and passages. By carefully planning the main and secondary avenues, through

traffic can be avoided and residential districts can be laid out in a far less costly manner, part of the space occupied by paved streets being utilized for open spaces, tennis courts, and children's playgrounds.

People's parks are universally provided on the continent, which contain sufficient acreage to include a complete natural landscape, typical, as far as possible, of rural country.

It has become a very general rule in making arrangements for the development of land on modern lines in Great Britain to stipulate that one acre in ten shall be set aside as public, or semi-public open spaces—this in addition to limiting the number of houses per acre.

In addition to the large people's parks, open spaces should be provided in each locality where games and recreation can be enjoyed by the people without having to travel any great distance from their homes.

The enjoyment of parks and open spaces is very much enhanced if they are connected and linked up with a system of park drives or boulevards.

The Administrative or Civic Centre.—The administrative or civic centre, which is usually the heart of a town or city, should be the dominating feature of the city. It is not only necessary to secure a central location, but also, if possible, to select a site which will provide a vista from several points of vantage.

The civic centre should be dignified and impressive, whilst at the same time in harmony with the characteristics of the town itself, and in keeping with the resources of the public.

The buildings, if possible, should be grouped along the water front, or if a winding river runs through the city, a site can usually be selected which will not only be central but which can be viewed from several points in the city. By the grouping of the administrative centre along a water front stateliness of architectural treatment can be obtained which is impossible when grouping the same buildings along a street.

The Architecture of Buildings.—The architecture of buildings is an important factor in the success of a town planning scheme, and is a distinct phase of civic æsthetics. In order to obtain harmony in design, plans should be submitted to some central authority of all buildings intended to be erected, showing proposed elevations. It is essential that a maximum height of a building under certain conditions should be fixed. In London and many places in Great Britain it is now established that a building shall not exceed in height the width of the street upon which it fronts.

In order to obviate overcrowding, it is essential that a maximum number of houses per acre should be adopted for different grades of property.

In limiting the number per acre it should be sufficient, in the case of land that is not planned out in detail, if it be stated that the rule should be so many houses to the acre; but the requirements of the local authority would be satisfied if the average number was obtained over a certain area with due safeguards for the space about each house not being too small. There should also be a maximum number of houses stated, more than which should not be erected on any one acre.

Thus, if the number limited was 12 to the acre, the local authority might be satisfied if on any ten acres no more than 120 houses were built.

In residential areas the height should also be limited. Houses should not be built more than three stories or more than a maximum height, to be defined.

METHOD OF FIXING TIME FOR THE PERFORMANCE OF CITY CONTRACTS FOR STREET IMPROVEMENTS.*

By G. L. Bennett, M.M.E., New York.
Efficiency Engineer Board of Estimate and Apportionment.

THE determination of the number of working days which shall be allowed for the completion of a given contract is a problem upon which little data is at present available. Where the contract is very largely for work on one sort alone, such as paving, the problem is simple; but where as in the grading of streets, a number of really different sorts of work, often requiring equipments partly or wholly different for each sort, is covered by the one contract, the amount of time which is proper to allow, is really a quite complicated problem.

Contracts commonly arise from demands which in themselves are either urgent and set for a particular time of fulfilment or are more complaisant as to time, requiring only ultimate completion within rather wide time limits.

Contracts of the former type, for emergency work or for supplying necessary links in larger schemes, can, in proportion to their needs, afford to sacrifice economy for dispatch. Contracts of the latter type, which includes a majority of street improvement work, can properly afford to disregard time as such and to seek economy of total costs alone.

There are comparatively few pieces of work which can only be economically accomplished by the use of some one particular equipment and of some one particular method. In general, there are a number of equipments and of methods which, depending upon the genius of those in control for management under the conditions obtaining, will yield economical results, but will require somewhat different times for completion. Leaving out of account variations in required time, due to such causes, there is, for each sort of work, some number of working days, more than which could not economically be used by the contractor. Thus, on a pick and shovel job, the employment of less than a certain number of men would not be economical because of the cost of the foreman and superintendence and therefore, in this case, the use of more than a certain number of working days by a contractor would be uneconomical. The same thing applies to any job for which an equipment and force are provided sufficient to complete that job in one of the perhaps several most economical ways so far as contractor's costs are concerned; and to this somewhat varying time may be applied the term, "Contractor's Economical Time."

It is to be recognized that small total contract quantities, in general, only warrant the employment of light and easily moved equipments and that, somewhat progressively, as the quantities become larger, more and still more effective equipments are warranted.

But this may be modified considerably by the amounts of work of this same sort or sorts which have been done or are yet to be done, in the locality of the contract in question. Thus a rather small contract for rock excavation could properly be given a shorter contract time in the northern part of Greater New York where the rock excavation is constantly in progress than it could somewhere out on the shores of Long Island or southern New Jersey.

---

*Paper presented before the Municipal Engineers of the City of New York, February 25, 1914.

The amount of equipment to be employed is seriously effected by the costs of labor and the ease of procuring equipment. Where satisfactory labor is expensive or difficult to procure, contractors will, in general, employ machinery of a type which otherwise would only be used on much larger contracts, resulting, of course, in a shorter Contractor's Economical Time. Where machinery can be easily hired, equipment will often be used on small jobs such as could not otherwise be afforded. This affects also very large jobs for which, where no satisfactory disposal can be made of worn machinery, equipment is often provided only in such quantities that it shall all be practically worn out when the job is completed.

The total cost of the work rather than the cost to the contractor is the matter which interests the engineer in his capacity of manager for the party contracting for the work. And the total cost is, of course, the contract price plus the costs of surveys and designs, plus the costs of inspection, superintendence and interest on the moneys invested by partial payments or otherwise, all of which latter vary nearly directly with the time taken for the work.

The cost of interest, inspection, etc., will decrease, therefore, with a decrease in contract time, but because of the greater cost of equipment, etc., necessary to complete the work in less than the contractor's economical time, the contract price will tend to increase. That time which will give the minimum total costs for the work and which should accordingly on this sort of contract be used as the contract time, will therefore be somewhat shorter than the contractor's economical time.

Two methods of ascertaining the time to be allowed were open:

(1) By the balancing of inspection, superintendence, interest and similar time charges against the increased costs of obtaining and operating equipments of more capacity than are required to complete the contract in the contractor's economical time, using that point with reference to time which gives the least total cost, as the correct time to allow for the contract.

(2) By plotting the times allowed on previously completed contracts composed mainly of one kind of work and which had, in the judgment of the engineers in charge thereof, been prosecuted vigorously and with adequate equipment, a series of curves of quantity with reference to time can be drawn for each kind of work, each curve recognizing in its equation some particular controlling factor of variation. Having such curves and knowing the total quantity of work to be done, the proper contract time for this can be ascertained and the results can be combined to give the time for a contract including various kinds of work.

The operation of the first method for arriving at the contract time can be shown diagrammatically by Fig. 1.

In Fig. 1 the curve of contractor's costs shows the variation in cost with the contract time; the curve of interest, inspection and other time charges, the variation of these with contract time and the curve of total costs which has for its ordinate at each point the sum of the ordinates of the other two curves at that point, the variation of both with the contract time.

As these curves do not show variations with regard to quantity or other conditions governing any one sort of work, one such set of curves is necessary to determine the proper contract time for each total quantity of each kind of work. The contract times so obtained can later be plotted against the total quantities, even as has been done for Model 2, as shown in Figs. 2, 3, 4 and 5.

It is to be noted that this method depends upon a curve of contractor's costs, which can be determined, point by point, for the total quantity and the kind of work to which this curve applies, only by designing the most efficient plant or equipment to do this amount of this kind of work in each of the varying times assumed and from the use and costs of these plants or equipments, arriving at the contractor's costs.

That there is a very considerable difference in judgment as to the most economical plant for any given contract time and total quantity of work to be done and still more difference as to the delays and other items summed up in the contractor's costs must be apparent to those who are familiar with the variations in bid prices on those works of such magnitude as call for new and specially designed equipments.

And that the very considerable variation in bid prices between the various bids received for any contract is not all due to differences in the profits which the different

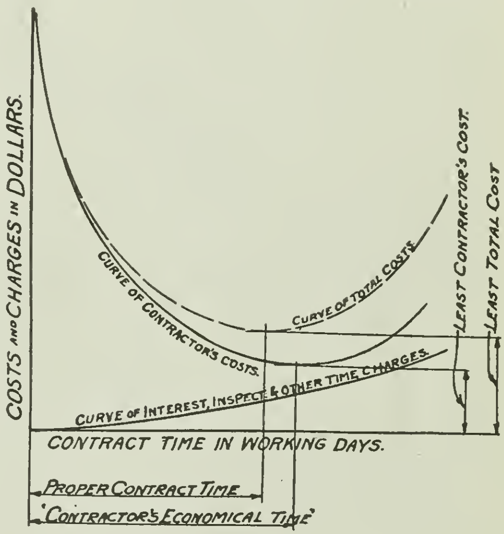

Fig. 1.

bidders desire, is quite clear to those who have studied prices bid when work was scarce and when therefore most, if not all, of the bidders were competing keenly for the job.

Also, that there is ample room for considerable differences between even the most carefully estimated contractor's costs and the actual contractor's costs is quite evident to those who have first planned and estimated and later built and operated contractor's plants.

In view, therefore, of the large number of assumptions which must be made and of the immense amount of work involved in creating such a "rope of sand" this seemingly more mathematical first method has been discarded in favor of the second method.

As an illustration of this method, the following set of rules, prepared by the author at the suggestion and under the direction of Mr. R. H. Gillespie, chief engineer of sewers and highways, for the use of the engineers of the Bureau of Highways in the Borough of The Bronx, New York City, in the determination of the contract time for regulating and grading are here introduced, the data

for which was furnished by the records of this bureau and the judgments as to which contracts had been prosecuted properly by the engineers thereof.

The Determination of Contract Time.—To determine the number of days which shall be written into any contract for regulating and grading as the number of working days to be allowed under that contract the curves hereto attached are to be used in accordance with the rules herein given.

Explanation.—The work to be done will consist of items of rock or earth excavation or of filling or of both, of curb, of flagging, and of bridge-stones. These may

The main items are liable to be earth and rock excavation or filling. The preliminary parts of items: The excavation of sufficient earth to permit earth and rock excavation to progress simultaneously; the building of sufficient of the pipe drains, inlets, manholes or basins to permit such building and the filling to progress simultaneously or the building of sufficient walls, in those few cases where such wall is necessary before any filling can be done, to permit such wall building and filling to progress simultaneously. The subsequent parts of items: Special structures which can not be completed until after the main item is completed; curb, flagging or bridgestone.

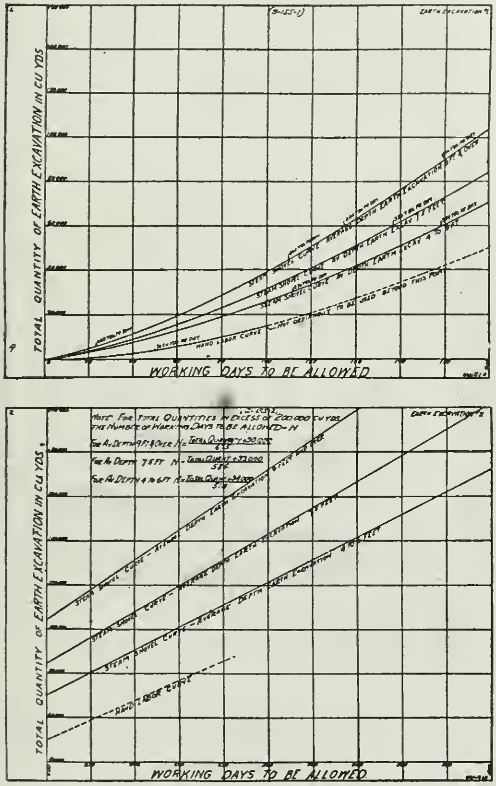

Fig. 2.—Curves for Earth Excavation.

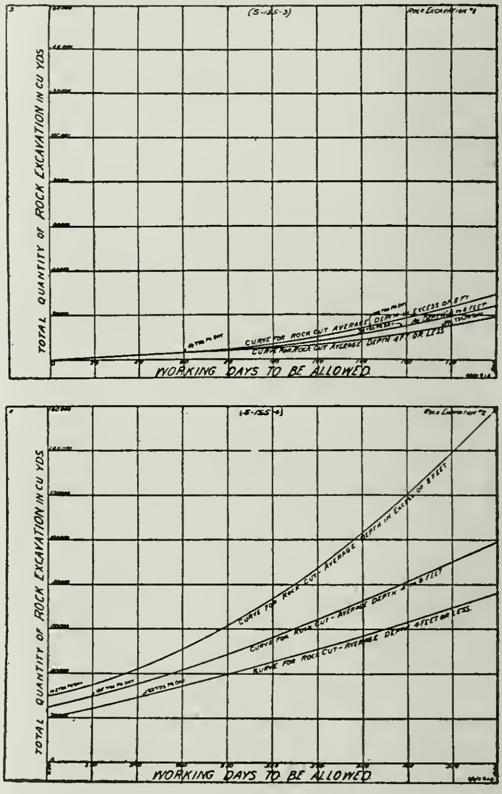

Fig. 3.—Curves for Rock Excavation.

or may not be accompanied by walls of dry rubble, rubble in mortar, or concrete; by pipe drains; by inlets; by receiving basins; by manholes; by piles; and by special constructions.

Items Which Govern.—Ordinarily, work on more than one of these items can be prosecuted at the same time. Care is therefore required to so use the information available of the special conditions surrounding a proposed work, as to eliminate from consideration all of those items and all parts of items which can properly be done during the progress of some other item. There will thus be left as the determining factor in the required time for such work, one, or more rarely, two main items which cannot be done simultaneously and some preliminary and subsequent parts of items.

The curves have been drawn to recognize, in view of the total quantity of an item to be done, the equipment and force which should be used.

They show, accordingly each for its condition, the amount of time for any total quantity which should be consumed in completing that quantity.

Rule "A."—If the time for a part of an item has to be estimated, it is to be taken therefore at the same rate of accomplishment per day as is the total quantity.

Rule "B."—Where conditions are clearly intermediate between those shown by the curves, interpolation is permissible, but where doubt exists, it is preferable as making for lower costs to take that nearest diagrammed condition which gives the longer contract time.

Rule "C."—Where a part of an item comes clearly under one condition recognized in the curves and the remainder as clearly under another, unless the equipment and force which should properly be used for doing these two parts is widely different, the time for the two parts, each taken at the same rate of accomplishment as if the total quantity came under that part's condition, shall be summed to give the time for that item.

Rule "D."—If the equipment, etc., should properly be different, the time for each part of the item is to be taken as if the quantity for this part item were a total quantity and the times so obtained, summed to give the total time for the item.

NOTE.—It is to be remembered that the contract provides that allowances of time for delays occasioned by the weather, or by any act or omission on the city's part, are to be made in addition to the number of working days; and that, therefore, no consideration need be given in this determination to any conditions arising from such causes.

The curves represent average good practice as determined from the records of many contracts done under this office. They do not represent the greatest progress which can be made under good management, and if, therefore, conditions arise not provided for in these curves, such as inability to attack the work in more than a few points, unless the condition is very severe, no additional working days are to be allowed as a total.

Rule "E."—For time necessary to get the work started after being ordered ahead and for stopping, after completion, 10 working days are to be allowed as a total.

Example 1.—On a contract with a centre line length of 8,900 ft. and a street width of 100 ft., there are the following items and quantities:

Earth excavation	88,000	cu. yd.
Rock excavation	26,700	" "
Fill	151,100	" "
Dry rubble masonry	700	" "
Rubble in mortar	25	" "
12-in. pipe	100	lin. ft.
18-in. pipe	575	" "
Manholes	4	
Guard rail	5,800	" "
Lumber	7,500	ft. (B.M.)

No bluestone.

Of the above items, only the earth, and rock excavation and the filling need be considered.

Filling.—It is known that over a portion of the work where filling is required that the street is located on a swamp where settlement will, in all probability, take place. Assume that this settlement will amount to 30,000 cu. yd. Then the total filling required to complete the work would be 151,100 + 30,000 = 181,100 cu. yd.

The sum of the earth and rock excavation equals 114,700 cu. yd. It should be assumed that the entire excavation is to be applied to making the fill so that the material can at least be considered as easily available. The balance of the material required for filling 66,400 cu. yd. must be obtained from outside sources. It is further known that the swamp section of the street is near tide water where material can be obtained by scows. This material, so obtained, should be classed as material "easily available." Even though the dock or nearest obtainable landing may be at some distance from the street under consideration, and especially in view of the possibility of obtaining and placing this filling during the progress of the grading on other portions of the work, it should be classed as "easily available."

An examination of the filling diagram will therefore indicate that considering 181,100 cu. yd. as "easily available," 332 days should be allowed, and adding to this 10 days for starting and stopping, we have 342 days, or, say, 345 days for the contract time.

Excavation.—If, on the other hand, we consider the excavation and know that the earth cutting averages from 4 to 6 ft. in depth, and the rock 4 to 8 ft. in depth, and that 10,000 cu. yd. of earth must be excavated before rock excavation can begin, and that thereafter both will be

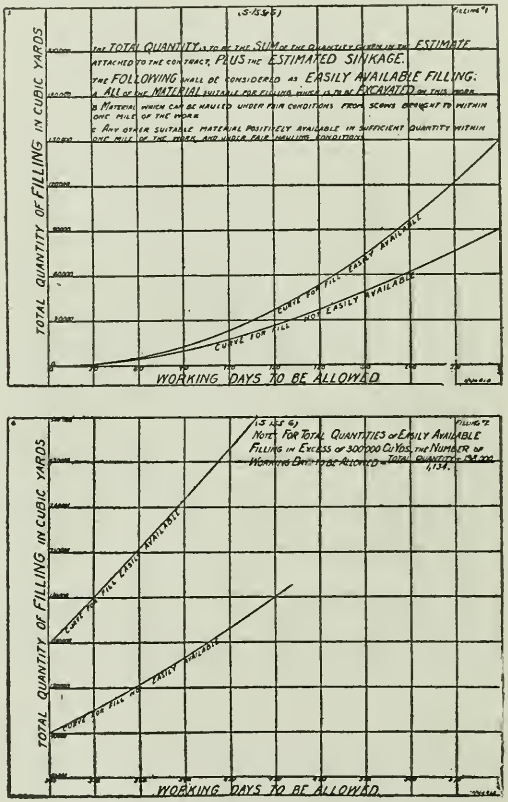

Fig. 4.—Curves for Filling.

carried on simultaneously, we will obtain from the curves the following:

10,000 cu. yd. earth excavation (at 88,000 rate)..	27 days
26,700 cu. yd. rock excavation	212 "
	239 days
Starting and stopping	10 "
	249 days

If we consider only the earth excavation, and assume that while same is in progress the rock will be excavated, we have from curves the following:

88,000 cu. yd. earth excavation	235 days
Starting and stopping	10 "
	245 days

It is evident from the above that the filling required on the work controls and that the contract time should be fixed at 345 days.

Example 2.—

Earth excavation	1,000 cu. yd.
Rock excavation	500 " "
Filling	120,000 " "

In this example the excavation is plainly not to be considered. The filling, if easily available, will, by the curves, require 268 days. If not easily available, filling will require 357 days.

To either of these 10 days should be added for starting and stopping, making either 278 days which call 280 days, or 367 days which call 370 days.

Example 3.—

Earth excavation	6,000 cu. yd.
Rock excavation	6,000 " "
Filling	12,000 " "

If earth overlays rock, the quantity of earth which must be removed to permit rock and earth excavation to progress simultaneously, must be determined from a knowledge of the local conditions. If these conditions

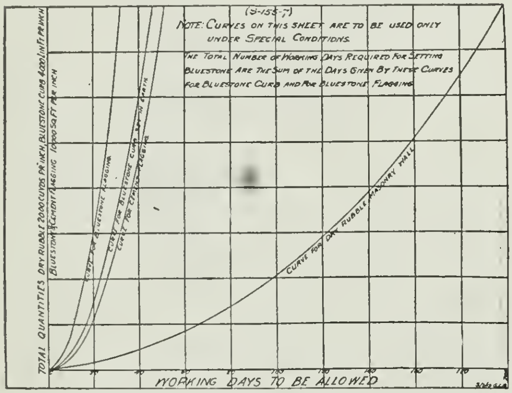

Fig. 5.—Curves for Flagging, Curb and Dry Wall.

show that, say, 35% of the earth has to be removed before the rock excavation can be properly commenced, and that the rock has an average depth of 4 ft. or less, the times required for excavation will be:

For earth 35% of the 64 days required by curve for hand labor for 6,000 yds.

For rock 114 days required by curve for 6,000 yd. of average depth 4 ft. or less.

The sum of these two, plus 10 days for starting and stopping, equals 146 days which call 150 days.

The filling, which is all easily available, would only require 90 days.

Therefore, the contract time for this job would be 150 days.

If earth and rock are in separate cuts and separately approachable so that the two sorts of excavation can properly progress simultaneously, the earth excavation need not be considered. The filling will, of course, not be the determining factor and the rock excavation will be. Under these conditions, the contract time should be for rock excavation, 114 days plus 10 days for starting and stopping equals 124 days, say, 125 days.

Example 4.—

Earth excavation	20,000 cu. yd.
Rock excavation	2,000 " "
Filling	3,000 " "

In this case, the earth overlies subgrade rock throughout most of the work.

The rock excavation remaining to be finished after the earth excavation is completed will amount to about 18% of the total rock excavation.

The filling will not determine the required time.

The earth excavation, being all in shallow cut, will be taken out by hand labor, thus requiring 118 days.

The 2,000 yd. rock, 4 ft. cut or less, would require 36 days, and 18% of this would require 6 days.

62288

The sum of the above plus 10 days start and stop equals 134 days which call 135 days.

Example 5.—

Earth excavation	1,000 cu. yd.
Rock excavation	6,000 " "
Filling	7,500 " "

Here, the 1,000 cu. yd. earth overlies the 6,000 cu. yd. rock and the conditions show that only a very little earth will be taken off, say, 200 yd., before the rock is commenced. Two hundred yards earth should require about one-fifth of the 24 days required by hand labor curve for the total 1,000 yd., say, 5 days.

Six thousand cubic yards rock, of a 4-ft. or less depth of cut, requires by the curve 114 days.

The sum of the above plus 10 days for start and stopping, equals 129 days which call 130 days, contract time.

Example 6.—

Earth excavation	30,000 cu. yd.
Rock excavation	45,000 " "
Filling (easily available)	120,000 " "

The filling will require by the curve 268 days.

The earth and rock excavation are such that they can be prosecuted quite simultaneously. The rock excavation will therefore control and has an average depth of 6 ft., requiring by the curve 270 days, so that 270 days is good for either.

Therefore, 270 plus 10 days stop and start gives 280 days as the contract time.

Example 7.—

Earth excavation	500 cu. yd.
Bluestone curb	15,000 lin. ft.
Cement flagging	60,000 sq. ft.

As cement flagging and bluestone work can progress simultaneously, the time required will be that for the longer of the two items.

The bluestone curb will, by the curve, require 32 days; the cement flagging 45 days.

Therefore, the cement flagging controls and the contract time should be 45 days plus 10 days start and stop = 55 days.

The application of this method to others of the more usual types of municipal work is obvious and in some cases is under way.

The confidence of contractors in general in the absolute fairness and in the knowledge of the engineer, will, perhaps as much as any other factor, tend to lower the costs of work to be done. And to this end a uniform method of figuring the contract time rather than guessing at it, will, it is believed, contribute in no small degree.

Editorial

ENGINEERING, A VEHICLE OF PRODUCTION.

Although there is no distinct mark of division, one is often led to believe that the relation between science and engineering should be better defined. At any rate, the engineer who recognizes that there exists a line of demarcation, however faint it may be, is less liable to enter upon schemes of an impracticable and therefore wasteful character.

It is perfectly true that the scientist and the engineer are engaged alike in a study of the forces of nature and of ways and means to properly guide and control these forces, so that they may be rendered more serviceable to mankind. But the work of the scientist precedes engineering. It leads him into new and unexplored fields and his investigation reveals the suitability of those fields for exploitation and development. Such is the work of the purely scientific man. It is a noble work; one that has rendered to the race the promotion of the new learning that has been behind the advancement of modern times. Nevertheless, it is perspective, in nature, and must, upon its conception, pass the muster of a combination of engineering and business ability before being presented to the world for assimilation and use. In other words, the purely scientific man must relinquish his conquest to the engineer and the financier in order that it may be judged productive and worthy of development. It is here that the engineer takes hold of the problem. Not previously, or he is encroaching upon the field of the scientist and hazarding his reputation as a reliable engineer.

The situation and its dangers were well protrayed editorially in a recent issue of Engineering (London), while on the subject of the business aspect of the profession. Here it was stated, "It cannot be denied that many engineers are inclined to become too much absorbed in the purely technical aspect of engineering, and to regard their profession a little too much from a standpoint which, though perfectly legitimate in the case of a physicist, is improper in the case of men whose labors are expected to contribute directly and immediately to the wealth of the world. An engineer—and examples are not uncommon—who interests himself solely in the scientific aspect of his profession undoubtedly greatly reduces his opportunities of benefiting his kind, and often is indirectly responsible for much wasteful expenditure. The complaint, for instance, is often made that funds appear to be easily found for the financing of engineering schemes of the most impossible and impracticable character, whilst really reasonable schemes go begging. Were those responsible for the latter better acquainted with the ways of business men, there would be a fair chance of diverting into productive channels resources which are now just as absolutely wasted as if they were invested in a timber yard and immediately fired."

THE TORONTO-HAMILTON HIGHWAY.

Ontario has now entered upon an excellent movement for better roads—one that seems to have the approval of the various classes of road users throughout the province. The appointment last July of the Good Roads and Public Highways Commission was followed by prompt activity resulting in the publication a few months ago of a comprehensive and valuable report. It is most encouraging that the government has seen fit to follow up the suggestions of the Commission, and to adopt its important proposals.

An important line of investigation recommended by the Commission, and one that has already been entered upon, is a motor survey of the main travelled roads in order to acquire an estimate of their present state and of the nature and amount of work necessary to bring them up to the required standard. Chief among the roads now being subjected to the motor survey and traffic census is the Lake Shore road between Toronto and Hamilton. Fourteen men were detailed for this work last week. It is perhaps the most important road falling in the interurban class, and it is one most in need of immediate attention. There are three roads under the travel of the Toronto-Hamilton traffic (including that to and from a number of intervening points) and none of them is in anything like a satisfactory condition. It is the desire of the Commission to construct a permanent road, with concrete base, 20 feet in width. The expense will be borne jointly by the province, the urban termini, the towns en route and the counties through which it passes.

There is every probability that the present investigation will be followed by early construction. The materialization of a thoroughfare commensurate with the importance of the route, its commercial and pleasure traffic, and its scenic possibilities will be a most praiseworthy achievement on the part of the Commission, and a work that will render easier the conception of similar highway enterprises in other parts of the province. Undoubtedly the successful carrying out of this 35-mile piece of permanent road by the Commission will have a farther reaching effect on the good roads movement that has swept the Dominion than one is led to believe from a mere consideration of the benefits that will accrue to the local municipalities.

NOVEL METHOD OF ADJUSTING CROSS-HAIRS.

A novel method of adjusting cross-hairs is described by a recent contributor to a mining contemporary, and shows one of the ways in which tedious and costly delays may sometimes be avoided in survey work. Breakages of cross-hairs in a transit are not common in instruments fitted with finely drawn metalic cross-hairs, but there are sets in use made of spider webs which are apt to give trouble with the slightest provocation. While new webs may conveniently be found, a means of cementing them in position is not always available. The writer found himself with a broken set of cross-hairs when far from headquarters and without any suitable means of adjusting new ones. The circumstances necessitated emergency measures and as an experiment new webs were fastened in place with the membrane next to the shell of a bird's egg, the desired tension being given to the web with the fingers, a pair of dividers being unavailable.

After six weeks of hard service the transit was sent to the repair factory for general repairs and the spider webs were found in good shape.

STEAM TRACTOR vs. TEAM LABOR IN THE HAULAGE OF ROAD MATERIAL.

THE advantages of steam tractor haulage over team labor in road work is the subject of a useful paper that was read on June 6th, 1914, at a meeting of the Institution of Municipal and County Engineers by Mr. W. L. Gibson, one of the road surveyors of Perthshire County. The paper presented some detailed statements of working expenses of tractors, and comparisons of cost of team labor. Several are given as examples of a year's work, and the method of keeping the cost, while others show abstracts and analyses of the whole time during which the tractors had been at work. A portion of Mr. Gibson's paper is given below:—

No small debt is due to the efforts of the makers of road plant in having contributed to the great advance made in modern times in the methods of road-making and maintenance, and not least in the manufacture and transportation of all kinds of material necessary for road work. The ratepayers, no less than road surveyors, owe them a debt for carrying out the great work at the minimum of cost.

Within the last thirty years the methods of road construction and maintenance have been revolutionized. For generations, we may say, no advance was made on the methods taught by the Romans. Insufficient attention was paid to the importance of good roads, and up to a generation ago the work was carried out by rule-of-thumb methods by the local blacksmith, who supplied the plant, consisting chiefly of tools, and the farmer and the local carting contractor who did the haulage.

Under this primitive system of haulage most of the material had to be distributed into depots along the roadside, entailing extra expenditure in relifting while road-surfacing, and often there was difficulty in securing the necessary amount of team labor when required in isolated districts. But now road-making has been elevated from the position of mere empiric practice to the dignity of a science. The local blacksmith, the farmer, and the local carting contractor are being replaced by engineering experts, who undertake the supply of all kinds of plant necessary for the most improved methods of road-making and maintenance and haulage of material.

In no department is the advance more notable than in the substitution of mechanically propelled vehicles for team labor. It is the purpose of this paper to consider some of the advantages possessed by tractor haulage as compared with team labor, and to present observations which may be useful to road engineers and surveyors who contemplate the adoption of the more modern method. The writer was the first county road surveyor in Scotland to adopt tractor haulage, and having now had ten years' experience of this method of transportation is in a position to submit some observations on the subject, accompanied by detailed statements of actual cost and comparative analyses of tractor haulage as compared with team labor.

It has been said that "the bigger the load the cheaper the cost per ton-mile." If this be true, haulage by heavy traction engines is still the cheapest known method of road transport, so far as cost per ton-mile is concerned. Nevertheless, road surveyors must consider the question of damage to road by such haulage, and it is, therefore, necessary for them to keep the axle weights within reasonable limits. If heavy plant is used surveyors must make and maintain their roads to meet this class of traffic, which means that a large initial expenditure as well as a large annual cost would be required to meet the expense of road maintenance for their own traffic. If, on the other hand, light tractor haulage be employed there is a marked saving in the wear and tear to the road surface as contrasted with the heavier plant. We must, therefore, qualify our axiom that "the bigger the load the cheaper the cost per ton-mile" by this rider, "The heavier the axle weight the greater the damage to roads," with its corollary of increased cost for maintenance.

To secure at one and the same time cheapness of transport and minimum damage to roads must be the aim and ideal of the skilful road engineer, and it is my opinion that the two aims are irreconcilable so long as heavy traction haulage is employed. On other grounds the use of heavy traction haulage is to be deprecated.

The question of easy working—i.e., turning and shunting on narrow roads, and in quarries and loading banks of railway sidings—is an important consideration, for it must be remembered that in haulage of road material the primary object is to ply between the quarry or the railway siding and the scene of steam road-rolling operations without the intervention of roadside storing depots, and the inevitable and unnecessary cost of depositing and relifting the material.

Let us consider briefly team labor as regards cheapness of transport and damage to roads.

As far as the first is concerned, team labor cannot compete with tractor haulage. But the difference in wear and tear between light tractor haulage and team labor is a more problematical question, though my own experience goes to confirm me in the view that in some cases —if not in most—there is a difference here also in favor of the former. Indeed, I would go further and affirm that in some cases where the effect of the use of team labor was to cut through the surface and cause deep ruts, the substitution of tractors resulted merely in a depression, which was more easily remedied by making up with metal, and that continued use of the tractor and wagon over the metal in the course of haulage actually producing a much stronger road than before. It is naturally to the advantage of the carting contractor when hauling under contract, to load to the full, but the greater the profit the greater the damage to the road. Here, again, though, of course, in a much less degree, the two aims of the road surveyor cannot be fully secured by the employment of team labor.

In considering as to the adoption of mechanical haulage for West Perthshire, the author recognized that many of the roads were lightly constructed and narrow, and the quarries restricted in area and not easy of access. To adopt heavy traction engines would be almost impracticable for the work contemplated. Under the heavy motor-car regulations the use of self-contained vehicles, such as steam and petrol wagons is permitted; but from the author's point of view they have the disadvantage of the great axle weight on the hind wheels, which are, as a rule, in the case of the steam wagon, only about 3 ft. 6 in. diameter by 10 in. wide, carrying a legal weight—often, unfortunately, exceeded—of 8 tons.

This is quite an extravagant load for an ordinary country road. This type of vehicle has also another disadvantage to road authorities, in that the whole plant must remain idle while being loaded, whereas the tractor, using two tipping wagons, can be hauling the one while the other is loading. The output of this plant, therefore, is greater than that of a steam or petrol wagon, and the produce of the breaker, or tar-macadam mixer, or material from the railway siding, is delivered on the road in a more regular manner. While the higher speed of motor wagons on rubber tires may be considered an advantage for this type, in the present state of develop-

ment of mechanical haulage, it appears that the cost of rubber tires alone, which could be calculated at not less than 4 cents per vehicle mile, and the cost of petrol where motor engines are used, make it impossible for this type to be compared with tractor haulage for the conveyance of road material, irrespective of the disadvantages already mentioned of the self-contained unit.

Notwithstanding rubber tires, the axle weight of this self-contained vehicle has proved to be very damaging to road surfaces where regular services of motor buses, heavy vans, etc., are in operation. It must, of course, be understood that where the roads are strong and smooth, and where facilities are provided for quick and cheap loading, the use of the fast-running motor wagon—either steam or petrol—may be seriously considered; but the author has yet to learn of instances in any way similar to his own work where this type of vehicle has been used at a cost which can be compared with his own experience.

The following points may be suggested for the consideration of road engineers and surveyors who may be contemplating the adoption of mechanical haulage:—

(1) Whether capable of carrying the maximum axle weight of the type of vehicle it is proposed to use.

(2) If the tonnage is small, or the distances unduly short, hire may be cheaper than purchase.

(3) There are still some districts where the prices of cartage are so cheap that purchase of plant may not at present be justified.

(4) Whether the work of the district suits the use of convertible tractor and roller. (The author finds the convertible tractor the most useful plant he has.)

(5) Whether the engine can be utilized for driving small stone-breaker for tar-macadam mixer, supplying steam for rock-drilling, pumping water out of quarries, removing accumulations of road scrapings, hauling tar-sprayers and boilers, or any of the many operations for which a surveyor requires power of any kind.

An analysis of Mr. Gibson's statement of expense for one of the tractors (3 tons) is given in Table I.

Table I.

No. of days hauling	239
Material hauled	5,357 tons
Material hauled per day	22.4 tons
Total distance travelled in 239 days	4,873 miles
Average distance travelled per day	20.4 miles
*Average cost per day	$6.25
Average cost per ton per mile	11.8 cents
Fuel consumed per day	3 cwts.

* This includes filling wagons, time of driver washing out boiler, cleaning, and repairs, with depreciation, etc., estimated at the rate of 22 per cent.

		In percentages.
Cost of carting by team labor	$3,191.13	100
Cost of steam tractor haulage	1,470.07	46
Total saving†	$1,721.06	54

† In addition, the tractor (after 8½ years' work) was sold for $720.00.

Another statement, covering a period of 8½ years, gives, as actual cost of this steam tractor haulage, $10,048.65, with an estimated cost of team labor, amounting to $21,495.00. Concerning another 5-ton tractor, convertible to a 7-ton roller, the figures given in Table II. apply.

Table II.

No. of days' hauling	142
Quantity of material hauled	3,158 tons
Average quantity hauled per day	22.23 tons
Average distance travelled per day	21.95 miles
Total distance travelled in 142 days	3,118 miles
Average cost per day, including filling into wagons and time of driver, washing out boiler, cleaning and repairing (Depreciation and tear and wear included at the rate of 15 per cent.)	$5.80
Average cost per ton mile	10.28 cents
Fuel consumed per day	3 cwt.

		In percentages.
Cost of carting by old contract system	$1,978.04	100.0
Cost of motor haulage	821.86	40.8
Total saving	$1,156.18	59.2

Note.—This tractor, being convertible to a 7-ton road roller, was engaged at rolling operations for 141 days at an average cost of $4.58 per day.

This tractor, during a period of six years, effected a saving of over $4,644.00, allowing for depreciation at the rate of 15 per cent. per annum, when compared with the estimated cost of team labor over that period.

ONTARIO ROAD SURVEY.

Motor surveys of the 18 Ontario counties where highway systems have not yet been organized, have been commenced under the auspices of the Good Roads Commission and directed by W. A. Maclean, Provincial Highways Engineer. Three parties will go north, east and west; and the fourth will cover the central district. The work is to be handled by trained engineers and surveyors. The first group will cover Ontario, Victoria, Peterboro, Northumberland and Durham; the second, Essex, Kent, Elgin and Lambton; the third, Bruce, Huron, Grey and Dufferin; the fourth, Dundas, Stormont, Glengarry, Prescott and Russell. A report will be made to the Government as to the best method of making the various township routes co-ordinate with the county market roads. The market and shipping points in all the counties will be ascertained as well as the population, the volume of traffic on the roads, the location of building materials, and the estimated cost of construction.

The department has plans of every township in the province in preparation, and these will be used in an effort to systematize the roadway system throughout Ontario.

The report of the chief of the Vancouver, B.C., fire department shows that its equipment consists of 18 pieces of automobile apparatus—two ladder trucks, eight hose wagons, one combination hose and chemical wagon, five chemical engines, one chief's car, and one assistant-chief's car; one self-propelled steam fire engine, 14 horse-drawn apparatus—four steam engines, two ladder trucks, five hose wagons, one combination hose and chemical wagon, and two chemical engines; and 31 horses. Owing to the city's recent rapid growth, it has been enabled in purchasing to secure apparatus of the latest improved makes, and in consequence has an excellent equipment for a city of its size and population. The first automobile apparatus was purchased in 1908, and since that time whenever old apparatus was replaced or the demands of the city required increased equipment, this class of apparatus has been added.

DESIGN OF STEEL TURNTABLE.

It is only when one attempts to find some data on the subject of turntables and their design that he discovers the lack of material on this phase of structural engineering. Text books practically ignore the subject, and data in the engineering periodicals is correspondingly scarce.

In *The Canadian Engineer* for November 21st, 1912, an article appeared dealing with the design of turntables for heavy locomotives. Some years previous the "American Engineer and Railway Review" published an article, written by a Mr. Greenleaf, a designer and builder of bridges. Later the "Engineering Record" contained in its columns an article chiefly commentary on the lack of knowledge on the subject. The latest information to appear respecting the design of turntables in that contributed by E. C. White, C.E., to the "Cornell Civil Engineer." Mr. White is an instructor of civil engineering at Cornell University. The following is from his treatment of the subject:

The early turntables were made of wood, and in general were quite unsatisfactory. Cast iron was later substituted for wood. The cast iron turntables were made in two pieces which were tied together by strips of iron set into the top. These were in turn replaced by the modern steel structure, thus keeping pace with the development on structural design. It is in the treatment of the modern steel turntable that data is so scarce. Practically the only data on the subject that was of any use to the author in making his design, outside of ordinary mechanics, was a stress diagram shown in "American Engineering and Railway Review."

The size and length of turntable to be used is governed by the maximum weight and length of the engines now used, with proper allowance for probable future increase. An ample length at the present time is 75 feet to 100 feet; but few of the longer types are now in use. The tendency, however, is toward gradual increase in size and length of locomotive, necessitating longer and heavier turntables.

The locomotive turntable may be said to be a swing bridge on a centre bearing. The bearing may be a nest of rollers, ball bearings, or a bronze disc. The design here shown is of the latter type, with Cooper's Class E 55 live loading. The design is quite similar to that of a plate girder with somewhat varying kinds of stresses depending on the position of the live load upon the structure. Under dead load and under balanced live load stresses the girders act as two cantilevers joined at the centre. When the load is moving onto the structure it may be treated as a continuous beam on two supports, or to produce the greatest stresses, as a simple beam from end to centre supports. In a full determination of the stresses the effect of the engine coming onto the structure must be considered. As an example, if an engine with trucks is considered, the stress will be found to be less than that produced by a switching engine as it comes on. Thus the stresses under this condition of loading, i.e., to produce the worst possible conditions, should be taken under wheel two. The results of these investigations are shown on the stress diagram in Fig. 1. The position of the wheels in the plate apply to the moment or stress diagram under the balanced condition, and also to the shear diagram under the same condition of loading. It will be noticed that under a balanced load for this type of loading the

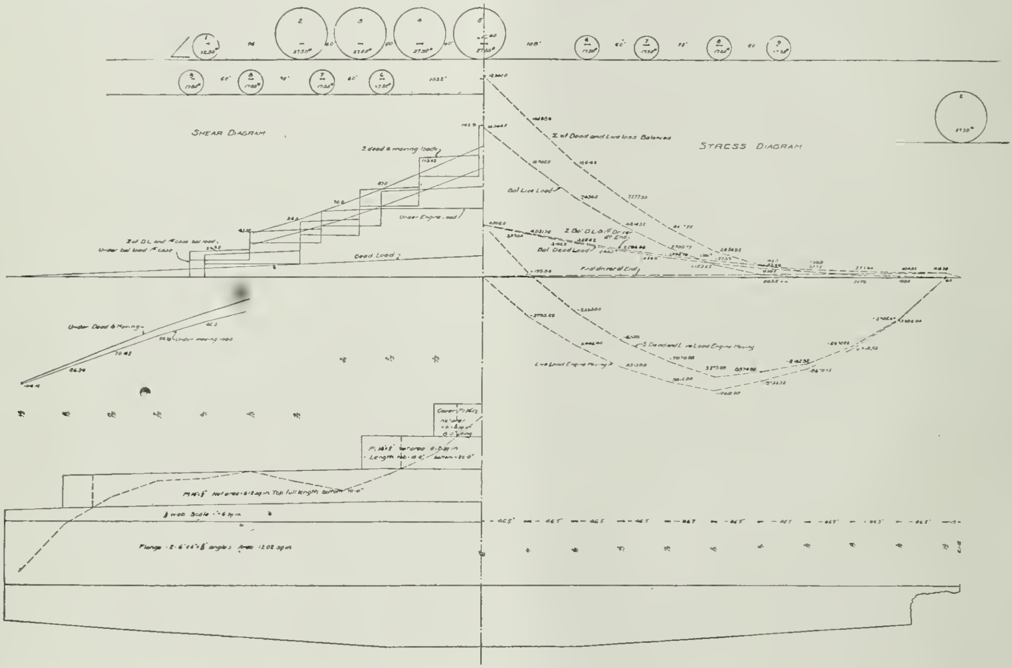

Fig. 1.—Shear and Stress Diagrams.

tender produces maximum stress. Also maximum stress is caused by both engine and tender, and in places, by moving load. The lower part of this plate shows flange

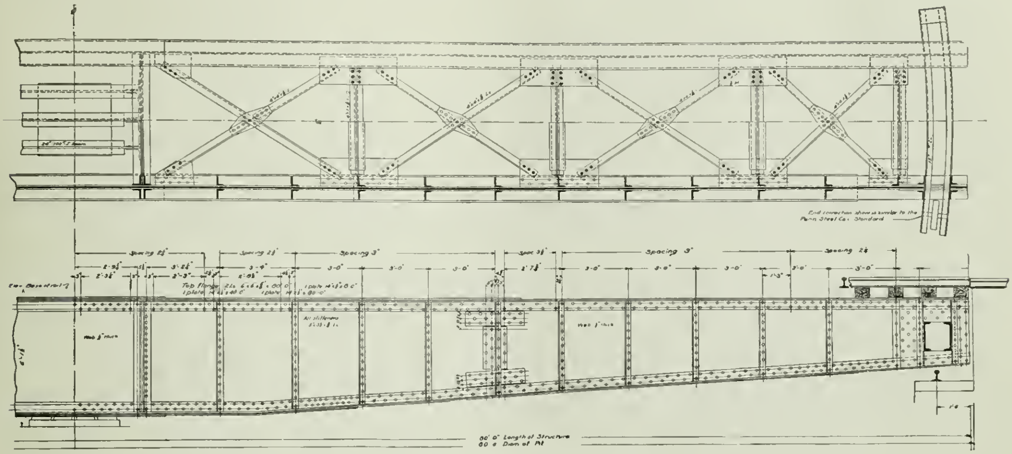

Fig. 2.—Details of Steel Turntable.

area required from point to point, and the make-up of the section used.

Having found the stresses and shear values, the next step in the design is the same as for a plate girder. As no impact is allowed except at the ends (where it was taken as 100%) the unit shearing stress used was 6,000 pounds per square inch, and a unit tension and compression of 10,000 pounds per square inch. The details are

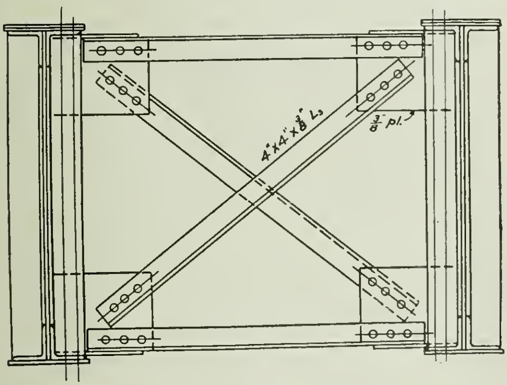

Fig. 3.—Lateral System.

shown in Fig. 2. The lateral stresses are indeterminate and angles are used according to standard practice, in plate girder design, with full section developed at all joints or plates. The details of the lateral system, are shown in Fig. 3. Fig. 4 shows a section through the bronze disc centre bearing.

The assumed dead load was taken as that given by the formula ($w = 10\ l + 100$) for a deck plate girder, using one-half the length of turntable as l. This value

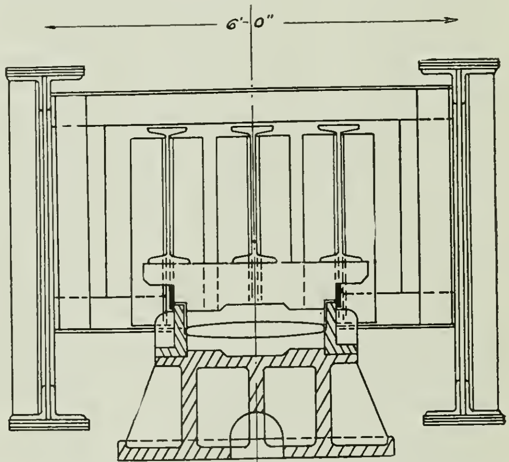

Fig. 4.—Section Through Bronze Disc, Centre Bearing.

checked slightly over the actual computed weight of the completed design, the difference being insufficient to affect the design.

Recently the City Council of Toronto unanimously adopted a minimum rate of wages of 25 cents per hour, for all organizations engaged upon civic contracts. The recommendation involves the recognition of a higher standard of wage for workmen engaged by the city. The present minimum rate of 18 cents per hour was established many years ago, since which time the cost of living has increased continuously from year to year.

Within a range of 10 miles of Lethbridge, a discovery of mica, which is stated to be almost pure, has been made by L. P. Tuff, a prospector, formerly of Montana. In some instances, the samples shown are several inches thick, and are perfect in cleavage. Specimens have been sent to the Ottawa Government for examination. Mr. Tuff is also of the opinion that silica sand also exists in the neighborhood of the mica formation.

DERIVATION OF RUN-OFF FROM RAINFALL DATA IN WATER SUPPLY AND WATER POWER PROJECTS.

HYDRAULIC, municipal, and consulting engineers fully comprehend the importance of run-off data in the study of water power or water supply propositions. Of particular interest to them is a paper on the subject by Mr. J. D. Justin, principal assistant engineer, Board of Public Works, Harrisburg, Pa., read last year before the American Society of Civil Engineers and published in the proceedings for August. It deals with a series of experiments undertaken by him to solve a method of deriving run-off from the rainfall data of a drainage basin. Mr. Justin's paper is, in part, as follows:

The quantity of rainfall appearing as run-off on any watershed is governed by many conditions, chief among which are character of vegetation, extent of forest covering, prevailing winds, relative humidity of atmosphere, barometric pressure, percentage of water surface, geology of basin, slope, and mean annual temperature. Before investigating the manner in which the relations between rainfall and run-off differ on various watersheds the writer will consider the manner in which they vary from year to year on any one watershed.

George W. Rafter showed that the relation of rainfall to run-off on a watershed could often be expressed as an exponential equation. For the upper Hudson he gives the two equations $P^2 = 84.5\ R$ and $P^{1.77} = 34.3\ R$; P being the annual precipitation and R the annual run-off, in inches, on the watershed. He does not, however, suggest any constant value for the exponent of P or R for other watersheds.

After plotting many rainfall and run-off data, the writer became convinced that the relations between rainfall and run-off on almost every watershed could be expressed by a logarithmic equation, of the form, $C = K\ R^n$, in which C = annual run-off, R = annual rainfall, K is an abstract number, constant for any one watershed, and n is an exponent constant for the watershed.

In solving the equations it was found that n always came out nearly equal to 2; hence it was chosen as a constant for all watersheds and always equal to 2.

The writer then plotted, on logarithmic cross-section paper, using annual run-off in inches as ordinates and annual rainfall in inches as abscissas, a considerable portion of the available reliable data. He found that on all these watersheds the relation may be well expressed by the formula:

$$C = KR^2,$$

in which C is the annual run-off in inches; R is the annual rainfall in inches, and K is a constant which is different for each watershed and has a value depending on those conditions which make the relations between rainfall and run-off on one watershed different from those on another.

Mr. Justin presents 19 diagrams in his paper to show the relation of rainfall to run-off. As stated above, the graph showing this relation is plotted on logarithmic paper and is, therefore, a straight line. The run-off C in inches is plotted as ordinates, and the rainfall R in inches as ordinates on each diagram. Table 1. has been prepared from these 19 diagrams. It gives the name of the watershed, area of watershed, locality for which the relation between rainfall and run-off is expressed, and the value of the coefficient K in the formula $C = KR^2$.

Accuracy of Data.—The accuracy of existing data does not justify precision. On some of the territories for which diagrams were prepared there is one rainfall station per 1,000 sq. miles of watershed. In the computation of run-off a discrepancy of 1 or 2 ins. is not worthy of discussion. In most cases one can safely assume a probable error of 10 per cent. in the observed rainfall for any one year for most watersheds. The error in any individual record at a certain station is undoubtedly less than this in most cases, but when several rainfall stations are combined to give the rainfall for an entire watershed the probable error is increased. In general, the larger the number of rainfall stations on a watershed the less the probable error.

Run-off records are usually more accurate, but up to a few years ago few streams were accurately gauged, and the error was generally positive. At present many of the records of the water resources branch of the United States Geological Survey and of many municipal water supplies are all that could be desired, the probable error not exceeding 5 per cent. Perhaps one of the most accurate

Table I.—Value of K for 19 Eastern Watersheds.

Name of watershed.	Area of watershed, sq. miles.	Locality.	Value of K.
Esopus Creek	239	Esopus Weir	0.01292

Neshaminy Creek	139.3	.....	0.0099

records for purposes of comparison between rainfall and run-off is that on the Esopus watershed (area 239 sq. miles) of the Catskill water supply system of New York City. On this watershed there have been maintained from 8 to 13 well-distributed rainfall stations. The measurement of run-off has been made at a concrete weir especially built for the purpose.

The relation between rainfall and run-off on this watershed is shown in Table I. All the points in the diagram fell almost precisely on the curve, $C=0.01292R^2$.

When rainfall and run-off data are plotted on diagrams the probable error in using the resulting curves in mass curve storage studies is much reduced.

Effect of Proportion of Water Surface.—The writer believes that many hydrologists have exaggerated the importance of the effect of water surfaces on a watershed in decreasing the quantity of run-off. Aside from regulating the distribution of the run-off throughout the year, the effect of any ordinary proportion of water surface is so small as to be negligible.

This is well shown by Mr. Rafter. In discussing the percentage of water surface on the Croton watershed (3.56 per cent.) he says:

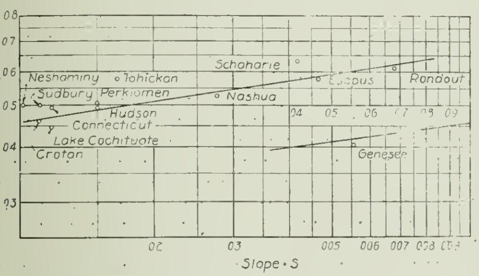

Fig. I.—Diagram Showing Relation Between K, T and S. (K = Const. in Eq.; $C = KR^2$; T = mean annual temp.; S = slope of watershed.)

"It may at first thought be imagined that these large water surfaces exposed to evaporation have considerably increased the ground evaporation over the entire catchment. When, however, one considers that it is only the difference between what a water-surface evaporation and what a ground-surface evaporation would be, the difference is seen to be not very much. For instance, assuming the water-surface evaporation at 36 ins. per year and the ground-surface evaporation at 27 ins. per year, the difference becomes 9 ins. With 12 square miles of water surface in 1900, giving 3.56 per cent. of the whole, the excess of water-surface evaporation over ground-surface evaporation is 0.32 in., a quantity which is so far within the limit of possible error in other directions as to be negligible.

Grouping of Data by Water Years.—In the comparison of rainfall and run-off grouped by water years, beginning October 1, December 1, or some other date, it is frequently observed that on any watershed certain years, having the same recorded rainfall, have recorded run-off differing by from 1 to 4 ins.

In the 19 diagrams, although most of the points fall on or near the curves represented by the equation, $C = KR^2$, there are some which are at some distance from the curves. Noting this condition, many claim it as proof that there is no definite relation between rainfall and run-off. In reality, the apparent discrepancy is due merely to variation from year to year in ground-water conditions on the date arbitrarily assumed for beginning the water year. The fact that a point does not fall on the curves does not necessarily show that the observations are at fault, but in most cases it does indicate that the date of beginning the water year assumed for the watershed is not the true one for that particular year.

It is an error to consider the water year as a hard and fast division of time. Many of the points which in the diagrams plot some distance from that curve would fall directly on or very near it, had the first of the preceding or succeeding month been used for beginning the water year.

The true water year does not begin or end at any particular date, but should be regulated so that ground-water conditions are nearly constant on the dates selected for the beginning of such years. It is believed that if this could be done all points for which the data are accurate would fall on or near the curve represented by the equation, $C = KR^2$.

Owing, however, to the almost utter lack of data on ground-water levels, it is impracticable to adopt this method of division. Especially in the study of large storage propositions the apparent discrepancies will balance each other and will not affect the conclusions.

Table II.—Values of K, T, S, and KT, for Various Watersheds.

Watershed	K—in the formula, $C=KR^2$	T—Mean annual temperature.	S—Slope of watershed.	KT=K×T.
Lake Cochituate	0.0092	48.5	0.0116	0.446

Schoharie	0.01485	42.3	0.0367	0.630

Manner in Which the Relations Between Rainfall and Run-off Vary from One Watershed to Another.—It has frequently been observed that, other things being equal, a steep watershed will have a greater run-off for the same rainfall than a flat one. The water, staying on the watershed a shorter length of time, has less chance to evaporate. Mr. Vermeule has shown successfully the great influence which the mean annual temperature of a watershed has on the relation of rainfall to run-off.

These two elements, slope and mean annual temperature, the writer believes are, in general, the chief factors determining the manner in which the relation between rainfall and run-off vary from one watershed to another. Hence he will use them in determining the value of K.

The slope of a watershed may be defined as the difference in elevation between the highest and lowest points divided by the square root of the area.

The proper value for the mean annual temperature of a watershed can generally be determined by a study of the data published by the United States Weather Bureau in

the "Summary of Climatological Data for the United States by Sections." In using these data it sometimes happens, especially on mountainous watersheds, that all the observations are at stations in the valleys. On such a watershed the mean annual temperature frequently varies directly with the elevation. In such a case a practical method of determining the mean annual temperature would be as follows: (1) Take the average temperature at the stations. (2) The average elevation for the same stations. (3) The average elevation of the watershed = the elevation of the highest point plus the elevation of the lowest, divided by 2. (4) Take the difference between the average elevation of the stations and the average elevation of the watershed. (5) Multiply this by the mean difference in temperature per foot of increase in elevation. (6) Finally, subtracting this from the average temperature at the stations will give the mean annual temperature of the watershed.

In Fig. 1 T is the mean annual temperature; S is the slope of the watershed, determined as previously described, and K is the constant in the equation, $C = K R^2$.

It was found that for several watersheds having about the same value of S, K varied very nearly as the first power of T. In Fig. 1 the values of KT (the product of K and T) have been plotted as ordinates and the values of S as abscissas.

Table II. gives the values of K, T, S, and KT for various watersheds.

Picking values off the logarithmic curve in Fig. 1 and solving the equation,

$$K\,T = P\,S^x,$$

P being the unknown coefficient and x the unknown exponent, we have, for the equation of the curve, $K\,T = 0.934\,S^{0.188}$

$$\text{but } C = K\,R^2,$$

$$\text{whence } C = 0.934\,S^{0.155}\,\frac{R^2}{T}$$

which is the general formula for the relation of run-off to rainfall.

C = Annual run-off, in inches, on the watershed;
R = Annual rainfall, in inches, on the watershed;
S = Slope of the watershed, equals the elevation of the highest point minus the elevation of the lowest point, divided by the square root of the area;
T = Mean annual temperature of the watershed, in degrees, Fahrenheit.

For convenience in using the formula, Table III., giving values of $S^{0.155}$ was computed. By using this table the formula is easily solved. Thus, for the Rondout watershed, $T = 47$, mean $R = 46.6$, and $S = 0.0664$. From Table III. for $S = 0.0664$, we have $S^{0.155} = 0.658$. Hence the expression for the mean annual run-off of the Rondout becomes

$$C = 0.934\,S^{0.155}\,\frac{R^2}{T} = 0.934 \times \frac{0.658 \times 2180}{47} = 28.5 \text{ ins.}$$

In this case the computed mean annual run-off is just equal to the actual.

The character of the various watersheds considered in the derivation of the formula varies widely. By reference to Table II. it is seen that the slope and the mean annual temperature vary between wide limits. The slope of the Genesee is 0.0054, and that of the Rondout is 0.0664. The mean annual temperature of the Hudson is 41.9 and that of the Neshaminy is 50.6 degrees. In area the variation is from 19 sq. miles for the Lake Cochituate watershed to 10,234 sq. miles for the Connecticut at Hartford. In the matter of forestation the variation is also large, from the watershed of the Genesee with its gently rolling farm lands and few woods, to the heavily forested head waters of the Rondout and upper Hudson. The effect of forests on the quantity of rainfall and run-off is believed to be slight, but on the distribution of run-off throughout the year it is very marked. Other things being equal, a watershed which has been denuded of its forest will have a much lower minimum discharge in summer and will be subject to more violent floods in times of high water.

Table IV. is a comparison, for various watersheds, of the run-off computed by the formula and the recorded observed run-off.

It will be noticed that the closest agreement between the computed and the observed run-off is for the water-

sheds where the data are the most reliable—for instance, the Hudson, Genesee, Esopus and Croton. Furthermore, where there is any material variation the computed quantities are generally less than the observed. Accordingly, the use of the formula for estimates of flow will be likely to give quantities which are less than the actual, rather than those that are more; that is, the error is on the side of safety.

The formula is also applicable for the computation of run-off for individual years. For illustration, take two watersheds—the Hudson and the Esopus. In the case of the Hudson, $S = 0.0149$ and $T = 41.9$, and the formula becomes

$$C = 0.934 \frac{0.520\ R^2}{41.9},$$

$$\text{or } C = 0.0116\ R^2.$$

In the case of the Esopus, $S = 0.0468$ and $T = 44.5$, and the formula becomes

$$C = 0.934 \frac{0.623\ R^2}{44.5} = 0.0130\ R^2.$$

These two illustrations serve to show the degree of accuracy that may be expected in the use of the formula when the rainfall and temperature data are fairly accurate.

The Supply of Missing Records.—It sometimes happens that only two or three years of good run-off records have been kept on a watershed, and that the rainfall records are available for a number of years. In such a case the record may be extended in the following manner:

Table IV.—Comparison Between Observed Run-off and Run-off Computed by the Formula, $C = 0.934\ S^{0.155} \frac{R^2}{T}$.

Watershed.	Mean annual rainfall observed, in inches.	Mean annual run-off observed, in inches.	Mean annual run-off computed, in inches.	Difference, in inches.
Rondout	46.7	28.5	28.5	0
Sudbury	45.7	23.6	21.3	2.3
Connecticut	43.5	23.8	21.1	2.7
Lake Cochituate	47.3	20.4	21.5	1.1
Esopus	48.3	30.1	30.4	0.3
Nashua	48.7	25.4	28.2	2.8
Tohickon	48.4	26.7	23.5	3.2
Croton	49.3	22.6	23.0	0.4
Perkiomen	47.6	23.6	22.6	1.0
Passaic	46.8	25.3	20.7	4.6
Neshaminy	47.8	22.8	20.7	2.1
Genesee	40.4	14.3	14.9	0.6
Muskingum	42.4	15.1	13.3	1.8
Hudson	44.5	23.5	22.9	0.6

Plot on logarithmic cross-section paper points for the two or three years of known run-off, using rainfall abscissas and run-off as ordinates. Compute the run-off for several other years, using the formula

$$C = 0.934\ S^{0.155} \frac{R^2}{T}.$$

Plot the corresponding points. Then draw a straight line parallel to the line $Y = X^2$, among these points giving greater weight to the observed data. This line will be represented by the equation $C = K\ R^2$. Having this curve, the run-off for any year may be read off, using the rainfall as argument.

Application to the Mass-Curve.—Engineers are frequently called on to construct reservoirs of considerable capacity on watersheds where accurate run-off data are lacking. For the determination of the necessary capacity of a proposed reservoir the mass-curve is the accepted method. Having given a watershed without run-off data, but with rainfall records available, a satisfactory mass-curve may be constructed by using the formula

$$C = 0.934\ S^{0.155} \frac{R^2}{T}.$$

The values of S and T are generally easy of determination for any particular watershed.

In using this formula for the construction of a mass-curve it is applied to the rainfall for each month consecutively, and the resulting monthly run-off is used in constructing the mass-curve in the usual manner. Of course, using the formula in this way, the resulting computed run-off for individual months will often be very different from the actual; but in the study of large water power or water supply projects, where water must be stored for several months, this will not affect the conclusions as to the necessary size of the reservoir for a given draft.

The most expeditious method of applying the formula for this purpose is as follows:

Compute several values of C for given monthly values of R. Plot these computed values of C, with the corresponding values of R, on logarithmic cross-section paper. The points will lie in a straight line. This logarithmic curve may then be used for picking off values of C for given values of R.

Two mass-curves for the Croton watershed were plotted by the author. The upper curve was obtained from the recorded run-off data, and the points on the lower curve were computed by the formula, $C = 0.934\ S^{0.155} \frac{R^2}{T}$. It was noticed that the cumulative totals of the observed run-off for 37 years differs from the computed by about 3 per cent., the computed being less than the observed. A draft on the watershed of 1.65 ins. per month, or 320,000,000 gals. per day, was assumed and applied to the curves. The greatest depletion shown on the curve of observed run-off was 14.2 ins., and the mass-curve of computed run-off showed a depletion of 18 ins., a difference of 21 per cent. This difference, however, is on the safe side. It is customary to build reservoirs with a capacity of from 20 to 30 per cent. in excess of the depletion shown by the mass-curve. Had there been no run-off data in existence on the Croton watershed, a reservoir of sufficient capacity could have been decided on from a study of the computed mass-curve.

In a similar manner, two mass-curves were plotted for the Nashua watershed, one from the observed run-off data and the other from computed run-off data obtained by using the formula. A draft of 1.852 ins. per month, or 125,000,000 gals. per day, was assumed. The greatest depletion on the curve of observed run-off was 10 ins., and on the curve of computed run-off, 12 ins., an error which is again on the safe side.

The mass-curves of observed run-off and of computed run-off were plotted for the Esopus watershed. A draft of 1.825 ins., or 250,000,000 gals. per day, was assumed. For the curve of observed run-off, the greatest depletion was 8.2 ins., and, for the curve of computed run-off, the greatest depletion was 7.5 ins. The difference, 0.7 ins., though not on the safe side, is so small that it could not affect materially the size of the reservoir decided on.

Conclusions.—The writer is not of the opinion that the gauging of streams and the accumulation of run-off data should be abandoned, and the method herein described established in their place. Accurate run-off data are scarce, and engineers need far more. These methods and formulas are applicable to watersheds where run-off data are meager or lacking, and it is believed that they will give more reliable results than those now generally in use.

The formula, $C = 0.934\ S^{0.155}\ \frac{R^2}{T}$, is, the writer believes, applicable to the Eastern United States, and, in general, should give results within 10 per cent. of the true run-off. In applying the formula to other watersheds, the writer would advise caution. Although the formula is believed to be general, it is possible that, if more data were at hand on the relation of run-off to rainfall, the value of the constant (here 0.934) and of the exponent of S (0.155) might vary somewhat in other sections of the country, where there is a marked difference in climatic conditions.

Table V.—Comparison Between Observed and Computed Run-off for Various Years, for the Upper Hudson.

Year ending December 1st.	Rainfall observed, in inches.	Run-off observed, in inches.	Run-off computed by formula, in inches.	Difference, in inches.
1888	43.9	23.6	22.3	1.3
1889	43.0	21.7	21.5	0.2
1890	50.4	28.9	29.5	0.6
1891	43.0	20.6	21.5	0.9
1892	53.9	33.1	33.5	0.4
1893	42.2	21.9	20.8	1.1
1894	42.0	19.4	20.4	1.0
1895	36.7	17.5	15.6	1.9
1896	45.2	23.6	23.7	0.1
1897	46.5	26.2	25.0	1.2
1898	48.5	27.1	27.3	0.2
1899	35.8	19.5	14.9	4.6
1900	45.4	20.7	23.8	3.1
1901	42.6	21.9	21.0	0.9

Of course, if this formula is applied to the rainfall for some particular month it will not give the true run-off. It has been shown, however, that it may be used for obtaining monthly run-off, and that the mass-curve when plotted gives depletions which do not differ materially from those obtained when the observed monthly run-off is used in constructing it.

At first sight, the application of the formula may appear to be complicated, but, by using Table III., which gives the values of $S^{0.155}$, it is simple; and if logarithmic plotting is utilized, as suggested, it becomes merely a matter of reading off the curve.

A recent report from Montreal states that a method of converting titanium ore into high grade steel has been discovered by Dr. G. D. Condle, of Montreal, who has been working on the solution of this process for 5 years. It is stated that a new industrial corporation is being formed with a nominal capital of $25,000,000 to take over the rights and all the interests of the new steel process; and a plant is to be set in operation where high grade steel will be produced and sold at about $100 per ton.

A NOTABLE GATHERING OF ENGINEERING EDUCATORS.

On June 23rd there assembled at Princeton, N.J., a group of some two hundred men upon whom largely depends the character of the engineers of this continent for many years to come. Here, for four days, enjoying the freedom of Princeton University, the Society for the Promotion of Engineering Education conducted its twenty-second annual convention.

The choice of meeting place was most happy. In historic Nassau Hall, named in honor of King William the Third, "a branch of the illustrious House of Nassau," and which opened its doors to students in 1756, the executive offices of the convention were located. Regular sessions were held in the Palmer Physical Laboratory, while the annual dinner took place in the magnificent new Graduate College, situated among green fields, three-quarters of a mile to the south of the main group of buildings.

It was a gathering at once representative and diverse. Engineering professors from Boston to Seattle, from Toronto to Mississippi, participated in the deliberations. Veterans like William Kent and Mansfield Merriman rubbed shoulders with vigorous young enthusiasts like Henry H. Norris, of Cornell; Dugald C. Jackson, of "Tech." and F. L. Bishop, the "Boy Dean" of Pittsburgh. Here, from day to day, was witnessed the graciousness and tact of President Anthony, the versatility and precision of Karapetoff and the power and picturesqueness of Franklin, of Lehigh. Silent, but contributive of weight to the deliberations, were Turneaure, of Wisconsin; Talbot, of Illinois, and Ketchum, of Colorado.

On Tuesday at 2.30 the meeting was formally opened with an address of welcome by John Grier Hibben, president of Princeton University. In a few earnest words he indicated the necessity of engineers being scientific, rather than technical, being searchers for the causes of the facts and not merely for the facts themselves. The engineer cannot afford to be a pragmatist—a judger of things in accordance with the way they turn out—but must know beforehand what the result will be and must be able to satisfy his client that he does know.

The receipt and consideration of reports of committees and a meeting of the delegates of the institutional members constituted the formal business of the first day.

At five o'clock a reception to the delegates was tendered by President and Mrs. Hibben at "Prospect," the official residence of the president.

In the evening an informal "get-together" smoker was held at the Nassau Club, facetiously described by one member as a club for gentlemen and members of the Faculty of Princeton University.

The formal welcome of the State of New Jersey was extended on Wednesday morning by the Hon. Jas. F. Fielder, Governor of the State.

With the exception of the few minutes thus occupied, the forenoon was devoted to a session on College Administration. Two admirable papers were presented on the subject, one on "The Financial Department of a School or University," by Mr. T. H. B. McKnight, treasurer of the Pennsylvania lines west of Pittsburgh, and the other on "The Relation of the Administrative Department to the Teacher," by Dr. C. R. Mann, of the University of Chicago, who has been commissioned by the Carnegie Foundation for the Advancement of Teaching to investigate the courses in engineering colleges for the Joint Committee on Engineering Education. From the character of Dr. Mann's address, some severe strictures

on over-administration may be expected in his report to the Joint Committee. In the report of the Committee on Statistics, the surprising fact was brought out that in thirty-two representative engineering colleges of the United States, the attendance for the session 1913-14 was 8.3 per cent. greater than for 1912-13.

Special attention was given on Wednesday afternoon to the relation of scientific management to education. Professor Hugo Diemer, author of "Factory Organization," presented a paper on "Education in Scientific Management," in which the course instituted by him at the Pennsylvania State College was outlined. A paper by Professor L. M. Passano, of the Massachusetts Institute of Technology severely criticizing certain claims of the advocates of scientific management in the matter of promoting "academic efficiency" was read in abstract. The "scientific manager" would, in Professor Passano's opinion, "like the suburbanite, make two blades of grass grow where only one ought to."

In the evening, an interesting lecture was given on "The Meteor Crater in Arizona," by Dean W. F. Magie, of Princeton University.

Thursday morning opened with fireworks: it was the mathematicians' field day. First, a paper by Professors W. S. Franklin, Barry MacNutt and R. L. Charles on "Practical Mathematics" was presented in characteristic style by Professor Franklin. Professor E. V. Huntington, of Harvard, followed with one on "The Use of the Differential in Calculus." Professor E. R. Hedrick, of the University of Missouri, completed the triology with one on "The Calculus Without Symbols." Correct statements of meaning formed the burden of the discussion—a most animated and entertaining one.

Methods of study next came under consideration and papers were read by Professor W. L. Upson, of Union College, on "The Preceptorial System and Electrical Engineering at Union College," by Professor George L. Sullivan, of the University of Santa Clara, on "Teaching Engineers How to Study," and by Professor W. H. Kennerson, Brown University, on "Giving Instruction in Methods of Study."

The afternoon opened with two papers on courses of instruction—one by Professor A. B. McDaniel, of the University of Illinois, on "Co-ordination in Engineering Instruction," and the other by Professor H. S. Jacoby, of Cornell University, on "A Study of Technical College Catalogues with Respect to Descriptions of Courses of Study and of Instruction." Fundamental pedagogical topics received consideration in papers by Professor C. F. Harding, of Purdue University, on "Grading of Students by Universities vs. Grading of Technical Graduates by Employers," and by Professor A. M. Wilson, University of Cincinnati, on "A Report of Progress in Co-operative Education."

At the annual dinner on Thursday evening, Dean Gardner C. Anthony, president of the society, delivered his presidential address—an eloquent plea for a training of more cultural content and for greater co-ordination between liberal arts and technical studies.

On Friday, the 26th, papers were presented by Professor L. F. Rondinella on "Constructive Drawing in High Schools and Engineering Colleges"; by Professor J. B. Whitehead on "A Department of Engineering at the Johns Hopkins University"; by Professor W. M. Wilson, University of Illinois, on "Proposed Courses in Structural Engineering for Civil Engineering Students," and by Professor Chas. E. Lucke, on "The New Mechanical Engineering Course at Columbia University."

At the final session Dean Anson Marston, of the University of Iowa, was elected president of the society, and Dean F. L. Bishop, of Pittsburgh, secretary for the ensuing year.

In the opinion of those present, the Princeton meeting was the best in the history of the society, and if future conventions keep pace with it, a powerful constructive force in engineering education will thereby be maintained from year to year.

ENGINEERING ACTIVITIES IN HALIFAX, N.S.

FROM an engineering standpoint, the city of Halifax is experiencing considerable activity this season compared with other centres of population throughout the Dominion. The Halifax ocean terminals, the construction and organization of which is under the supervision of Mr. Jas. McGregor, C.E., have exhibited marked progress of late, a large quantity of excavation and filling having been completed. Work has progressed on the bulkhead, which is to extend into the harbor for approximately ¼ of a mile and as far south as the proposed breakwater. The plans, together with the construction work as it is at present, indicate that the completed terminal will be one of the finest in North America.

The city engineer's staff has under construction, or supervision, many new sidewalks, sewers and water extensions. The new terminals create further activity in this department owing to the establishment of grades, street lines, building sites, etc.

The city has just completed a pavement on Cogswell Street, the principal artery leading north from the central portion of the town. Granite block pavement was used. It is the intention of the department to use this material for the construction of pavements on a number of hilly streets at an early date. Of these, Argyle Street, the next street of importance outside of the already paved business streets, will be paved this year. There are nearly 50 concrete sidewalks of varying lengths to be under construction at an early date. A considerable length of sewers, chiefly in the outlying districts, is being laid, and it is expected that the question of a large intercepting trunk sewer with an outlet near the mouth of the north-west arm will be up for consideration at an early date.

The high service reservoir, commenced last year, is nearing completion. It will be a great addition to the water system, especially to the north and higher sections of the city. It is built of reinforced concrete, and is located at an elevation of 247 ft. above mean low tide. Mr. H. W. Johnston, C.E., assistant city engineer, was designing engineer and is superintending its construction.

Building operations are decidedly brisk, the largest building being the new market, Dalhousie University science building, St. Mary's College and St. Matthias' Church.

PROGRESS ON ROADS IN NORTHERN ONTARIO.

Mr. J. F. Whitson, Provincial Road Commissioner of Ontario, states in connection with the work on roads in Northern Ontario now in progress, that new roads are being opened up, and many others completed. The trunk road along the Timiskaming and Northern Ontario Railway is being opened up in sections; and this road is now available for almost all of the distance between the swamp outside of Cochrane on the north to the rocky ridge crossing the country near Sesikinika on the south. The trunk road between Charlton and Englehart, and between Charlton and Long Lake is being graded; while road work is also in progress around Matheson.

AMERICAN SOCIETY FOR TESTING MATERIALS.

The American Society for Testing Materials in holding its 17th annual meeting this week at Atlantic City. The convention is divided into nine sessions terminating on Friday, July 3rd. Among the reports of committees which are being presented are the following:—Standard Specifications for Steel. This report is an exhaustive one and bespeaks an extremely active year for the committee. The recommendations occupy 106 pages and cover the proposed revisions in present standard specifications for steel and steel products; factor table and curve for values of elongation and reduction of area; proof tests of finished forgings; permissible variations in weight and gauge of sheared plates; proposed revised standard specifications for carbon-steel rails, for carbon-steel and alloy-steel forgings, for quenched and tempered carbon-steel axles, shafts and other forgings for locomotives and cars, for structural steel for cars, and for carbon-steel bars for springs. In connection with the proposed new standard methods of chemical analysis for plain carbon steel the report deals with the direct combustion and colorimetric method of determination of carbon and other methods for the determination of manganese, phosphorous, sulphur, silicon, copper, nickel and chromium.

The report upon standard specifications for wrought iron includes the consideration of the activities of sub-committees upon tubes and pipe; staybolt and engine bolt iron, chain iron, and iron chain.

The committee on the heat treatment of iron and steel presents a report on proposed recommended practices of (1) annealing of carbon-steel castings; (2) heat treatment of case-hardened carbon-steel objects.

Proposed standard specifications for coal-drawn steel are presented, together with tentative specifications.

The committee on magnetic testing of iron and steel submits a report which contained a number of recommendations in the existing specifications.

The committee on standard specifications for quicklime and hydrated lime is presenting specifications to cover each.

The most extensive committee report is that on preservative coatings for structural materials. The committee presents proposed standard definitions of terms used in paint specifications besides the reports of the various sub-committees, including those on paints, oils, turpentines and also on steel plates.

The committee on lubricants has a report outlining proposed provisional tests for lubricants. A minority report is being brought in with respect to viscosity.

The committee on standard testing for road materials recommends provisional tests and methods for: (1) determination of apparent specific gravity of rock; (2) determination of the absorption of water per cubic foot of rock; (3) making a mechanical analysis of broken stone or broken slag; (4) making a mechanical analysis of mixtures of other fine material with broken stone or broken slag. The report also contains proposed definitions of non-bituminous and bituminous road materials. A report is also brought in respecting regulations governing the form of specifications, in which a number of revisions are made.

Proposed standard specifications are brought in for strength tests, quality, design and construction of drain tiles.

The committee for the methods of sampling and analysis of coal is bringing in its second preliminary report.

Other reports being presented are on standard methods of tests, fire proof materials, non-ferrous metals and alloys, and standard specifications for copper wire, cement, brick, timber, rubber products and locomotive cylinders.

The annual report of the executive committee shows a membership of 1687.

The following are the papers being read at the various sessions:—"Magnetic Habits of Alloy Steels," by J. A. Mathews; "An Efficiency Testing Machine for Testing Drills, Caps and Dies," by T. Y. Olsen; "Are the Effects of Simple Overstrain Monotropic?" by Henry M. Howe; "Rubber Belting and Methods of Testing," by W. E. Campbell; "Report on Proceedings of Turin Meeting of the Council of the International Association for Testing Materials," by Henry M. Howe, Life Member of Council; "A New Vibratory Testing Machine and Results Obtained by its Use," by S. V. Hunnings; "Testing Concrete Aggregates," by Lloyd M. Chapman; "Some Considerations Affecting Specifications for Wrought Non-Ferrous Materials: Examination of Concrete Failures for their Determining Causes," by R. S. Greenman; "Specifications and Tests of Glue," by Oscar Linder and E. C. Frost.

CANADIAN ELECTRICAL ASSOCIATION.

The 24th annual convention of the Canadian Electrical Association was held in Montreal, June 24th, 25th and 26th, with the Ritz-Carlton as head-quarters. The president, Col. D. R. Street, of Ottawa, conducted the proceedings. Over 200 members and guests were in attendance. The convention was divided into morning and afternoon sessions and many instructive and valuable addresses were given. The entertainment of the delegates throughout the convention was very efficiently carried out. The entertainment committee, with Mr. Lawford Grant as chairman, made it a very pleasant occasion, particularly for the out-of-town members and visitors.

Among the papers presented at the technical sessions were the following:—"Modern Switching Equipment," by L. B. Chubbuck, Canadian Westinghouse Co.; "Maximum Demand Determination and its Relation to the Cost of Supply of Electrical Energy," by P. T. Davies, Montreal Light, Heat and Power Co.; "Legal Points in Connection with Central Station Matters," by G. H. Montgomery, K.C.; "Grounding of Distribution Circuits," by S. Bingham Hood, Toronto Electric Light Co.; "The Value of Electrical Heating Devices to the Central Station," by Harold S. Brown, Canadian General Electric Co.; "Some Notes on Steam Railway Electrification," by J. A. Shaw, Canadian Pacific Railway Co.; "Interruptions on Long Distance Transmission Lines," by P. Ackerman, Toronto Power Co. Numerous other papers and discussions were presented, together with reports on the work of various International Electric Light Association Committees. The election of officers for the coming year resulted as follows:—

President, Col. D. R. Street, sec.-treas. Ottawa Electric Co.; first vice-president, D. H. McDougall, sec.-treas. Toronto Power Company; second vice-president, R. M. Wilson, Montreal Light, Heat and Power Co.; third vice-president, Wills MacLachlan, Electric Power Company, Toronto; honorary secretary, T. S. Young, Hugh C. MacLean Co., Toronto; secretary-treasurer, Alan Sullivan, Toronto. Managing committee—J. S. Gould, Smith's Falls; G. W. Magalhaes, Toronto; P. T. Davies, Montreal; H. G. Matthews, Quebec; A. E. Dunlop, Pembroke; J. S. Norris, Montreal; George Kidd, Vancouver; Robin Boyle, Niagara Falls; W. G. Angus, Hamilton; W. S. Robertson, Toronto; E. L. Milliken, Sydney, N.S.; L. W. Pratt, Hamilton; H. R. Mallison, Montreal; H. Hulme, Montreal.

The next place of meeting was left to be decided by the managing committee.

Coast to Coast

Toronto, Ont.—The bridge at Sunnyside, Toronto, has been completed, and is now open for traffic.

St. Catharines, Ont.—Hydro-Electric was turned on in St. Catharines for the first time officially on June 27.

Vance, Sask.—Another gas and oil strike has been made at Vance, Sask., at a depth of 47 feet. Vance is located on the Winnipeg-Edmonton line of the C.P.R.

Calgary, Alta.—The latest report from the Street Railway Department of Calgary shows a gross deficit of approximately $70,000; and it is expected that this will be greatly augmented before the end of the year.

West Vancouver, B.C.—On property, known as George Mars' property, which is located half a mile due north of Dundarave station on the P.G.E. railway, oil has been discovered. It is proposed to form a company and to place stock upon the market almost immediately.

Winnipeg, Man.—The new elevated track at the C.P.R. depot, Winnipeg, is in operation. This track is about 6 feet higher than the present level of the station. The improvements at the depot are reported as proceeding rapidly. The track adjacent to the finished elevated track is being torn up preparatory to laying the foundations for the steel girders which will carry the tracks.

Montreal, Que.—While the big concrete conduit, which supplies Montreal with water from the St. Lawrence river, is being inspected in August by the New York experts, Messrs. Hering and Fuller, the emergency conduit from the Lachine canal will be used by the city. Contamination of the canal water will be prevented during the period of inspection and repairs—if any are found necessary—to as great a degree as possible.

Montreal, Que.—The section of the C.N.R. tunnel which extends from the upper end of the McGill University grounds to Cathcart street is now being lined with cement blocks, which are blocks weighing about one ton each. Some 40 or 50 feet of this lining has been put in position, and the work will be completed during the summer. The other sections of the tunnel have been bored practically through the solid rock and will not require this lining.

Vancouver, B.C.—The first section of the second new 18-inch water main, a 750-foot length of pipe, has been hauled across the First Narrows and has been placed in position. Some time ago, the work of hauling was commenced, but had to be stopped on account of ledges being encountered beneath the surface; and these had to be blasted away. Two other sections must be hauled across the Narrows, and will be connected under water.

Brantford, Ont.—Preparatory work for the raising of Lorne Bridge at Brantford is being advanced rapidly by the contractors for the work, P. H. Secord and Sons. The big abutment stones are being undermined and removed to make way for the new inner wall now under construction on both sides; and just as soon as these walls are completed, the bridge will be raised. This work is being carried on with very little interruption of traffic to and from West Brantford.

Lethbridge, Alta.—It is reported that work on the Thirteenth Street subway is progressing rapidly. The grading on the south side is practically finished; while, to the north of the regular main track of the C.P.R., piles have been driven, and a temporary trestle constructed. When grading on the north side is completed, trains will be run over the trestle while the work of excavation proceeds. The structure is to be completed by August 1.

Edmonton, Alta.—Mr. McArthur reports in connection with railroad construction on the E.D. and B.C. and on the A. and G.W. Railway, that 2,000 men are engaged on the former railway and 1,500 on the latter; that the big bridge over the Athabasca River at Smith will be completed in about one month's time; that the ballasting of the track between Edmonton and Smith will be completed in from 6 to 8 weeks; while, on the A. and G.W. Railway, the laying of steel is to be commenced at once.

Toronto, Ont.—First among the roads on the program of the provincial highways commission which will be surveyed and constructed, will be the road extending along the lake shore from Toronto to Hamilton. It has been decided to construct a substantially paved highway 20 feet in width, and to have it ready for traffic in the fall of 1915. A staff of 14 men are now engaged in a motor survey of the intervening district between the two cities; and following their report, legislation will be introduced to allow the letting of contracts and the immediate procedure with building.

Cranbrook, B.C.—Already the Cranbrook city council has commenced action in connection with the work covered by new money by-laws which have received the favorable vote of Cranbrook ratepayers. The water system which will be constructed will cost about $110,000, and will be one of the best in Western Canada. Mannesman steel pipe, the contract for the supply of which is now held by J. B. Turney and Co., Limited, of Lethbridge, Alta., will replace all of the old wooden pipe now in use. A supply of 110 cars of pipe, or over 5,000 tons, will be necessary.

Vancouver, B.C.—The G.N.R. bridge on Broadway avenue, Vancouver, has reached the stage of practical completion, and is being used for vehicular and pedestrian traffic. The bridge is 288 feet in length and 70 feet wide. The sidewalks are of cement, and the roadway is paved with wood blocks; while tracks have been installed on the bridge to provide for the possibility of a future extension of the street railway along Broadway. The G.N.R. company is now proceeding with the construction of abutments on the viaduct which passes over the Grandview cutting at Victoria drive.

Red Deer, Alta.—A press to manufacture pressed cement brick and building blocks is being started in Woodlands to the north of Red Deer, Alta. It is stated that in the manufacture of these brick, they are subjected to a pressure of 40 tons, and will stand a pressure test of 2,742 lbs. A brick was tested by placing it upon two blades 7 inches apart; and it took 850 pounds of pressure on a blade in the middle to break it. The press has a capacity of 5,000 bricks or 500 building blocks a day. The faced brick is manufactured plain, rock-faced, or ornamental, and of any color.

Winnipeg, Man.—Arrangements are now under way in connection with the erection of the big power plant which is to be built by the Winnipeg Electric Railway Company at Big Bonnet Falls, and which is to serve for the development of power not only for consumption by the street railway but for manufacturing purposes as well. The location at Big Bonnet Falls is about 70 miles north of Winnipeg. The plant will have a final capacity of about 150,000 h.p., and will cost close to $6,000,000. Only from 50,000 to 60,000 h.p. will be developed at first, or sufficient for immediate need.

London, Ont.—The engineers of the Hydro-Electric Commission who have been investigating the power possibilities of the northern peninsula, have sent in a report to the effect that over 22,000 h.p. of electric energy is available, and that the approximate cost of development would be $2,000,000. The Big Shute, purchased by the Commission for $400,000, is capable of delivering 6,000 h.p.; Port Severn, 1,200 h.p.; Eugenia Falls, 8,000; Wadsdell's Falls, 1,200; the Saugeen River, in Bruce, 4,000; and Swift Rapids, 6,000. The counties to be supplied from these sources are Simcoe, Ontario, Dufferin, Grey, Wellington, Bruce, and a portion of Huron.

Victoria, B.C.—It is given as an assured fact that towards the end of July, a service between Victoria and Courtenay over the new East Coast extension of the E. and N. Railway, will be opened. Steel-laying has now reached the Trent River, where the Dominion Bridge Co. is installing the last bridge which must be erected before entering Courtenay. This bridge is about 5 miles from the town; and since the viaduct will be sufficiently advanced for use in a week or so, rails will soon be carried into the temporary terminal and permanent divisional centre of this section of the Island railway. Arrangements are under way for the official inauguration of the service.

Port Nelson, Ont.—This year, early in July, the Dominion Government purposes despatching from Halifax to Port Nelson 5 steamers of materials and supplies necessary for the construction of the railway terminals, elevators, and harbor work at that port. Up to date, over $6,000,000 has been expended on the railway and terminals; and, at the session just closed, further appropriations were voted to the extent of $4,500,000 for the terminals and elevators. The Hudson Bay Railway has now been completed over half the distance from Le Pas. And, this year, the Government will undertake the construction of lighthouses and wireless stations on the Hudson Straits along the northern route to Port Nelson.

Hamilton, Ont.—Of the $620,000 which has been granted by the Dominion government for works at Hamilton, $250,000 is to be expended at Stipe's inlet on part of the harbor improvement scheme mapped out at Hamilton. The inlet will be deepened and widened, and large docks will be built, so as to afford good shipping facilities in the very heart of the industrial annex. $165,000 has been secured for the purchase of property and the commencement of work on the new customs house and post-office extension. $100,000 is the grant obtained for completing the work at the revetment wall; $50,000, for a wharf at the foot of Wentworth street; $40,000, for a new east end post-office; and $15,000 for improving the central post-office.

Edmonton, Alta.—In July, 1913, the Ulen Contracting Company, Chicago, commenced work on the contract of laying sewers in Edmonton. Since September 13 to the week ending May 30, over 1,000 feet of trunk sewers has been laid each week, while in one week, 1,142 feet were laid. In all 39,215 lineal feet have been laid, the sewers varying from 4.4½ inches to 6 inches in diameter. The sewers which have been laid by the company are those provided for in what is known as the Potter report, which was designed to prepare for a population of 200,000 people. Only about 1,900 feet remain to be laid, and the contract will have been completed, though the company has until the end of March, 1915, to fulfil its contract. The total value of the work is about $1,500,000; and it is the largest contract ever awarded by Edmonton officials.

North Vancouver, B.C.—On June 17, actual work commenced at North Vancouver upon the construction of the great dry docks and engineering works, including foundries, shipbuilding yards and graving docks, of the Dominion Shipbuilding, Engineering and Dry Dock Company. The incident was made the occasion of a ceremony, the nature and magnitude of the proposed works being pointed out to over 500 citizens of Vancouver. Already a large amount of money has been expended in clearing lands, in making roadways, and in planning and surveying the site, as well as in laying the water mains. According to the expressed intention of officers of the company, work will be vigorously pressed, and orders will be taken, as early as January of next year, when the first unit of the plant will have been completed.

Red Deer, Alta.—Seymour and Dawe, city engineers of Red Deer, have submitted to the city council a plan of the present and proposed sewerage system and a detailed estimate of the cost of the extensions, amounting, in all, to $101,394.60. The engineers were instructed in 1912 to proceed with a topographical survey for the purpose of preparing plans for extensions to the present sewer system. The plans presented indicate the rates of grade, elevations at intersections, location of manholes and depth of fill at all the principal points. The general idea is to construct a fairly large concrete or vitrified pipe trunk sewer with a storm outlet for the total sewage until such time as the city will be expected by the Provincial Board of Health to construct a sewage disposal plant, after which this storm outlet will only be used for storm water. The sewage disposal works are designed to be located some distance down the river.

Fort George, B.C.—The construction of the new winter road, which is to be built between Fort George and the Peace River district, is being urged upon the British Columbia authorities by the Fort George board of trade and the trade organizations of Vancouver and other coast cities. The road as at present planned will make use of all lakes, rivers and streams, cuttings being made so as to connect these natural winter highways, thus practically eliminating all grades, and providing the most convenient means of reaching the Peace River country before the institution of railway service. The road will follow the Giscombe Trail from Fort George to Giscombe Portage, along the Crooked River, with cut-offs in convenient places to shorten the mileage, across McLeod Lake, along the Missinchinka River to the Pine Pass, across the pass and down the Pine River to the Pouce Coupe country, with cuttings at various places to enable settlers to get down to the river easily.

Mount Dennis, Ont.—Work is now in progress at Kodak Heights, in Mount Dennis, on the plant of the Canadian Kodak Company, Limited, which is being erected at a cost of about $1,500,000. In the new plant, there will be seven buildings, with a floor area of more than 480,000 square feet, or about 11 acres. The largest building will be 460 feet long by 80 feet in width and 5 storys high. The plans call for reinforced concrete construction, with metal sashes and wire glass. In the seven structures, there will be used 2,500 tons of steel bars, 600 tons of fabricated structural steel, 80,000 square feet of metal sash, with 25,000 cubic yards of concrete requiring 45,000 barrels of cement. There will be a complete system of fire protection, consisting of outside hydrants, hose-houses and sprinkling systems for each building; and water for manufacturing purposes will be drawn from two concrete reservoirs with a capacity of 1,000,000 gallons. As Kodak Heights is about a mile beyond the limits of the city of Toronto, the water supply will be taken from 150-foot wells located on the company's property. The combined flow of these wells will be about 175,000 gallons per day. The manufacturing buildings proper will be located on a plateau, at the foot of which the power plant will be set. The contractors for the general construction of the plant are C. E. Deakin, Limited, of Montreal.

Vancouver, B.C.—The Vancouver and District Joint Sewerage Board is now advertising for tenders for the construction of what is officially known as Contract No. 2 of trunk sewer mains, which will cost at least $350,000. The work under this contract means the extension of a branch of the China Creek sewer to Central Park, with tributary mains to Gladstone, Collingwood and Earls road districts and a separate trunk sewer to Trout Lake. Contract No. 1, which is now under way, will probably be completed by November next. It covers the China Creek and Canoe Creek mains in wards Five and Eight and a portion of South Vancouver; and represents a cost of about $250,000. It is expected to com-

mence work on Contract No. 2 in August, and to have this completed within a year. The Joint Sewerage Board also proposes to proceed this year with the levelling of Burnaby Lake. When the water is at its lowest in July and August, it is intended to clean out the Brunette River from North road to the lake, and thus to increase the flow of water out of the lake, dropping the level several feet. This will have the effect also of increasing the flow from Still Creek, west of Burnaby Lake. The board will probably straighten Still Creek and endeavor to make it a better carrier of drainage water from this district. There is also a possibility that the sewerage board may take steps this season to extend the Balaclava main trunk in Kitsilano south to the city boundary line.

Fraser River, B.C.—The boring at the mouth of the North Arm of the Fraser river for the location of the best course for the channel in connection with the proposed harbor works, has proven satisfactory. The contract for this work was awarded to K. S. Robinson, of Vancouver. One hole sunk on the south of McMillan's Island, between that island and Sea Island, went down 45 feet and found nothing but sand and clay. Another off the Indian reserve was sunk 75 feet and down to 63 feet only sand and clay were encountered, when hard pan was struck. Several other holes have been bored at the mouth of the stream, and all have been equally satisfactory. Surveyors, also, are making current and water observations in the river, as well as surveying the foreshore and locating suitable places for test-boring. Also, good progress is reported on the construction of the long jetty at the mouth of the North Arm at the point of McMillan's Island. This, which will be 4 miles in length, will run parallel with and about 1,500 to 2,000 feet from the shore, and is being built by the Federal authorities for the protection of the channel, so as to prevent the sand from the sand heads silting up the channel, by the action of the tides. About a mile of bulkheading is already done, and work is now proceeding a mile further out towards the gulf, from the end of McMillan's Island, and directed landwards. Mattressing will be commenced when the jetty has progressed somewhat further.

PERSONAL.

J. C. NELSON, of Fort Rouge, Man., has been appointed traffic superintendent on the new railway in connection with the Greater Winnipeg Water District. Mr. Nelson has been in railway work for 23 years. In 1907 he joined the staff of the Northern Pacific Ry., at Winnipeg.

R. W. LEONARD, C.E., is resigning his position as commissioner of the National Transcontinental Railway, and the Department of Railways and Canals, Ottawa, will assume charge of his duties. It is reported that F. P. Gutelius, general manager of the Intercolonial Railway will be given charge for the Government of its whole system of railways —i.e., the I.C.R., the N.T.R. and the Hudson Bay Ry.

OBITUARY.

From Brandon, Man., comes the report of the death of Arch. M. Leitch, for many years a prominent contractor on the western lines of the Canadian Pacific Railway Company. Mr. Leitch was born in Argyle, Scotland, 66 years ago, and at the age of 36, became engaged in railway building in Canada.

An extremely sad fatality occurred at Copper Cliff, Ont., on the morning of June 25th, when Fred. J. Bedford, a '08 graduate in mining of the University of Toronto, was instantly killed while examining the mechanical operation of a skip in Mine No. 2 of the Canadian Copper Company.

Mr. Bedford had proceeded to the 10th level and was stationed at the side of the shaft when, owing to a mistaken signal, the skip descended upon him from the 9th level, causing instant death.

Mr. Bedford entered the employ of the company in 1908. Shortly afterward he proceeded to Porcupine and took charge of the Dome Mine at its opening. Later he entered into private practice in a consulting capacity and in assessment work. In November, 1913, he returned to Copper Cliff where he had since occupied the position of shift boss of No. 2 mine.

COMING MEETINGS.

AMERICAN SOCIETY FOR TESTING MATERIALS. —Seventeenth Annual Meeting to be held in Atlantic City, N.J., June 30th to July 4th, 1914. Edgar Marburg, Secretary-Treasurer, University of Pennsylvania, Philadelphia, Pa.

AMERICAN SOCIETY OF ENGINEERING CONTRACTORS.—Summer convention to be held at Brighton Beach, N.Y., July 3rd and 4th, 1914. Secretary, J. R. Wemlinger, 11 Broadway, New York.

UNION OF CANADIAN MUNICIPALITIES.—Annual Convention to be held in Sherbrooke, Que., August 3rd, 4th and 5th, 1914. Hon. Secretary, W. D. Lighthall, Westmount, Que. Assistant-Secretary, G. S. Wilson, 402 Coristine Building, Montreal.

WESTERN CANADA IRRIGATION ASSOCIATION.— Eighth Annual Meeting to be held at Penticton, B.C., on August 17, 18 and 19. Secretary, Norman S. Rankin, P.O. Box 1317, Calgary, Alta.

AMERICAN PEAT SOCIETY.—Eight Annual Meeting will be held in Duluth, Minn., on August 20th, 21st and 22nd, 1914. Secretary-Treasurer, Julius Bordollo, 17 Battery Place, New York, N.Y.

CANADIAN FORESTRY ASSOCIATION.—Annual Convention to be held in Halifax, N.S., September 1st to 4th, 1914. Secretary, James Lawler, Journal Building, Ottawa.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown, Indianapolis, Ind., Secretary.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.— 11th Annual Convention; 5th American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau St., New York, N.Y.

The Ottawa branch of the Canadian Society of Civil Engineers announces the date of its annual meeting as the first Wednesday in October. During the summer months the rooms at 177 Sparks Street will be closed.

ORDERS OF THE RAILWAY COMMISSIONERS OF CANADA

Each week on this page may be found summaries of orders passed by the Board of Railway Commissioners, to date. This will facilitate ready reference and easy filing. Copies of these orders may be secured from *The Canadian Engineer* for small fee.

22011—June 13—Amending Order No. 21751, dated April 29th, 1914, by striking out paragraphs 4, 5 and 6 of operative part of Order.

22012—June 16—Relieving G.T.R. from providing further protection at crossing of Waterloo St., town of New Hamburg, Ont.

22013—June 17—Approving proposed Supplement No. 3 to Canadian Freight Classification No. 16, as finally revised and submitted for approval by G. C. Ransom, Chairman, Canadian Freight Association, by letter dated at Montreal, June 10th, 1914, and with which is consolidated Supplement No. 2 approved by Order No. 20967, Dec. 10th, 1913, to become effective with the least delay necessary, subject to certain provisions.

22014—June 17—Authorizing G.T.R. to construct siding into premises of John R. Booth, on Lot 29, Con. 2, Tp. Dickens, District Nipissing, Ont., near Opeongo.

22015—June 17—Authorizing G.T.R. to construct siding and spur therefrom, into premises occupied by Ross, Church Road Co., Limited, Lot 260, 6th Range, Tp. Godmanchester, Co. Huntingdon, Que.

22016—June 17—Approving city of Montreal plans No. B-1-1342-1 and No. B-1-1342-2, showing diagram of material and general details of steelwork and details of sidewalk brackets, of subway proposed to be constructed under C.P.R. at Park Ave., Montreal.

22017—June 17—Authorizing G.T.R. to construct siding into premises of Interprovincial Brick Company of Canada, Limited, on Lot 29, Con. 5, Tp. Chinguacousy, Co. Peel, Ont., near Cheltenham.

22018—June 15—Authorizing Dominion Stock and Bond Corporation to construct subways at Corporation and Government Streets, under G.T.P. Ry., town of Fort Fraser, B.C.

22019—June 16—Authorizing C.N.R. to operate trains over railway between Saskatoon and Harris, 49.4 miles, at speed not exceeding 25 miles an hour, instead of 20 miles. And relieving company of speed limitation of 15 and 20 miles an hour over portion from Harris to Kindersley, 76.7 miles.

22020—June 18—Approving plan showing alterations and additions to C.N.R. Co.'s station building at Alsask, Sask.

22021—June 16—Approving and authorizing clearances, as shown on G.T.R. plan, of bridge over siding to premises of Dominion Tire Co., Limited, Berlin, Ont., subject to certain conditions.

22022—June 17—Authorizing G.T.R. to construct siding into premises of Dominion Glass Co., Limited, Toronto, Ont.

22023—June 18—Authorizing G.T.R. to construct siding into premises of Kirkfield Portland Cement Co., Limited, Lot 18, Con. 2, Tp. Somerville, Co. Victoria, Ontario.

22024—June 16—Authorizing C.P.R. to construct Bassano-Easterly Branch Line across fifty-eight (58) highways, mileages 0.82 to 50.95, with some diversions.

22025—June 17—Extending, until August 1st, 1914, time within which C.P.R. install electric bell at crossing of highway at Port Haney, B.C.

22026—June 18—Relieving Michigan Central R.R. from maintaining day and night flagman at crossing of highway about 2 miles west of Mull, Tp. Harwich, Ontario.

22027—June 18—Authorizing C.L.O. & W. Ry. (C.P.R.) to include within limits of right-of-way shown in plans approved under Order Nos. 17024 and 17105, lands edged in red on plan referred to in book of reference dated June 8th, 1914.

22028—June 10—Authorizing City of Vancouver, B.C., at own expense, to construct highway over V.V. and E. Ry. and Nav. Co., at Venables St.

22029—June 8—Directing that Esquimalt and Nanaimo Ry. file plans showing culvert sufficient to properly drain lands of Adam Gordon, Hillbank, B.C., for approval of Engineer of Board; work be completed to satisfaction of Engineer of Board within 2 months from date of approval of plans; and be done at expense of Ry. Co. Upon completion of work Adam Gordon pay to Ry. Co. sum of $50.00 towards expense of said work.

22030—June 22—Authorizing C.P.R. to open for traffic double track from Herbert to Notman, mileage 91.9 to 95.1. Sask.

22031—June 22—Granting leave to Government of Sask., at own expense, to construct highway over C.P.R. blind line north of Sec. 15-30-22, W. 2 M., Sask.

22032—June 22—Authorizing G.T.R. to construct siding into premises of Welch Grape Juice Co., Lot 21, Con. 6. Tp. Grantham, Ont.

22033—June 22—Approving location C.N.O.R. station grounds at Vaughan, Tp. Deacon, Dist. Nipissing, Ont., mileage 151.1 from Ottawa.

22034—June 23—Authorizing C.N.R. to construct across 37 highways, mileage 44.84 to 93.85, Sask.

22035—June 22—Granting leave to Winnipeg, Selkirk and Lake Winnipeg Ry. to cross, for construction purposes only, until September 1st, 1914, Selkirk Branch of C.P.R. Applicant operate its trains over crossing between hours of 6 a.m. and 11 p.m.; during these hours crossing be protected by watchmen, appointed by C.P.R., at expense of applicant—watchman be supplied with C.P.R. train time table, and if possible be notified by it of any extra train requiring to make the crossing during the hours of operation by Applicant.

22036—June 17—Approving agreement between Bell Telephone Company and Caradoc-Ekfrid Telephone Company, Limited, dated June 9th, 1914.

22037—June 22—Authorizing Shale Products, Limited, to construct aerial tramway over Hamilton and Allandale Branch of G.T.R. near Inglewood Jct., Ont., subject to certain conditions.

22038—June 18—Authorizing Department Railways and Canals to construct Welland Ship Canal Construction Ry. across N. St. C. & T. Ry. at Lake Shore Road, Port Weller, Ont., subject to and upon certain conditions. Department to bear and pay whole cost of providing, maintaining interlocking plant.

22039—June 19—Amending Order No. 20240, Sept. 2nd, 1913, by adding clause,—"The Ry. Co. bear and pay cost of filling side ditches and installing crossing planks, cattle guards, and culverts."

22040—June 20—Authorizing G.T.P. Ry. to construct across Government Road Diversion, N.W. ¼ Sec. 24-53-7, W. 5 M., mileage 60.2, Dist. North Alberta, Alta.

22041—June 19—Authorizing G.T.R. to construct siding into premises of Pilkington Bros., Limited, Lot 5, Con. 2, Tp. Wainfleet, Co. Welland, Ont., and west of Port Colborne.

22042—June 22—Amending Order No. 19199, dated May 6th, 1913, in so far as diversions on plan covered by said Order are concerned.

22043—June 19—Authorizing C.P.R. to construct siding for G. A. MacIver, Sherbrooke, Que., from point on southerly limit of main, mileage 19.66, Megantic Sub. Div., Lot 544, R. 1, Victoria North, Tp. Hampton, Co. Compton, Que.

22044—June 20—Authorizing Lake Erie and Northern Ry. to connect with T.H. & B. between station 866-92.5, equal to 00-00, in village of Waterford, and station 58-95.4, Tp. of Townsend, Ontario.

22045—June 11—Dismissing application B. C. Express Co. for Order directing G.T.P. Ry. to remove temporary bridge built across Fraser River below confluence with Nechaco River, and make openings in permanent steel bridge across Fraser River, at Ry. Mile No. 142; also Mile No. 189, etc.

A weekly paper for engineers and engineering-contractors

SUBSTRUCTURE OF THE QUEBEC BRIDGE.

COMPLETE RESUME OF THE CONSTRUCTION OF THE PIERS AND ABUTMENTS—SOME INTERESTING CAISSON SINKING FOR THE SOUTH MAIN PIER—PLANT OPERATION.

By H. P. BORDEN,
Assistant to Chief Engineer, Quebec Bridge Commission.

NOTE :—The construction of the new Quebec Bridge is a most illustrative piece of engineering, and has been closely followed, since its beginning, in the columns of THE CANADIAN ENGINEER. *The substructure, now complete with the exception of a few finishing details mentioned in the first paragraph below, is a vital part of the world renowned undertaking, and engineers of all countries have been interested in its progress. In the following article Mr. Borden has reviewed for us its entire construction. For greater detail respecting the piers and abutments the reader is referred to previous issues of* THE CANADIAN ENGINEER *as follows : July 14, and Oct. 6, 1910 ; June 13, 1911 ; Oct. 31, 1912 ; Feb. 13, 1913, and April 9, 1914. These deal with their design and constructional progress. Other articles appearing in various issues refer similarly to the superstructure.*
—*EDITOR.*

THE contract for the construction of the piers for the Quebec Bridge was awarded to Messrs. M. P. and J. T. Davis, of Quebec, in February, 1910. This work has been continued constantly since that date, and is now practically completed with the exception of pointing and cleaning the masonry and dressing the bridge seats.

This contract, as finally completed, is divided into the following units: North abutment (alterations), 404.5 cu. yds. ; north intermediate pier, 1,665.6 cu. yds. ; north anchor pier, 17,736.0 cu. yds. ; north main pier, 31,870.4 cu. yds. ; south main pier, 38,279.4 cu. yds. ; south anchor pier, 16,073.0 cu. yds. ; south abutment (alterations), 61.1 cu. yds. Total, 106,090 cu. yds.

At the start, a careful study was made by the board appointed by the government, to determine whether it was possible to use the old masonry. After a thorough investigation it was found that, owing to the increased weight of the steelwork, all the old masonry, with the exception of the abutments, would have to be taken down and new piers constructed. It was, therefore, decided to move the whole bridge to the south about 65 ft., retaining the original longitudinal centre line. This brought the north main pier further into the water and the south main pier the same distance towards shore, the same centre to centre length of span of 1,800 ft. being retained. It was impossible to place the south main pier nearer the river on account of the wreckage which lies in the water at that point.

Before the contract was awarded, a series of borings were made at and about the location of the two main and anchor piers. Nineteen borings in all were taken, each boring penetrating at least 15 ft. into solid rock in order to make sure that it was bed rock rather than a boulder that had been struck. These borings showed that bed rock would be encountered approximately at El. 0.0 on the location of both north and south main piers, which elevation was about 101 ft. below extreme high water and 70 and 85 ft. below the bed of the river on the north and south sides respectively. The formation of the bed of the river on the two sides, however, was found to be totally different. On the north side heavy boulder formation was encountered for the entire depth, the boulders being closely packed together with coarse sand and gravel. On the south side the borings showed sand formation for the entire depth with only a sprinkling of boulders at various points. The bed rock was a hard sand-stone, called "Sillery grit," overlaid with a red and gray shale. On the south side 2 ft. of hardpan overlaid this shale.

The caisson for the north main pier was started first and was constructed at Sillery, about 3 miles down the river. This caisson was 180 ft. long and 55 ft. wide. It was constructed of 12 x 12-in. southern pine with a cutting edge of the same material 30 in. square. This cutting edge was shod with a 6 x 12-in. oak timber instead of the steel shoe, as usually used. It was claimed in this case that if any distortion of the caisson took place the steel shoe would tend to prevent the caisson from readily readjusting itself—as would be the case with a wooden shoe—and that the wooden shoe gave sufficient service during the process of sinking. The caisson had a working chamber 8 ft. high in the clear, divided by longitudinal and transverse bulkheads into 18 compartments. It was built in the winter under a construction shed, thus enabling the men to work without interruption from the weather. The caisson was built over launchways with a 10% grade which led out into deep water. The walls of the caisson were built up about 40 ft. before it was launched. When ready for launching, the caisson was lowered down to its inclined position on the launchways by means of heavy jacks. When everything was ready an impetus was given by jacks placed at the rear horizontally, and launching was effected without mishap.

It was towed to the bridge June 14, 1910, and placed in position over the site which had been previously dredged to an average depth of about 20 ft. in order to push ahead the work of sinking as fast as possible.

The work of filling it with concrete was started immediately and some 2,000 yds. of concrete had been deposited before the caisson began to touch bottom as its

corners. The caisson was leaking to a certain extent, but could be readily kept dry by means of two pumps. At this time, however, an accident happened to the boiler equipment and before it could be repaired the caisson had been filled with water to such an extent that it grounded on an uneven bottom. The result was that the caisson was seriously strained and the seams opened up to such an extent that it was found impossible to keep air in the working chamber. It was decided to remove the concrete from the caisson and tow it to St. Joseph de Levis and have permanent repairs made there during the coming winter.

In view of this accident a re-consideration of the masonry design was made by the board, with the result that it was decided, in consequence of the difficult sinking on the north side, to use two caissons for the north main pier and to use the reconstructed larger caisson for the south side, where the sinking operations would be much simpler and the material to be penetrated would be, as shown by the borings, composed mostly of sand. This entailed the abandonment of the enlargement of the south main pier and meant the sinking of a caisson south of the old pier and entirely distinct from it. It was, therefore, decided to sink this new large caisson, or caisson No. 1 as it has been designated, 65 ft. nearer the shore, or south of the existing main pier, and to sink the caissons for the north main pier the same distance towards the river, or south of the existing north main pier, thus making the span 1,800 ft.—the same as that of the original bridge. This change in the plans allowed the board to keep the centre line of the bridge coincident with that of the old structure which was a very important item, as it would avoid the large expense of changing the location of the railroads approaching both ends of the bridge.

It was found that caisson No. 1 could be satisfactorily repaired in dry-dock, and on May 28, 1911, it was floated out and towed up the river about nine miles to the site on the south side which, being exposed at low water, had been carefully levelled off. At extreme high water there is about 15 ft. of water over this prepared bed. As the caisson from its construction had a pretty deep draught, a false bottom was constructed with a view to decreasing this draught before floating into position. The result was that the caisson floated with a draught of 11 ft. and was placed in its exact position for sinking without serious difficulty.

The openings in the various shafts were then left unobstructed in order that the rise and fall of the tide would not lift the caisson from its permanent bed. This caisson was left in this position throughout the season of 1910, the work of the contractor being directed towards the sinking of the caissons on the north side of the river.

Caissons Nos. 2 and 3, for the north main pier, were constructed at Sillery on the same location as caisson No. 1, the same details of construction being followed throughout. Each of these caissons were 85 ft. long by 60 ft. wide. No. 2 was started June 15, and No. 3 on June 29th, 1911. Both these caissons reached their permanent location at El. 20.0 about October 20th, 1911.

The average rate of progress of sinking the westerly caisson (No. 2) was 0.37 ft. per day, and that of the easterly caisson (No. 3) 0.47 ft. per day. It was the original intention to sink these caissons to rock, but as the work progressed the sinking became more difficult, and finally, when the caissons had reached El. 20.0, it was considered that the foundations at this point were quite satisfactory for many times the load that the piers would be called upon to carry.

Bearing tests were made at this point to determine the supporting value of the foundation. A cube of granite 2 ft. square was placed on an average section of the bottom and over this was placed a lever composed of 2 I-beams supported on pin bearings. The short end of the I-beams was supported against the roof of the caisson. A hydraulic jack was placed to exercise a definite load at the end of the longer lever arm. A load of 59 tons per sq. ft. showed a settlement of only ⅛ in., practically no settlement at all being noticed at 20 to 30 tons. As the average working load at the foot of this pier was only 8 tons per sq. ft., it was considered that the board would not be justified in carrying the foundations to a lower level.

In the operation of sinking these caissons, the contractor met with considerable difficulty owing to large bounders fouling the cutting edge, and in several places this cutting edge was forced inward from 6 to 10 in., and, as it was feared that if the sinking was continued in the same manner this cutting edge would be further distorted and sinking operations endangered, the method of sinking was then changed so as to avoid any such contingency.

Timber blocking was placed beneath the bulkheads and at the centre of the chambers. A trench was then excavated all around and below the cutting edge and for several inches outside the exterior surface of the caisson. This trench was excavated to a depth of about 2 ft., after which it was filled with blue clay in bags and when all was ready the blocking was under-scoured with water jets and the caisson lowered on a cushion of clay. The clay tended to act as a lubricant and also prevented considerable air leakage, and as all boulders were removed from beneath the cutting edge before the caisson was lowered, all further damage to the cutting edge was prevented, and it was found that the sinking was carried on even more rapidly.

After the caisson had reached its final location the working chamber was filled with concrete composed of one part of cement, two parts of sand, and four parts of small crushed stone. This concrete was made much drier than the concrete used in the main caisson, it being found that concrete deposited under compressed air gave better results when very dry than in a more or less liquid state.

Concrete was deposited in terraces, the men working towards the centre from the sides and ends. Great care was taken to ram the concrete thoroughly round the roof timbers so that a bearing would be assured under the roof of the working chamber. After the working chamber was filled as carefully as possible by hand the shafts were filled with concrete. As a still further precaution, a rich grout was forced in through 4-in. blow pipes by compressed air under a pressure of 100 pounds per sq. in. One hundred and fifty-four bags of cement were used in grouting caisson No. 2, and 274 for caisson No. 3.

Caissons Nos. 2 and 3 were sunk with 10 ft. space between the two ends, thus making the overall length of the two caissons 180 ft., the same as No. 1. After they had been filled with concrete, the space between them was dredged by a clam-shell bucket to a depth of 25 ft. below high water, the boulders and hard sand being excavated with considerable difficulty. Shutters 40 ft. high, made of 12 x 12-in. timbers, were placed vertically against the outside walls of the adjacent caissons so as to close each end of the space between the caissons and overlap about 12 in. on their sides. The bottoms of the caissons were banked up on the outside with clay dumped in the river and covered with heavy rip-rap. The shutters were securely bolted to the caisson walls down to low-water level, and thus formed coffer dam walls enclosing this space between the caissons. This space was then filled with concrete deposited under water up to an elevation of 7 ft. below low-water mark. After the concrete was de-

posited the water was pumped out and the space between the caissons was then bridged by six old steel girders, 6 ft. deep, resting in pockets left in the concrete in the adjacent ends of the caisson, the wooden walls of the caisson having been cut away to allow this to be done. Afterwards the concrete was deposited in a continuous mass in and between both coffer dams and caisson, thus forming a monolith upon which the masonry shaft of the pier could be carried. The masonry of the pier was then built up inside of the crib work, which was kept in place until the mason work had extended above high water.

The sinking of the large caisson for the south main pier was started July 28, 1912, and was completed October 24, 1912, or at the rate of 0.75 ft. per day during the entire period. The material encountered at this point was, as indicated by the borings, chiefly sand, and required that the pier be carried down to rock, which was reached at El. 0.0, 101 ft. below high water, and 86 ft. below the bed of the river. The difficulty experienced on the north side in keeping the cutting edge intact, and also on account of the fact that the caisson had previously been overstrained, and the fear that it might yet be weak, led the contractors to take unusual precautions to prevent the possibility of any accident happening to the caisson during the sinking operations. For this reason, special appliances were devised for relieving the cutting edge from carrying all the load, and by the use of sand-jacks the total weight of the caisson was distributed over the entire bottom area. The manner of using these sand-jacks was one of the most interesting features connected with the sinking of this caisson, and possibly merits especial description.

The jacks themselves were of very simple construction. The cylinders of the sand jacks had an internal diameter of 31 in., and were 36 in. long, constructed of ¼-in. steel plate with 4-in. lap joint; two angles 1½ x 1½ x ¼-in. reinforced the cylinder at top and bottom. The piston was a block of yellow pine 2½ ft. square and 5 ft. long. Four feet at one end was round with a diameter of 29 in., thereby allowing 1 in. play in the cylinder. The lower end of the piston was reinforced by a 2½ x ⅜-in. welded iron band. During operation the piston was attached rigidly to the roof of the working chamber by long screw bolts, and remained there permanently during the entire period of sinking.

In preparing for a drop, the first step was to excavate a hole under the piston. The cylinder was filled about ⅔ full of sand, placed in position under the piston, and blocked up hard against it by means of timbers. While this was being done the caisson was supported on timber blocking under the bulkheads and other points. At the bottom of the sand-jack was a 2-in. iron pipe extending entirely across the cylinder, the centre of which was split and opened up to allow the sand to escape. This type had no bottom to the cylinder, the timbers acting as a support for the sand. Another type used had a steel bottom and two 3-in. holes with sliding cover at each side at the foot of the cylinder. The operation in both cases was the same.

When everything was ready for a drop, the timber blocking supporting the caisson was undermined by a water jet and the full load taken by the sand jacks. A man was stationed at every jack, and at a given signal, afforded by the flashing of electric lights, each man turned a hydraulic jet with 60 lbs. pressure into the hole at the bottom of the cylinder, thus washing the sand out. The sand was caught in canvas bags of uniform size. When the canvas bag was full the lights flashed again and the water jet was turned off. Another bag was then obtained, and at the signal the jet was again turned on and the bags filled. Each cylinder contained in the neighborhood of 16 bags of sand. This operation was continued until the required settlement was obtained. By adopting the signal system and emptying the sand into bags, it was possible to guarantee that the whole caisson was being sunk at a uniform rate, and that there was no reasonable possibility of any part of the caisson being strained by being sunk more rapidly than another portion. As a rule, a drop of from 1½ to 2 ft. could be effected at each operation, the recurrence of the operations depending entirely on the nature of the material to be removed. When the drop had been finished the blocking was again placed under the bulkheads to take the load of the caisson, and the holes under the sand-jacks deepened in order that the operation might be repeated. The greater part of the material excavated in this caisson, being sand, was forced out through blow pipes.

Practically no problems were encountered in the construction of the north and south anchor piers and the north intermediate pier. Both anchor piers were constructed on a location south of the existing anchor piers. For the north anchor pier a coffer dam had to be constructed around the foundations since the foot of the pier was below high-water mark. The south anchor pier was well above high-water mark, so that all excavation was in the dry.

The anchorage girders were embedded in concrete and the first length of anchorage eyebars set in place, two shafts being left in each anchor pier for connecting up the anchor eyebars of the main anchorage. It is the intention ultimately to embed the bottom section of eyebars in concrete, but this will be deferred until they receive the full dead load stress.

The concrete used in the caisson and backing of the piers was 1:2½:5 by volume, except the concrete in the working chamber, which was 1:2½:4. The cement was required to pass a tensile test for neat cement of 450 and 540 lbs., for 7 and 28 days respectively; and for 1 part of cement and 3 parts of sand, 140 and 220 lbs. respectively. For the main piers entirely new quarry cut stone was used. For the anchor and intermediate pier the specification allowed the use of stone from the old masonry. The greater portion of the old stone demolished from the old masonry was consequently used in the construction of these piers. The abutments were not radically changed, it being only necessary to raise the ballast walls and make minor alterations to suit the new design.

The masonry in the pier shafts consists of grey granite rock faced ashlar, laid with alternate headers and stretchers and backed with concrete, in which were embedded displacer stones usually about 1 cu. yd. in size. Headers were required to have a length of at least 2½ times their build, with a minimum length of 7 ft. Bed joints were ½ in. throughout and vertical joints ⅜ in. for 12 in. back from the face and not exceeding 4 in. wide at any point.

All stones in rounded ends of main piers were clamped together and connected vertically by dowels. The upper 18 ft. of these piers were built with cut granite backing. About 40% of the stones in these backing courses were made to project up through the course above, in this way giving a very strong vertical bond. The bridge seats proper are built 2 ft. higher than the surrounding upper coping course, and are 4 ft. deep, extending to the bottom of this coping, thus providing heavy stones under the main bearings.

The anchor piers are in plan about 136 ft. long by 29 ft. wide at the bottom, with a batter of 1 in 24, and re-

duced in section for 41 ft. at the centre to a vertical wall 18 ft. thick, thus forming pilasters at the ends, through which the anchor wells are built.

Owing to the importance of the work, the contractor spared no effort or expense to provide a plant up-to-date in every respect.

On the north side a large wooden trestle was built around the four sides of the caissons, all supported on piles and cribs. As the current here reaches 7 miles per hour and there is an average tide of 16 ft. and a maximum of 20 ft. it was necessary to have this trestle very strongly built. Platforms extended to the shore from the up- and down-stream ends of the pier carrying standard gauge double tracks which formed loops around the caisson and connected with the concrete plant 600 ft. inshore and located at the foot of the cliff.

The power plant, dining-room for "sand-hogs," and two-story bunk house were also located at the water's edge—just upstream from the pier. All supplies and material required were received by rail or team at the top of the cliff, some 160 ft. above high-water level and were delivered by gravity to the concrete plant and service tracks at the foot. A service elevator was operated by cable and hoisting engine at the top of the cliff which was an angle of about 45° at this point connected the tracks at the top with those at the bottom. A stairway provided means for the men to reach the upper and lower levels. The board of engineers' office was located at the top of the cliff.

At the foot of the cliff were situated the mechanical plants which furnished the power for the various operations. To supply compressed air, five Ingersoll-Sargeant compressors were employed. Four had a capacity of 1,250 cu. ft. and one 2,500 cu. ft. per min. These compressors discharged into a 12-in. main from which 7-in. branches led into the two caissons. Each branch was fitted with a gate valve so that the air could be cut out of either caisson at will. The main pipe was carried in a sluice of running water about 400 ft. long, which kept the temperature of the air down to about 75° F. As a consequence, the temperature of the working chamber rarely exceeded 90° F., although the service shaft, on account of the heat generated by the setting of the concrete around it, generally exceeded 100° F. For this same reason the temperature of the working chamber reached as high as 110° F. when being finally filled with concrete.

The compressors were at first supplied with power from six 100-h.p. horizontal boilers. As the work proceeded it was found that the demand on the compressors was greater than was anticipated. As a consequence, an extra 100-h.p. boiler was installed, together with one 500-h.p., one 75-h.p. and one 250-h.p. boilers, making a battery of 10 boilers, aggregating 1,075 h.p. These boilers were all coupled up, and in addition to the compressor plant, supplied power to the power-house, rock crusher and concrete mixing plant. There were also one 100-h.p. vertical and two 50-h.p. horizontal boilers on the platform near the caissons, and were used to furnish power to six 15-ton stiff-leg derricks which were used for handling stone, concrete, etc., during the sinking operations. They also furnished power to one 8-in. high-pressure pump used for washing material in the working chamber and to two 4-in. pumps which supplied water to the high-level tank on the top of the hill, thus furnishing the water supply for the whole plant.

The plant was supplied with electric light from its own power set situated near the boiler-house. It was equipped with a 30-kw. C.G.E. generator, capable of operating 16 arc lights and 100 incandescent lights (16 c.p.). There was also a blacksmith and machine shop in connection, so that all minor repairs to plant and equipment could be made on the job.

The concrete mixing plant was placed just at the foot of the cliff. Half-way up the slope was the rock crushing plant. The rock used for the concrete was obtained from an adjoining cut and was brought to the brow of the hill in cars which dumped into a chute leading to the crusher plant. The stone was fed into 2 gyratory crushers which were capable of dealing with about 500 cu. yd. in 12 hours. After passing through the crushers the stone was led over an inclined screen of 2-in. mesh, and thence into a storage hopper bin of about 200 yds. capacity. These chutes led from this to the concrete mixing platform below, the mouth of each chute being directly over a mixer. From this platform the sand, stone, cement and water, were fed in the proper proportions to the mixers underneath the platform, which in turn dumped into self-discharging buckets on trucks, which were hauled to the caissons by horses. Three Ransome mixers were used on the work, two having a capacity of ⅔ cu. yd. and the other 1⅓ cu. yds. Owing to the conditions under which the work was carried on the mixers never had a chance to work to their full capacity; their best day's work being 450 cu. yds. for the 24 hours.

The sand used in the concrete was conveyed to the concrete mixing platform in the same manner as the stone, i.e., by means of a chute from the upper level, where it was unloaded from hopper bottom cars. The chute was 8 ft. wide by 6 ft. high and was kept practically full all the time, the sand being taken from the lower end as required. The coal for the boilers was also delivered from the upper level through a chute, which emptied into 2-yard side-dump cars at the boiler-house level. By means of a track these cars delivered the coal to each boiler-house as required. On the top of the coal chute was a double line of rails with balanced trucks, which conveyed the cement from cars at the upper level to the storage shed at the level of the concrete mixing platform. The cars could, therefore, be unloaded as they arrived and the cement placed where required for use with the minimum amount of handling.

For the convenience of the "sand hogs," who were compelled to work on shifts through the whole 24 hours, the contractor erected both sleeping and dining quarters for a large number of his men. On the lower level a bunk-house had been provided to accommodate about 100 men, and a dining room that would seat as many more. On the upper level was a similar house with bunks for about 60 men and dining quarters of about the same capacity. On the dock the contractor erected a number of buildings, which included an office and bath accommodation for the inspectors, a hospital with a doctor in continual attendance, where first aid might be administered in case of serious accidents, or regular treatment in case of minor troubles. There was also provided a coffee-house, kept at a high temperature, where the "sand hogs" could change their clothes and receive hot coffee at the end of their shift in the working chamber. In addition to the above were the usual stores, offices, etc., for the contractor's own use. In connection with the hospital arrangements there was also provided a steel hospital tank connected with the compressed air system, to which men suffering from the "bends" could be immediately transferred and treated.

For serving each caisson four 30-in. shafts for material and two 30-in. ladder shafts were employed. For ejecting the sand and smaller stones four 4-in. blow pipes were used. The larger boulders were broken up and

hoisted through the material shaft in buckets having a capacity of ⅔ cu. yd. Four 7-in. compressed air pipes supplied air to the working chamber and served the blow pipes. Two 6-in. pipes supplied the water for "washing" the sand. One 2-in. pipe supplied high-pressure air for drilling, etc., and a second 2-in. pipe carried the wires for the electric lighting of the working chamber and ladder shaft.

As soon as the sinking was completed on the north shore as much of the plant as could be spared was moved to the south side. The men's dining-rooms and sleeping quarters were placed on skids, launched into the river, floated across, and placed in position on the other side. The layout for the mixing plant, sand chute, coal chute, etc., was practically the same as on the north side of the river, all the materials being led to the lower level by gravity. The stone for the crushers was quarried directly from the top of the cliff so that one derrick could pick up the stone in the quarry and deposit it in the hopper leading to the crushing plant half-way down the cliff. While the boiler and compressor plants used on the south side were drawn as much as possible from the north side, yet they had to be materially increased. The steam plant included three 125- and one 250-h.p. Heine boilers, twelve 100-h.p. locomotive boilers, and seven Ingersoll-Rand and Ingersoll-Sergeant air compressors delivering to 2 coupled receivers from which a pair of 12-in. mains led to the caisson and were carried for about 200 ft. in a wooden flume constantly filled by water. This reduced the high temperature developed at the compressors to about 80° in the working chamber of the caisson. There were also two 12-in. Worthington high-pressure pumps which delivered water to the caisson for the hydraulic jets used for excavation.

On account of the very high tide which prevailed at the site, the air pressure in the caissons constantly varied and was controlled by an operator in the compressor house who adjusted it to correspond with the indications of an automatic register showing a continuous tide pressure.

The stone from the quarry on the top of the cliff was delivered by derricks into a No. 8 McCully rotary crusher near the top of the bank, which broke the larger pieces and delivered them through a chute to a No. 5 Allis-Chalmers crusher about 25 ft. below it. The second crusher reduced the stone to a diameter of 2 in. and delivered it through another chute to a storage bin adjacent to the sand bin. Both stone and sand bins delivered by gravity through gates to measured compartments in a triple charging hopper just below the floor of the working platform. This hopper was lined with steel and had a compartment into which the requisite number of bags of cement were poured by hand. The hopper gate was operated from the charging platform and delivered all of the aggregate for one batch of concrete to one of the two Ransome mixers under the platform, which discharged into 1½-yd. bottom-dump Stuebner steel buckets which were set in pairs on 2 coupled cars drawn by one horse on a 600-ft. service track to the main pier caisson, or to the anchor pier, where they were unloaded and emptied by the derricks installed there.

The compressed air, with a maximum pressure of 40 lbs. per sq. in., was delivered to the working chamber of the south caisson through two 12-in. pipes, as stated above, which in turn was distributed into four 7-in. mains.

Water at 100-lb. pressure was distributed around all four sides of the working chamber in a horizontal main from 4 to 6 in. in diameter, provided each of the 18 compartments with a valved outlet and jet pipe with 1-in. nozzle used to loosen the sand and excavate the earth and gravel. Each chamber was also provided with a 6-in. vertical blow-out pipe and with electric lights. The caisson was fitted with six 3-ft. material shafts, each having a Moran air lock with four 3-ft. ladder shafts having simple air-locks composed of short upper sections with top and bottom diaphragms, and with one large man-lock. The latter was a 6-ft. horizontal steel cylinder about 30 ft. long, located on the deck of the caisson, and was built permanently into the solid concrete of the pier, being approached through a 4 x 4-ft. vertical stair shaft. The lock was large enough to accommodate many "sand hogs" at once, thus greatly expediting the entrance and exit of each successive shift, effecting an economy of air consumption and considerably reducing the waste of lock air.

A hospital lock was also established on the shore near the "sand hog" house. Under moderate pressures, 100 men worked 8 hours in each shift. As the pressure increased the lengths of the shifts were diminished to a minimum of 1 hour. As many more sand hogs were required to carry on the work, great difficulty was experienced in securing enough men, so that eventually the number of men in each shift was considerably reduced. Some of the men lived in an adjacent boarding house provided by the contractors, but the majority of them lived in local villages up to five miles distant.

At the present time the contractor is at work pointing the joints in the masonry and cleaning these piers thoroughly by sand blast. There is also some work still to be done on the dressing of the bridge seats. This work is very important and has proved a very difficult operation. These bridge seats are about 32 ft. x 26½ ft. and it is necessary that they should be absolutely level to distribute the load from the main steel pedestal, the base of which is shipped in four pieces. It requires about six weeks to complete the dressing on one of these beds, and it has been found that the work can be done with such accuracy that not more than a variation of 2/100 of an inch is possible.

This work is under the supervision of the Board of Engineers, Quebec Bridge, which is composed of C. N. Monsarrat (chairman and chief engineer), Ralph Modjeski and C. C. Schneider.

RESERVING WATER POWER SITES.

Consistent with the policy of the Dominion government to preserve the water powers for the people, the department of the interior is placing under reservation all vacant Dominion land that the superintendent of water powers may recommend to be valuable for the development of water power, says Conservation.

Six whole sections of land, in township 108, range 6, west of the 5th meridian, have recently been reserved from disposition of any kind until the engineers of the water power branch have had an opportunity to make a complete survey of the famous power site at Vermilion falls, on the Peace River in northern Alberta.

Similar reservations have been made on the various rivers in the provinces of Manitoba, Saskatchewan, Alberta, and in the railway belt of British Columbia. Particular mention might be made of reservations covering land contiguous to Grand Rapids on the Athabasca River, the various power sites on the Elbow and the Bow Rivers, in the province of Alberta; for land required for the development of power at Grand Rapids on the Saskatchewan River, and all unoccupied land along the Winnipeg River, in the province of Manitoba.

Other reservations will be made from time to time upon the receipt of sufficient information to enable the superintendent of water powers to make a definite recommendation covering a description of the land that might be required for power purposes.

PROGRESS AT CEDARS RAPIDS, QUEBEC.

THE Cedars Rapids Manufacturing and Power Co. has under construction an extensive power plant at Cedars Rapids on the St. Lawrence River, about 30 miles west of Montreal. There is a fall of 32 feet and the installation is designed for an output of 160,000 h.p., of which 100,000 h.p. is for immediate consumption. The ultimate consumption will utilize 56,000 ft. per sec.

The development begins with a canal which is being built along the north bank of the St. Lawrence, a distance of 12,000 ft., in which is concentrated the fall of 32 ft. The width of the canal is approximately 1,000 ft. The power house at the lower end of the canal, and forming a portion of the dam, is 663 ft. long and 140 ft. in width. Details with respect to the development, including the power house equipment and general methods of construction were given in an article appearing in January 1st, 1914, issue of *The Canadian Engineer*. The accompanying photographs and data relate particularly to the work which has been accomplished since then.

The south bank of the canal which, when completed, will be practically a straight earth wall two miles in length extending the entire length of the headrace, is progressing rapidly. Water is excluded from the canal by an earth bank serving as a cofferdam. Upon the completion of the canal, this bank will be removed. Fig. 1 shows the work near the upper end of the canal. Excavation is practically completed at this point. The illustration shows, in the south bank, a portion of the spillway and ice sluice. Various portions of the canal between its extremities are down to grade with the bottom more or less clean. For a greater part of the distance the south bank is also practically completed. Fig. 2 shows another portion of the canal and bank, in an advanced stage.

The construction of the power house has reached the stage shown in Figs. 3 and 4. On the north end a single dam will connect temporarily this end of the building with the north bank of the river. It is on the north side that future extensions will be made for the additional 60,000 h.p. at a later date. The south end of the power house will connect with the south bank of the canal. Fig. 3, illustrating the east or downstream side of the power house, shows the draft tubes and the tail race under construction. The latter is being brought down to grade at the present time and a little excavation remains to be done. The work at this portion of the development involves nothing beyond the disposal of excavated material. In the view of the west or upstream side (Fig. 4) every three openings will provide water for one of the 10,800-h.p. water-wheels which are being installed. These wheels are of the single runner vertical shaft type and will operate at 56 r.p.m. under a head of 30 ft. The height of the water will thus reach about midway between the bottom ledge of the large windows and the top of the openings shown in the illustration. The smaller openings in the centre of the building are the intakes for the three 1,500-h.p. exciter units, to operate under the same head at 150 r.p.m. The higher opening in the concrete about the middle of the wall is for the purpose of ice disposal.

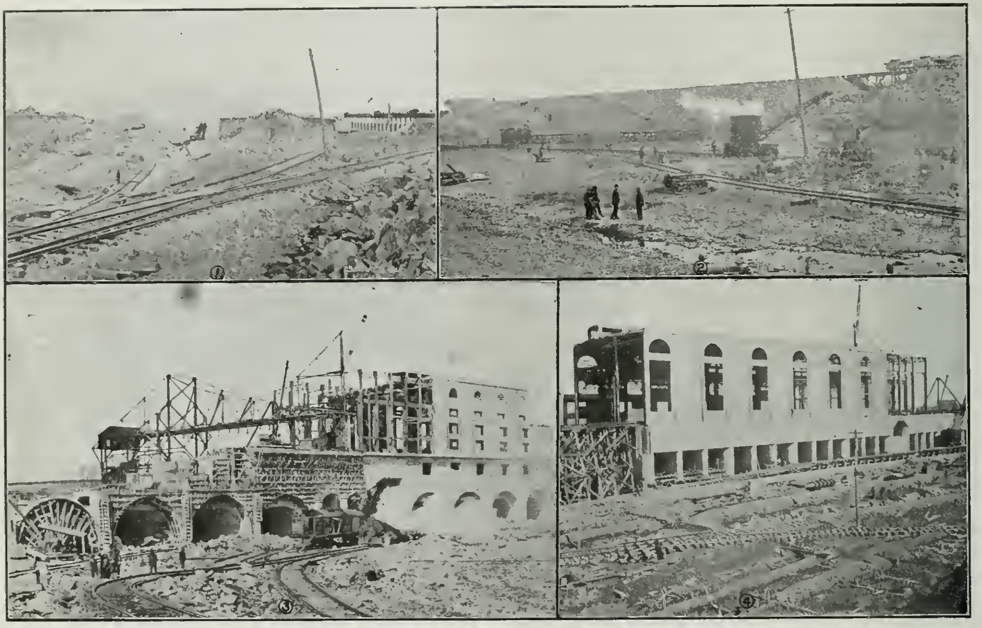

Fig. 1.—Upper end of Canal as it appeared on May 15th, 1914. Fig. 2.—Portion of Canal down to grade and bank almost completed. Fig. 3.—Downstream side of power house, showing manner of construction. Fig. 4.—Upstream side of power house, which will form portion of dam.

The large crane, shown in Fig. 3, is used to convey buckets of concrete from dump cars to the forms. The

rock-crushing, concrete and mixing plant is located considerably to the north of the power house.

Of the views illustrating the interior of the power house, Fig. 5 illustrates the general method of erection and the location of the wheel-pits, which are shown in various stages. The cover plate of a water-wheel, shown in the background, has a diameter of 20 ft., and weighs about 60 tons. Portions of the spiders which are to support the field coils of the generators are also shown near the western wall. In the foreground are some of the guide vanes of the water-wheels. Fig. 6 shows one of the pit-liners being lowered into a wheel-pit, while Fig. 7 illustrates the speed ring of one of the wheels. Fig. 8 shows one of the cover plates which rests immediately over the water-wheel, with a shaft 27 in. in diameter projecting through the shaft chamber shown. Upon this shaft is mounted the generator, supported by a thrust-bearing. Each generator is 37 ft. in diameter.

The transformer house, which is about 800 ft. distance from the present north end of the power house, has been completed as far as the foundations. Concrete is being placed by means of tremie pipes.

The following table illustrates the progress which has been made upon the work and the stage of construction on May 1st, 1914:

	Aug. 23, 1913.	Dec. 1, 1913.	May 1, 1914.
Rock excavation	21%	23%	58%
Earth excavation other than stripping and trench work...	43%	60%	73%
Earth excavation in trenches and ditches, and stripping seats of banks	36%	84%	Complete
Transporting and placing excavated rock	20%	28%	62%
Stone protection	2%	3%	5%
Transporting and placing excavated earth	43%	63%	77%
Concrete in power house substructure	16%	26%	69%

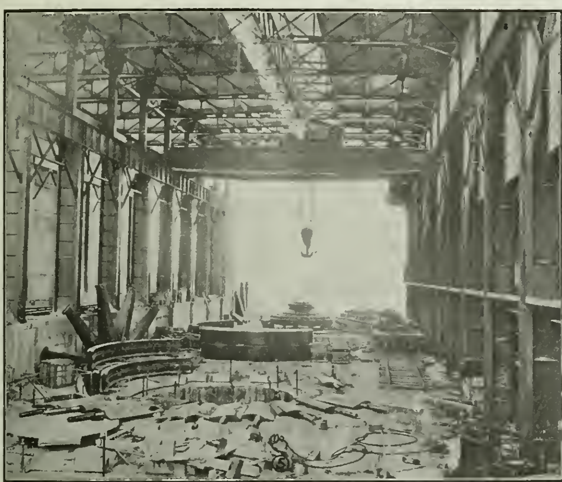

Fig. 5.—Interior view, showing unassembled parts of water-wheel and generator. Fig. 6.—Pit-liner being lowered into position.

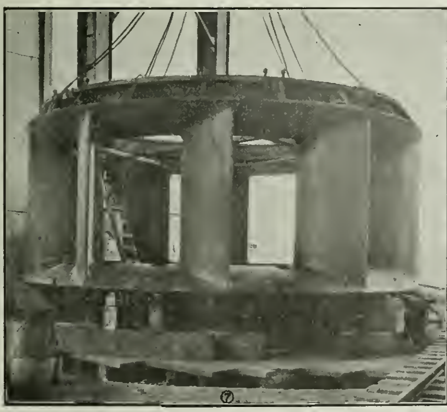

Fig. 7.—Speed-ring of one of the twelve 10,800-h.p. water-wheels (of the single-runner, vertical shaft type). Fig. 8.—Assembling a waterwheel cover-plate.

The Cedars Rapids Manufacturing and Power Company awarded the contracts for the supply and installation of the water turbines to the I. P. Morris Company, Philadelphia, and Wellman-Seaver-Morgan Company, Cleveland. The General Electric Company, Schenectady, N.Y., are supplying the electrical equipment. The structural steel is being supplied by the Phœnix Bridge and Iron Works, Montreal. The power house units and transformer station superstructure are being erected by the Unit Construction Company, St. Louis. Messrs. Fraser, Brace & Company are the general contractors.

CLAY COATING FOR WOOD PIPE.

It is generally known that the durability of wood pipe for water transportation depends largely upon its continuous and perfect saturation with water. In this connection it has been contended that pipes should be thin enough to insure the penetration of water through the pores of the wood, at a more rapid rate than the loss of water by evaporation from its surface. The difference in the porosity of different timbers causes a variation in proper thicknesses.

There are many incidences of the long life of wood pipe. Most of them are accompanied by the fact that the pipe was buried in clay and the whole is an indication of the preservative properties to be found in clay relative to wood pipe laying. Most clay is not a good culture bed for the growth of fungus that causes decay. Further, clay holds moisture and thus insures continuous and thorough saturation of the wood at the surface of the pipe.

In view of this preservative quality of clay "Engineering and Contracting" suggests incasing wooden pipe with clay to the thickness of several inches where the clay is within comparatively easy reach and particularly where the trench is in soil that is either very porous or contains much vegetable humus. It is suggested that a clay jacket around wooden pipe would prove economical. A concrete jacket would be likely to serve a similar purpose, but ordinarily at a greater cost than clay.

The suggestion is one which might well be tried out. Wooden pipe has many advantages for water transportation, and if its liability to rapid decay could be substantially offset the result would be of extreme value.

REPAIRING A STEEL TAPE IN THE FIELD.

In the progress of the day's work there are few more annoying incidences productive of delay to a survey party than the breaking of a steel tape. The process of repairing it by riveting has been superseded by several other methods of greater convenience and rapidity. The outfit required for riveting cannot be carried about so as to be ready for use when the emergency calls for it. The same applies largely to a soldering outfit of sufficient size to be of material use.

A tape repairer that has been found very satisfactory and a splendid time saver consists of a strip of tin about ¾ inches long with two of its edges bent over until they almost meet. The inner faces have a coating of soft solder. To repair a broken tape the fractured ends are inserted, the overlapped edges of the tin forced together by a little hammering and the solder heated by holding a lighted match under the splice.

Two or three of these devices can conveniently be carried in the field and will be found a very useful part of the outfit. They are prepared in different widths to fit any tape. The Chicago Steel Tape Co. are the manufacturers.

There are, of course, new soldering pastes on the market which require no soldering iron or separate flux, a small amount of which, together with a few strips of tin can be conveniently carried about. They are not so convenient, however, and there is less liability of making a strong and satisfactory repair as with the device suggested above.

NEW PROCESS OF RUST PREVENTION.

Making use of the common knowledge that chemically pure iron is practically rustless, a new process has been devised by which steel surfaces are coated with almost pure iron. This process has been termed ferro-zincing or ironizing. In it hydrogen is the chief impurity, the presence of which appears to be advantageous in that the iron coating containing it is slightly more electro-positive to the underlying steel than it would otherwise be.

The coating of electrolytic iron has another advantage, that of being homogeneous, and, according to "Engineering," London, is not under an equal strain caused by mechanical operations, such as drawing or hammering. Further, it has not been subjected to any heat or mechanical treatment, which of necessity causes impurities to be absorbed by the metals so treated.

This process, if commercially applicable, should mark a new era in the use of steel. The preservation of iron and steel from corrosion by galvanizing has been largely used by engineers with considerable success. There are in reality two processes: the first, dipping the iron in molten zinc in combination with suitable fluxes—called hot-galvanizing; and, coating the iron or steel surface by electro-zincing—cold-galvanizing. The reason that zinc, as a protective coating for iron and steel, has held its own so long is that it is electro-positive to the underlying metal. In the presence of moisture, the iron and zinc form a galvanic couple, and as long as there is any zinc remaining in contact with the iron within a given area the zinc corrodes in preference to the iron, thus protecting it.

In the new process it is found advantageous to coat the electrolytic iron surface with zinc, for the reason that a zinc coating with an immediate layer of pure iron hydrogen alloy gives a greatly increased life to the ordinary steel tube or plate.

The inventor of the process, Mr. S. Cowper Coles, Westminster, has arranged with the British Mannesmann Tube Co. for the protection of boiler tubes, and is applying the process to a number of other purposes.

EQUALITY OF WATER FLOW DEPENDENT ON FOREST COVER.

It has been urged that in the interests of navigation the Dominion Government should purchase such denuded forest land in the eastern provinces as might be necessary to reforest in order to prevent floods and the filling up of streams with sediment. In this connection the report on the Trent Watershed Survey, recently published by the Commission of Conservation, is of considerable interest. In this region of Ontario, as a result of fires, 150,000 acres are practically a desert and the report urges a policy of forest conservation under Dominion, provincial or municipal control, in order to preserve the usefulness of the Trent Valley Canal, in which over $10,000,000 are invested. There are many such barren areas in the eastern provinces, which with the assistance of the Dominion Government might be made to produce valuable forest crops.

In Canada disastrous floods and low-water stages have been largely prevented by the timely action of the Dominion Government in setting aside as forest reserves the wooded slops where the great rivers of the interior of the Dominion have their origin. On the east slope of the Rocky Mountains over 20,896 square miles of non-agricultural land have been thus reserved, for the double purpose of regulating the run-off and of providing a perpetual supply of timber to meet the ever-increasing needs of the prairie settlers. In the Railway Belt in British Columbia smaller reserves have also been set aside, chiefly for the purpose of maintaining a steady flow in the streams on which the fruit-growing industry is absolutely dependent.

STEAM RAILWAY ELECTRIFICATION.

THE factors entering into the selection of a system when contemplating the electrification of a steam railway were ably discussed in a paper read by Mr. J. A. Shaw, of the Canadian Pacific Railway Company, at the 24th annual convention of the Canadian Electrical Association, held last week in Montreal. The importance of choosing a system suitable for general conditions, to permit interchangeability of rolling stock between different sections, and to allow extensions to be made as economical and reliable operation, or other conditions warrant, were properly emphasized. We reproduce the following from Mr. Shaw's paper:—

Three systems now exist which include all which need be considered in view of the present state of electrical development. One, the three-phase alternating, is not suitable for general electrification, on account of requiring two trolley wires, with the resulting complications and the peculiar characteristics of the motors employed. The remaining systems are single-phase alternating current, and the 2,400-volt direct current.

The single-phase system has been used in the electrification of the New York, New Haven and Hartford Railway from New York to Stamford, and is now being considerably extended. It has also been used on a number of light railways, notably the Spokane and Inland. Abroad it is in use on the London, Brighton and South Coast Railway, the Swedish State Railway and others, and has been adopted by the German, Swiss and Austrian State Railways as their approved system, although it cannot as yet be considered as completely through the experimental stage.

The 2,400-volt d.c. system is a development from the 600-volt system, which is practically the standard in all street railway and interurban work, and which has been so successful on that field. The electrification of the New York Terminals of the New York Central and the Pennsylvania lines, the Atlantic City Line of the Pennsylvania, the New York Subway, and all elevated railways have also employed this system. Abroad it has been used on the Lancashire and Yorkshire Ry., and in general under conditions similar to those in this country. During the past three years a number of light railways have been installed using 1,200-volt d.c., in most cases, however, using 600-volt motors, and from the experience obtained, the 2-400-volt system has been developed, using 1,200-volt motors, and this system has now been in use on the Butte, Anaconda and Pacific Ry., preparatory to a further use of it on two divisions of the Chicago, Milwaukee and Puget Sound Ry., for the past 10 months. A lower voltage installation at 1,500 volts has been in service over three years on the Piedmont Ry. in South Carolina.

Supply of Power.—It is possible that in the majority of cases for years to come that power will be generated for locomotive purposes alone, without considering its use for other purposes. However, electrification will be made possible more through cheap power being available from existing power plants, where if a separate plant had to be erected it would be too expensive. Possibly in the future power plants will be constructed at points where commercial power is not available, but even in that case at other points on adjoining divisions commercial power might be obtained, and to permit of uniform equipment the power generated would either have to be uniform with that purchased or the latter converted to the character required. Throughout the West and in the Montreal district, 60-cycle, 3-phase transmission is practically universal, and, while 25-cycle, 3-phase current is employed on the Hydro-Electric and Toronto-Niagara transmissions from which 25-cycle single-phase could be obtained by stationary transformers, balancing apparatus would be required. In view of the tendency to use 15-cycle in place of 25-cycle current in single-phase electrification and the remoteness of general electrification in Ontario, it is reasonably safe to assume that converting apparatus will be required for either single-phase or direct-current installation. The application of 15-cycle generators in 60-cycle power stations or of frequency changing apparatus to furnish single-phase current, while possible, does not actually change this assumption, as the increased price asked for by the power companies equals the cost of conversion by the railroad in addition to requiring the erection of separate transmission lines.

The general arrangement of the two systems is outlined in Table I.

TABLE I.

Single Phase.	Direct Current.
A 1. Power line of supply company.	D 1. Power line of supply company.
A 2. Conversion station at one or two points per division furnishing single-phase current from motor-generator apparatus and step-up transformer for raising potential. If power lines are available at several points on division, number of conversion stations may be increased, and length of transmission lines correspondingly reduced.	D 2. Transmission line to sub-stations. Where supply company power lines are available at several points on division, sub-stations may be conveniently located at such points, and length of transmission line correspondingly reduced.
	D 3. Sub-stations in which three-phase power is converted to direct current by motor generator apparatus.
A 3. Transmission line from conversion stations to transformer stations.	D 4. Feeder line by which direct current is supplied to trolley line.
A 4. Transformer station in which high voltage single-phase current is transformed to 11,000 volts for trolley line.	D 5. Trolley line and bonding.
A 5. Trolley line and bonding.	D 6. Electric locomotives or motor cars.
A 6. Electric locomotives or motor cars.	

Cost of Installation.—An inspection of above table shows that as a general proposition certain of the items are practically common to both systems. Transmission lines A-3 and D-2 will be required for the entire length of the division if power were received at one point: whereas if power were received at several points, while several single-phase conversion stations could be installed, that would not prove practically economical, and with direct current there would be a saving in the transmission line required. The transmission line for single-phase current costs 20 per cent. more per mile than that for 3-phase, so that it is entirely fair to the single-phase to consider the cost of transmission lines equal.

The trolley line and bonding are practically the same. For single-phase, higher insulation is required on account of the higher voltage and the surging which occurs. With the improvements that have been made in the manufacture of insulators, the difference would not exceed 10 per cent. of the cost of the trolley line.

The conversion stations and transformer stations A-2 and A-4 for single-phase will correspond to the sub-stations D-3 for direct current. For heavy traction work on the Chicago, Milwaukee and St. Paul Ry., where it is proposed to handle 1,600 tons on 1 per cent. grades, the sub-stations will be located from 18 to 24 miles apart, the feeder being 1,000,000 cm. Considering a direct

current section having sub-stations 20 miles apart, the distance between transformer stations for single-phase current will depend on the worst conditions that should be permitted to occur. Thus with the direct current with a voltage drop of 50 per cent. trains could be handled at one-half speed with full tractive power. With single-phase the maximum drop permitting this condition would be from 20 to 30 per cent. The latter figure will be taken as most favorable to single phase, and the distance apart of stations calculated: 1st, when the number of trains on a section is proportional to its length; 2nd, when the same number of trains are concentrated at the centre of a section irrespective of its length. The spacing of the stations can also be calculated when the efficiency is the same for both systems, the number of trains per mile of track being the same. The results are as follows:—

Limiting operating conditions, trains uniformly distributed or number proportioned to length of section .... 30 miles.
Limiting operating conditions, same number of trains at centre of section........... 45 miles.
Equal efficiency, number of trains proportioned to length of section .... 30 miles.

The limiting operating condition with the number of trains proportioned to the length of the section is evidently most important from a general railroad standpoint, and transformer stations, say, 33 1-3 miles apart, would apparently give substantially equal service compared with direct-current sub-stations 20 miles apart. The total capacity of the direct-current sub-station will exceed that required in the conversion station, since each sub-station must be able to carry the load of the trains that may be starting in its vicinity. The total cost of the single-phase stations is, however, increased by that of the transformer stations, which cost one-third as much per kilowatt capacity as the conversion or sub-stations. The two systems are thus equal in cost when the sub-station capacity with direct current is 44 per cent. greater than the conversion station for single-phase. In some cases the difference is not sufficient, but lines will not be electrified on which traffic is insufficient to render the load reasonably uniform. As in the case of the transmission line and trolley the single-phase was more expensive; in this case the direct current will be in general slightly higher—the net results being very closely the same.

The remaining items are: A-6 the single-phase locomotives, D-4 the d.c. feeder, and D-6 the d.c. locomotives. The feeder proposed is of 788,000 cm. area, costing at 18 cents per lb., $2,250 per mile, or $2,500 per mile erected. The cost of the locomotives will vary according to the type and capacity, but based on d.c. locomotives costing $40,000, those for single-phase current will cost $60,000, so that if one locomotive is used for each eight miles of track, the total cost of the two items is again substantially equal.

The net result is that where power is obtained from 3-phase distribution, the cost of electrification by single-phase or d.c. is substantially the same. This is confirmed by several careful independent estimates. With direct current the expenditure on feeder copper and sub-station apparatus is balanced by the slightly increased cost of the trolley and transmission line for single-phase current and the much greater cost of the locomotives.

Cost of Operation.—Cost of operation is affected by the efficiency of the system, the cost of operation of the sub-stations and the cost of the maintenance of the locomotives and other apparatus.

The efficiency of the system will determine the cost of the power supplied, and, if the movement of the trains and the power they each consume is known, could be calculated with considerable accuracy. When power is purchased, especially water-power, the cost depends on the peak load during certain hours, and trains will be operated to reduce this as much as possible. It is, therefore, difficult to forecast the train distribution. There is, however, no general evidence to show that greater efficiency may be obtained with single-phase than with direct-current equipment. Several records of actual service show that with direct-current under similar conditions the results are more economical than single phase. This is especially so when the power per car mile is considered on account of the greater weight of the single-phase equipment. From what we have already learned and figures published, it may be safely assumed that on any section of a railway on which there is sufficient traffic to justify electrification, the power required by direct current will not exceed that required for single phase.

The cost of sub-station maintenance and operation is greater for direct current. On a 100-mile division there would probably be five (5) sub-stations, each containing moving apparatus which requires attention as against one for single-phase system. Each of these sub-stations would cost from $3,000 to $4,000 per year, or, say, $18,000 per annum, against $4,000 for the single-phase station. It is doubtful whether the wages cost of $2,000 per year per station, or $10,000, is a proper charge against the direct current. On main line work it will be absolutely necessary to arrange to cut out any portion of the road on which accidents may occur, and for this purpose attendance will be required. Trains must be moved away from any section temporarily disabled to prevent congestion, and of the $14,000 additional cost it would appear entirely fair to estimate that about $8,000 is the most that would be entailed by the sub-stations. This is more than equalized by the greater cost of maintenance of the single-phase locomotive. Direct-current locomotives are being maintained for 3¼ cents per mile, of which 2 cents is entirely separate from the electric motor, control, etc. On the single-phase locomotives, the cost has been higher, but it is hoped to reduce it to between 5 and 6 cents. For short distances the direct-current locomotives as used out of New York will handle a train that requires two single-phase, and if this were allowed for, the difference would be very great. The new switching and freight locomotives on the New Haven, it is stated, have been maintained for a comparatively low figure, but they have as yet not been in service sufficiently long to give a final value. The construction of all single-phase locomotives is far less sturdy than that of direct current, on account of the difficulty of keeping the weight down to a reasonable amount, and the construction is far more complicated. It cannot be expected, therefore, that they can be maintained for a lower percentage of their total cost. A fair difference to assume is that cost cannot be taken at less than 2 cents per mile for locomotives of equal power, say, 1,000-h.p. each. Considering a division with 1,000,000 miles per year, or $20,000 at this figure, so that the cost of operation and maintenance of sub-stations is more than taken care of by the increased cost of maintenance of equipment. The single-phase locomotive is also considerably heavier than the direct-current for equal power, and this is especially true when motor car equipment is considered. This increase in weight means a correspondingly reduced train load, unimportant on level districts, but of appreciable amount on heavy grades. It also entails an additional expense for power which is serious in light passenger or motor car service. There is, of course, a possibility that 2,400-volt d.c. apparatus will cost more to maintain than 600 or 1,200-volt, but there does not

appear to be any reason to fear its becoming excessive. While there is no doubt that the New Haven have had more electrical trouble than the New York Central and the cost of repairs has been higher, due to the mechanical construction of the locomotives rather than to the electrical equipment. This mechanical construction is, however, necessitated by the use of the single-phase motor. While there is no reason why the same construction should not be employed with the 2,400-volt d.c. system as with the 600-volt. In general, there is no reason to expect the cost of operation with the single-phase system to be less than that with the direct current.

Possible Difficulties with 2,400 Volts.—The above discussion considers that 2,400-volt d.c. will prove equally satisfactory as 600 or 1,200-volt installations. In a system that has not been thoroughly demonstrated in practical service, there are some features from which trouble may be experienced, and these are discussed as follows:—

The simple and strong design of the d.c. locomotive is partly due to the use of geared locomotives for freight service and gearless for passenger service. The construction which has been adopted and which is practically necessary for single-phase locomotives of any size, supports the motor entirely independent of the wheels, the latter being driven through springs or connecting rods, thus reducing the dead weight to that of the wheels and axles alone, while retaining the same total weight on each wheel. The centre of gravity of the locomotive is also raised to a point approximating that general for steam locomotives. From experiments conducted on engine and tender trucks and the experience of maintaining track under various types of locomotives, it is safe to assume that the dead weight of 9,000 to 10,000 lbs. per axle on gearless locomotives and the slightly greater weight on geared, does not, for the services in which they will be respectively used, appear likely to affect the cost of track maintenance sufficiently to justify the additional expense and complication involved in reducing it. In view of the greater total weight of the single-phase locomotive it is very doubtful whether its effect on the track will not be greater than the direct-current locomotive, even though the dead weight per axle is higher in the latter. Increasing the height of the centre of gravity reduces the lateral shocks on the rail, but this action is caused by these shocks in steam locomotive design being absorbed by the vertical movement of the springs. It will be unfortunate if electric locomotive design cannot be developed in which these shocks are absorbed by springs, or frictional methods of restraint, so that the simplicity which should accompany the application of motors to drive the wheels of a locomotive may be retained; there is no reason to doubt this being accomplished. Should it prove impossible, the direct-current locomotives would become more complicated and approach the single-phase more closely in cost, the difference being probably 25 per cent. in place of 50 per cent.

The question of current collection at 2,400 volts at high speed has been experimented with, but not fully demonstrated as yet in service. It has been found practical to collect 200 amperes at 60 miles per hour from one roller trolley without injurious sparking, which at 2,400 volts equals 480 kw. Two trolleys can be located 20 feet apart, thus permitting 960 kw. on one locomotive. This question is important, but there seems little question of its being solved satisfactorily. The control of 2,400-volt current does not appear to present any difficulty. Contractors will be arranged to break the current in series, and from results in operation there seems no reason to anticipate any more trouble with 2,400 volts than with 600. Maintenance of motors may be higher with 2,400 volts than with 600 volts. The motors will, however, operate under 1,200 volts each, and the fields in both motors will practically be at ground potential. Twelve hundred volt motors have operated interurban work for five years without indicating any increased cost on maintenance, and while this has been in a dry climate, the forced ventilation to be employed in railway work will give very closely the same condition. The 2,400-volt motor will have the same capacity to stand heavy starting load, the same freedom from commutation trouble, and in general the same ability to stand the severe service imposed upon it by locomotive or traction work that the 600-volt motor has been proved to possess.

The operation of fan and compressor motors on high voltage has to be properly worked out. There are no doubt some difficulties in this respect, but they should certainly be overcome by experience.

Comparison of Systems.—It has been shown that on the assumption that the 2,400 d.c. and the 11,000-volt single-phase a.c. system each operate as satisfactorily as their advocates claim, that there is comparatively little difference in their cost of installation and operation. Each is equally flexible, each will operate and in all probability give a high degree of satisfaction compared to steam locomotives. The principal difference is that, with the direct current a larger portion of the cost of installation is in feeder copper and conversion apparatus, and less in the locomotives, and a larger portion of the cost of operation is in the sub-stations, attendance and maintenance in place of locomotive maintenance. This of itself should prove decidedly to the advantage of the direct-current system, as the sub-station apparatus is stationary and can be carefully maintained, and the simpler and cheaper the locomotive the less danger there will be of a breakdown. In addition, the investment in copper is permanent, while that in locomotives may rapidly depreciate with any new developments. There are, in addition, some minor points worth attention which may be referred to.

The regulation of speed on the single-phase system is in many ways preferable to that on the direct current. By drawing current from the transformer at the voltage suitable to the speed and power required, all speeds are equally efficient, and the use of resistance in the circuit is avoided. This is an exceedingly ingenious method, but it is doubtful whether it is of great practical importance. While the direct-current motors have only two full-power efficient speeds, decreased power can be obtained at higher speeds than either of them by field control with very small loss in efficiency. This would apply particularly in passenger service, since in freight service the characteristics of the motor are such that it would not be required. The use of a transformer on the single-phase locomotive permits the operation of the motors at low voltages, and on ungrounded circuits. There seems, however, no reason to fear the use of high voltage on the direct-current motors, or danger, providing it is properly insulated. There has certainly been more trouble on the single phase from grounds than on the direct current, and it appears to be entirely a question of proper insulation. The relation between the speed of the motor and the power it will develop is different for single phase and direct current. Taking two motors which will develop the same power at a given speed, the direct current will develop greater power at lower speeds and less power at higher speeds than the single-phase motor. This is the reason for the success of the direct-current motor in traction service. It can exert a greater pull without injury and is less liable to damage from overheating when starting a heavy load than any other type of motor. It is also this feature which makes the gearless locomo-

tive a possibility for passenger service, as it enables a motor of reasonable size to start a passenger train without the use of gearing to furnish the necessary power. Direct-current motors can certainly be constructed to handle passenger trains at high speed if desired, so that in this respect the advantage is greatly in its favor. The direct-current motor has obtained its reputation for ruggedness from its capacity to withstand heavy loading without injury, and this quality is of the greatest importance in railroad work.

Conclusion.—If in place of discussing the relative advantage of single-phase and direct-current traction, the start is made from the direct-current system with its simple and strong electrical apparatus developed after years of experience by simply an increase of voltage, and assuming that this increase does not lead to unforeseen difficulties, the question becomes, What is gained by the use of single-phase current?

It does not save in cost of installation or operation.

Its application is not more flexible.

It introduces a locomotive that is more complicated, in which the motor is necessarily far more expensive and elaborately constructed, and which weighs considerably more than one for direct current.

It reduces cost of sub-station attendance at the expense of locomotive maintenance, and consequent reduction in reliability.

The general advantages to be gained by electrification are too well known to bear repetition, but it might be mentioned from the data now becoming available from those installations now in operation that results obtained confirm estimates very closely. The engineers of the Chicago, Milwaukee and St. Paul Ry. estimate that at least a saving of 25 per cent. will be made in operating costs on the 440-mile division now to be electrified in the Western States, and part of this saving is confirmed by the showing already on the Butte, Anaconda and Pacific Ry., where power cost has been found to be but one-third of the previous coal cost. The decision to electrify the suburban lines of the Pennsylvania Ry. about Philadelphia was made to relieve the existing congestion by increasing the capacity of terminal 15 to 20 per cent., or sufficient to relieve the situation for the next five or six years and at less expense than any other method.

PROGRESS OF NEW GANGES BRIDGE.

The largest steel bridge ever made for shipment from England is rapidly nearing completion. Six spans are being constructed by an engineering firm at West Bromwich, and the remaining nine at Darlington. This bridge will carry the Indian State Railway over the Ganges at a point about 120 miles above Calcutta, and it will be just a mile in length.

Steel to the quantity of 30,000 tons (all rolled in England) is being employed in its construction, 20,000 tons for the superstructure, and 10,000 tons for the piers. Each of the sections has a span of 345 feet, a height of 49 feet, and a weight of 1,400 tons. To hold the sections in position steel caissons were sunk 150 feet below the bed of the river. The shipment of these 15 spans to India will entail an outlay of some $300,000, and the total cost of the bridge will be $6,250,000. The erection of the bridge is under the direction of the Public Works Department of India. The first span shipped from West Bromwich arrived at Calcutta on May 26 last, and it was erected in three weeks' time before the rainy season, with its river floods, sets in. It is hoped that this bridge will be open to traffic this year.

A gigantic floating dock, said to be the largest in the world, is being constructed at Odessa. It will be capable of carrying a vessel of 40,000 tons, and will cost $2,000,000.

SOME PRACTICAL POINTS ON MODERN ROAD-WORK.*

By W. H. Maxwell, A.M.I.C.E.

In the planning of new through routes, directness of line is usually an important feature to be considered, from an engineering and utilitarian point of view, but leads to monotony in the use of the road, and from an æsthetic standpoint compares unfavorably with winding roads.

As a general rule, it will be more advantageous to carry a new through route past the outskirts of a town, and connect up with some good branch road to the urban area, rather than attempt to carry the new main thoroughfare through the heart of a populated centre, as the difficulties and costs of widening existing narrow roads through built-up areas are necessarily excessive, owing to the property and business interests disturbed. Very wide roads are not favored by shopkeepers, as they are not conducive to good trade—the bulk of pedestrian traffic usually keeping to one side of such a road.

Curves on a new main road should, of course, be as easy as circumstances will permit, but a radius of 100 ft. should be the minimum where fast through traffic is to be accommodated. On this curve, a person travelling along the centre line of a clear 40-ft. roadway could see approaching traffic within the limits of the road-width about 120 ft. ahead. Under similar conditions, with a 150-ft. curve, a distance of about 150 ft. ahead could be seen. On rural roads, traffic invariably uses the centre of the road by preference, and modern high speeds render an ample, unobstructed view essential.

The easing of curves invariably quickens the speed and reduces that degree of commendable caution in drivers which formerly existed. On a sharp curve the motorist is bound to materially reduce his speed or perish.

Curves should in all cases be freed from side sight-blocking obstructions, and for increased safety to fast traffic, the road surface on the outside curve should be given a suitable degree of super-elevation.

On a part of the Holyhead road on the north of the city of Coventry, Telford adopted a ruling or maximum longitudinal gradient of 1 in 35. Such a moderate gradient will present no impediment to fast driving, either up-hill or down, and in one on which tar-macadam and all modern methods of surfacing may be used with safety, but in hilly country will be difficult to maintain, except by much contouring and consequent increased length of route, or by heavy cutting and bridge work.

Dead-level roads are to be avoided. If the longitudinal inclination is less than about 1 in 100, the surface water will be difficult to drain away and more cross camber must be provided. With a longitudinal gradient of 1 in 50, or sharper, the camber may be flattened considerably, as the needful surface drainage is obtained longitudinally. This flattening of cross-section should not, however, be carried too far, otherwise watercourses will speedily form down the centre of the roadway on steep gradients.

Suitable cambers for different surfaces under ordinary conditions are: granite macadam, 1 in 25; tar-macadam, 1 in 30 or 1 in 40 on incline; creosoted deal paving, 1 in 36; hard wood and granite, 1 in 45; and asphalt paving,

*A paper read at the 41st Annual General Meeting and Conference of the Institution of Municipal and County Engineers, held at Cheltenham, June 24th-27th, 1914.

1 in 50. The longitudinal fall of water channels should not be less than 1 in 100 for a granite channel, and 1 in 150 for asphalt.

Improvement of Existing Roads.—Inadequate Foundations.—The majority of the old highways of this country have come into existence in a more or less haphazard fashion, and in the past the provision made for their maintenance has been uncertain and inadequate. The entire absence of foundations suitable for carrying modern weights brought upon the surface is revealed by the upward movement of the sides of the roadway into the channels—a weakness to be observed generally throughout the country.

Vast sums are now being spent in laying down expensive so-called waterproof surface crusts of various kinds, in order to give an immediate show for the money expended, but the writer is of opinion that, wherever there is evidence of underlying weakness, money may be more advantageously applied by first putting in proper foundations and drainage. However excellent, well laid or expensive may be the surfacing material, it can never prove really satisfactory on a weak foundation. There will be gradual but constant movement of the road crust, local sinkages of the central portion and rising of the sides, and generally the annual expense of wear and tear of the surface will be greatly enhanced in cases where no solid and unyielding foundation exists.

The initial cost of such work is, of course, necessarily heavy, but where suitable foundations do not already exist, it is submitted that it is the only sound course to pursue, both from an engineering and financial point of view, and is essentially a capital work for which State "grants" on liberal terms should be made.

Thin Crusts.—The wisdom of recent practice in laying thin surface wearing crusts or armourings of asphalt and bituminous preparations over existing macadam surfaces is open to great question, except where an absolutely rigid and dry foundation can be relied upon. In the absence of this, most ordinary road surfaces are subjected to consider movement under modern speeds and weights, and in these circumstances, thin wearing crusts are liable to fracture and disintegrate. Great caution in the selection of a suitable site is necessary, except where laid on a good concrete foundation, which, unfortunately in most cases, would make the cost of the work prohibitive.

Bituminous Methods.—In what are now known under the general name of "bituminous methods," the presence of coal-tar and pitch is the distinguishing feature, and the main object of all such processes is to exclude water from the crust of the road. These methods consist mainly in the revival and extended use of "tar-macadam," "pitch-grouting," "tar binders," and other like forms, and in suitable situations and conditions give very serviceable surfaces at a not unreasonable cost, but much discrimination is needed in their application.

The arch enemy of the tar-macadam road is the traction engine, and this cumbersome vexatious contrivance is, unfortunately, rather in evidence in the writer's district, especially during the spring and early summer months. These engines, with destructive diagonal steel strips on the wheels, weigh over 16 tons on the road, and haul three lumbering wagons weighing about 12 tons each when loaded. Under this burden the very best of tar-macadam work suffers substantial damage. Even after having been laid many months the material, owing to its plastic nature, will slightly soften on a hot day, sufficient to permit of its being crushed out of shape and torn up under traffic of the class named.

A well-made granite macadam road surface withstands this class of traffic very much better than tar-macadam, or any of the bituminous processes.

To the enthusiast for tar-macadam, in addition to the above caution, the writer suggests that consideration of the following points will help to keep him out of trouble:

1. The quality of tar available for such work is very variable and unreliable, and requires constant watching to avoid failure.

2. Good fine weather is an important factor for successful work. If the weather is too cold there is great risk of too much tar being used, thus causing the tar-macadam to become very soft and easily damaged during the warm weather.

3. Tar-macadam is hopeless on a weak, yielding foundation.

4. It cannot be satisfactorily repaired during wet, cold weather. This is important in streets where much opening of trenches for gas, water, electric and other services is likely to be required.

5. Where there is much traffic a continual watch must be kept on the work for some time after it has been completed, which considerably adds to its cost.

6. Tar-macadam is liable to "creep" during hot weather towards the sides of the roads, especially in country districts, where the lateral support of a curb and footpath is not usually available, and some provision to meet this tendency should be made.

7. The cost of tar-macadam is, as a rule, much beyond that of a granite macadam tar-painted surface, and its serviceable life cannot always be so accurately predicted.

The foregoing matters are mentioned, not with any desire to discourage the use of this type of road surface, but simply with the object of drawing attention to a few points which require consideration to ensure successful work.

With regard to the "pitch-grouting" of road macadam, the writer is of opinion that this process has not yet been proved to be so satisfactory under like conditions of traffic, as good class tar-macadam well laid. The work is expensive, its serviceable life is not great, the surface soon becomes deeply corrugated and carries much slippery mud during wet weather.

Coatings of tar-macadam of a total thickness of 4½ inches are sometimes laid with a layer of coarse material at the bottom, and finished with a fine grade for the surface. A coating of the thickness named is best laid in two layers, but there is no advantage in separating the fine and coarse grades; the same mixed grade material should be used for both coats.

Rolling of tar-macadam is best done with a "light" steam roller (6 or 7 ton weight), and there is nothing to be gained by an excessive amount of rolling.

Tar-macadam may be laid on gradients as steep as about 1 in 25, and even sharper if the surface is kept clean. The degree of slipperiness experienced depends greatly on the weather and the skill of the driver.

It is a great mistake to lay tar-macadam, or any other bituminous road surface, over an existing macadam roadway as a foundation, without first lightly scarifying the surface all over and consolidating by rolling to a *uniform* condition before the bituminous material is laid. Where this precaution has been neglected the old inequalities and "pot-holes" in the road crust will soon re-appear on the surface of the newly laid coat, as the greater depth of bituminous material over the "pot-hole" consolidates more than the thinner coating around.

Tar and Tar-painting.—Experience of recent years has led to the settling down of much preliminary clamor about "dust-layers" to the very general use of coal-tar. This new demand has brought about a very substantial increase in the price of tar, and, with the continued extension of bituminous methods of road construction, the demand appears likely to exceed the supply, and so set a limit on this form of road improvement unless competitive processes are adopted.

The specially prepared tar for road surface painting used by the writer weighs 12.95 lbs. per gallon, or 173 gallons to the ton. This is heavier than the weights recommended in the Road Board Specifications, but the tar is found to make very satisfactory work.

Tar-painting is not usually very successful on roads with damp clayey sub-soils, in shady situations, or under trees. A dry sandy or chalky sub-soil is the most favorable for the work, and in these areas operations can be started earlier in the season.

The heavy, complicated, costly tarring machines of early tar-painting days have almost disappeared in favor of much simpler plant, and hand work—the latter giving the best results in this class of work.

For town work granite chippings ⅜ in. to ⅝ in. gauge make the best class of "grit" for covering the tar. Sand, though usually much cheaper, produces an increased quantity of mud and causes the tar-painting to tear up more readily under heavy traffic.

In the author's experience the amount of money spent on road tarring is about equivalent to the saving obtained in ordinary maintenance and wear and tear on the roadways, so that no increase on the total cost of highways arises, whilst a greatly improved surface is obtained during the summer and autumn months. Tar-painting gives most economical results on secondary roads, *culs de sac*, and other thoroughfares with light traffic, as, in such cases, the tarred surface remains in good condition for several years without repair, and very little attention of any kind is needed.

Repairs.—Systematic inspection of the roadways, and regular and prompt patching of depressions and "potholes" is very desirable, especially on motor omnibus routes. For this work the writer uses a light roller of the convertible tractor type, which is well adapted for the purpose.

Under modern traffic conditions the highways require to be regularly patrolled and repaired, much in the same way as a railway track.

Old screened road metal, of small gauge, is well suited for patching, as it consolidates quickly.

Ordinary macadam surfaces should not be patched with tar-macadam as, after a little wear, a most unsightly and intolerably bumpy surface results, owing to want of uniformity in wear of the variegated surface.

When recoating a roadway, the thoroughfare should be closed wherever possible, and the whole width of road coated and rolled in one operation. Work of this class done in half-widths is seldom satisfactory, as rapid wear invariably occurs at the central joint. In cases where this system cannot be avoided it is best, if possible, to first treat about two-thirds of the width, so as to keep the joint out of the centre of the road; but many roadways are too narrow to permit of this being done.

Weather conditions are among the most powerful factors influencing the wear and tear and deterioration of roads. Prolonged rain, and heavy traffic following the break-up of frost immediately succeeding a wet period are particularly destructive.

In town streets where a macadam surface has to be renewed about every two years, and patched frequently, a wood-paved surface will probably be more advantageous. A maintenance cost of 20c. per sq. yd. per annum is about the economical limit for macadam, and, from the point of view of traffic weight, a load of some 250 tons per yd. of width per day is about the maximum for an ordinary macadam surface.

Steam Rollers.—In the opinion of the writer the usual so-called "10-ton" steam roller is much too heavy for the majority of surface recoating work. These rollers, when loaded ready for the road, often weigh nearer 13 to 14 tons than 10, and frequently cause much damage to the new metalling by crushing and weakening it during the process of consolidation. In some cases metal is put on the hard crust of the old road, without preliminary scarifying, and rolled down with a heavy steam roller, with the result that the stone, being severely crushed between hard surfaces, is permanently damaged at the outset, and the serviceable life of the new coat thus sadly reduced.

For much of his work the writer uses what is described by the makers as a 7-ton roller, of the convertible roller-tractor type already referred to. This machine is found to be of the greatest service for all classes of work as well as for haulage. The small tractor-roller can be moved quickly from job to job, and can be converted to a tractor in about a couple of hours. This roller, with awning, water, etc., fitted up ready for work on the roads actually weighs 9.42 tons.

Mechanical Haulage for Municipal Work.—Whatever may be the views held as to the desirability of public highway authorities employing steam, petrol, or other motor vehicles for haulage purposes, the writer has been practically compelled to do so, on account of the difficulty experienced, during the busy spring and summer seasons, in procuring sufficient suitable horses. It is usually impracticable to keep, during the relatively quieter winter months, a full stud of horses sufficient to cope with all work during the busier period of the year, and such work as street-watering and road tar-painting greatly accentuates the variation between winter and summer haulage demands. The hiring of the surplus summer requirements affords one way out where the horses can be got, but horse contractors are fast changing to mechanical haulage, thus greatly limiting the supply.

Slippery Road Surfaces.—In these days of improved road surfaces, tar-painting, tar-macadam and such like, complaints are perhaps a little more frequent in respect of slipperiness, and requests for "gritting" or sanding are often made. The best plan to overcome slipperiness is to keep the surface as *clean* as possible, by removing (and washing off if necessary) stiff pasty mud which is liable to accumulate during the foggy, damp weather of the winter months. Gritting and sanding greatly increases the production of this stiff slippery mud, as the material is speedily crushed by the traffic. The application of grit, therefore, should be done as sparingly as possible, and cleansing of the surface should take its place.

Road Signs.—Generally speaking, there is room for improvement in road direction signs. Frequently they are so placed that an approaching traveller cannot read the sign without stopping, and even sometimes dismounting. The direction arm should be at the most favorable angle, the letters not less than 3 in. in depth, and the mileage stated in bold block figures to the nearest quarter. Strangers motoring long distances often find it impossible to quickly gather the name of the place they are passing through, and it would be a great convenience to have the name of the village or town boldly erected on the through

roads near the commencement of the village buildings.

Street corner "mirrors" are costly to erect and maintain, and the moving reflected image is liable to mislead a motorist unaccustomed to them.

It is a mistake to multiply danger and caution signs unnecessarily. They should be confined to the most awkward spots, and be erected by a public authority. No private signs should appear on a public highway. If too numerous, the familiarity of their appearance leads to a general neglect of the warning intended to be conveyed.

Statistics of Traffic.—The expression of traffic records in tons per yard width of roadway does not, in many cases, give a true representation of the amount of wear and tear over a roadway. On roads through rural districts with a comparatively small amount of traffic, a very large percentage of vehicles keep to the centre of the road—in fact, the less the volume of traffic the higher will be the proportion using the centre of the roadway. Thus the sides suffer but little wear, whilst the centres soon become worn out. The average traffic record per yard width does not therefore correctly show the conditions which obtain and a minimum and maximum record is necessary to convey the true facts.

Much the same thing often occurs on very wide roads, as a portion of the width only is used by a high percentage of the traffic.

On busy town roads of medium width the traffic is very fairly distributed, and it is mainly to this class of road that the average tonnage per yard has any reliable significance.

On some roads, owing to the nature of local industries, the *night* traffic is quite an important item, and should not be omitted if a true record of actual conditions is to be obtained.

The collection of information and statistics, in reference to roads, traffic, materials, and other like matters, is a useful occupation from many points of view so far as it goes, but the road engineer should be cautious as to the conclusions he may safely draw from the collected data placed before him. So much depends on the actual conditions in any given case, and it does not by any means follow that because a road material has proved satisfactory or otherwise in one place it will necessarily do so in another. A new set of conditions will produce its own set of results, and the engineer must use his judgment in each case according to his local knowledge and experience.

Experiments and Tests.—Laboratory and other indoor tests of road materials serve a useful purpose in arriving at the physical and chemical properties of the materials, and assist the engineer when the information so derived is seasoned and matured by practical experience on the road. Weather and traffic are of paramount importance in all road-making matters, and there is no test to be relied upon other than that of actual and adequate trial on the road under ordinary conditions of traffic, rain, frost, and numerous other distributing influences to which any road material must necessarily be subjected.

Administration of Highway Maintenance.—Good administration, particularly in reference to the disposition of labor, materials, and plant, is one of the leading factors in highway maintenance essential to efficient and economical work. In urban areas suitably placed central depôts, with railway sidings into which materials can be delivered direct, are a great convenience, and involve the minimum haulage of materials. In these days of frequent labor disturbances, as in the case of the railway, dock, and colliery strikes, the necessity of getting all materials on the spot well in advance of requirements has been greatly emphasized of late, in order that annoying delays may be avoided. Delay in any form means increased cost of the work in hand, frequently entails loss of good weather suitable for the work, and always gives regrettable inconvenience to the general public.

Wherever much work is in progress constant inspection and supervision is a good investment, and to this end the inspecting staff should be provided with appropriate means of quick and convenient locomotion.

Local materials should be employed wherever of suitable quality, but some counties are particularly deficient in good quality stone suitable for first-class roads carrying considerable traffic.

Over-"centralization" of the practical work of road maintenance is not desirable. It is apt to lead to so-called "red-tape" methods, costly delays, and lack of individual attention.

Road maintenance should be carried out through the responsible highway authorities by the direct employment of labor, thus ensuring a local interest in the work, close supervision, and prompt attention, which is almost impracticable under any too distant and highly centralized system of administration.

Stereotyped standardized methods in many matters connected with road-making and maintenance are to be deprecated. Such methods destroy the useful application of personal experience and judgment to individual cases, and so lead to mere routine and lack of interest. It is unlikely that there can ever be any universal solution of the road-problem, inasmuch as local conditions and requirements, character and extent of the traffic, local facilities of obtaining suitable materials, considerations of cost and the like, must ever be deciding factors in arriving at the most suitable and satisfactory mode of treatment in each particular case.

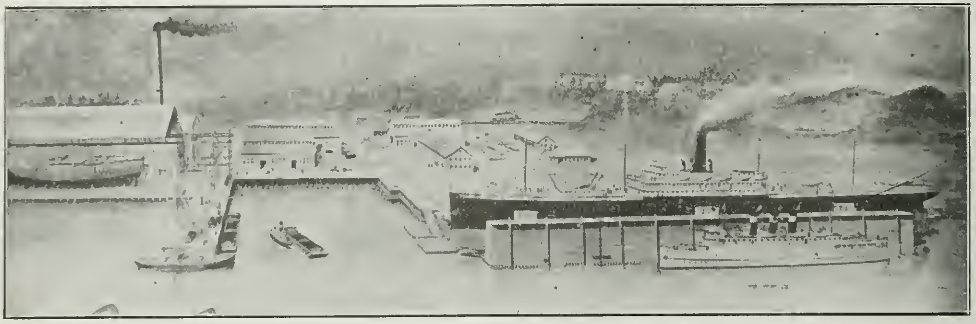
INTERNATIONAL ENGINEERING CONGRESS, SEPTEMBER 20th-25th, 1915.

The International Engineering Congress at San Francisco is to be conducted under the auspices of the American Society of Civil Engineers, the American Institute of Mining Engineers, the American Society of Mechanical Engineers, the American Institute of Electrical Engineers and the Society of Naval Architects and Marine Engineers, assisted by a committee of 18 California engineers. The vast scope of the congress is indicated by the fact that it will be divided into 11 groups of sub-congresses, the reports of which it is calculated will fill 11 large volumes. Chief among these branches will be that dealing exhaustively with the problem worked out in the construction of the Panama Canal, and the influence of the canal on world commerce, commercial trade routes and general transportation problems. Col. Geo. W. Goethals will have charge of the presentation of all canal topics. Aside from general engineering topics, the section devoted to the canal will be treated as follows:—

1. Col. Goethals' general report. 2. Dry excavation of the Panama Canal by Col. Goethals. 3. Dredging the canal. 4. Terminal works, dry docks and wharves of the canal. 5. Meteorology and hydrology of the zone. 8. Designs of locks, dams and regulating works. 9. Methods of construction of same on the Atlantic side. 10. Same on the Pacific side. 11. Designs of lock walls and valves. 12. Spillways. 13. Gates of the canal. 14. Electrical and mechanical installation. 15. Emergency dams above locks. 16. Municipal engineering and domestic water supply in the zone. 17. Reconstruction of the Panama railroad. 18. Aids to navigation of the canal. 19. Geology of the canal zone. 20. The working force of the canal. 21. Sanitation in the zone. 22. Purchase of supplies for the canal. These papers and addresses will constitute practically the official technical record of the work.

PRINCE RUPERT, B.C., SHIP-BUILDING PLANT.

Work was started in June, 1913, on the construction of a ship-building plant at Prince Rupert, B.C. The contracting firm of Beer's, Limited, has under construction, in addition to the ship-building plant, the power-house, machine, boiler and blacksmith shops and foundry building, and hope to have the entire contract completed by August of this year. The accompanying illustration gives a general view of the arrangement of the plant.



General View of the G.T.P. Ship-building Plant at Prince Rupert, B.C.

The power-house is constructed of steel and concrete on a heavy concrete foundation, with a slate roof. It measures 104 x 148 ft. and is about 65 ft. in height. The machine shop is also a steel frame building, 75 x 150 ft., resting on a concrete foundation. The boiler, blacksmith shop and foundry are similar to the machine shop in size and general construction. The shipbuilding plant is constructed with a steel frame, and is equipped with a large travelling crane. Its size is 160 x 300 ft.

The above-mentioned firm, of which Mr. N. B. Beer is manager, is executing the contract for the Grand Trunk Pacific Railway.

TIMBER FLUME CONSTRUCTION.

Timber flume construction and fluming are discussed in a bulletin just issued by the United States Department of Agriculture. The publication considers the subject from the practical standpoint of the logger who has to get his material out by these means.

The V-shaped wooden flume is held to be superior to the box or square-sided form, because it requires less water and, on the average, less repairs than the other type, is better adapted to act as a slide on steep grades, and offers fewer chances for jams. Concerning a third type, the "sectional" metal flume, semicircular in form, the prediction is made that it will eventually come into wide use. Such a flume is strong and light, and can be quickly taken apart and transported from one place to another to be set up again.

When building flumes a good plan is to erect a small sawmill at or near the upper end of the flume location to saw out the material needed for construction. Such material can be floated down the flume as fast as the latter is built and used for its further extension.

For handling railroad cross-ties, cants, poles, cordwood and the like, a flume with the sides of the V, 30 in. in height is large enough. For handling logs, piling, long timber, or brailed sawed lumber, a height of from 40 to 60 in. is recommended. The best angle for the V is put at 90°.

Flume lines should be surveyed with enough care to ensure evenness of grade. Grades should be kept below 15% wherever possible, and the best results are obtained with grades between 2 and 10%. A careful preliminary survey, followed by a location survey, using a transit and level, will make it possible to obtain a reliable profile map which will serve to show the prospective operator what the grading should be at different points along his line.

Abrupt curvatures in a flume should be avoided, for they are likely to cause jams. Curves should rarely be permitted to exceed 20°. The longer the material to be handled in the flume, the less abrupt should the curvatures be. It may be necessary to blast out rocks and boulders, or projecting points of bluffs, or to trestle, or even tunnel, to eliminate abrupt curves or maintain an even grade.

Some flumes are built with only the lining or inside of the box of sawed lumber, the brackets or frames which support the sides of the V being made from round pole wood flattened on one side, and the sills, stringers, braces and trestling of small round timber or poles. Sawed material is recommended for flume construction, however, wherever it can be obtained at reasonable cost.

The "boxes" or sections of a flume vary in length from 6 to 20 ft. Sometimes the boxes are made of only one thickness of boards, but more often of two thicknesses with the joints broken by varying the width of the boards. Sometimes, also, a single thickness of boards is used, with battens spiked over the joints on the outside in the section between the brackets. In still another form the battens are continuous. On curves the boxes should be shorter than on straightaways, and the bents, arms, and braces correspondingly closer spaced. In general, on curves of from 0 to 10°, the boxes should be jointed at least once in every 12 ft.; on curves exceeding 10° and less than 15°, every 8 ft.; and on curves of more than 15°, at least every 6 ft. Very abrupt curves also require increased bracing, in addition to shorter spacing of the arms and brackets. Flumes should also be strongly reinforced at points where extensive shipping is to be done or much material loaded into the flume over the sides.

If the storage facilities at the lower end of a flume are not sufficient for all the material that can be handled during the period in the spring when melting snow and early rains furnish an unusual volume of water, the construction of small holding reservoirs or "catch basins" at different points along the line is recommended. These may be formed by damming up some small stream; or natural ponds, favorably located, may be used for the purpose. In this way such material as it is not necessary to handle clear through at once can be diverted temporarily. A small artificial pond or reservoir at the upper end of a flume in which to "land" or "bank" the material to be shipped is also advisable, especially when handling logs, cross-ties, or heavy manufactured material of any kind.

Editorial

THE CONSERVATION OF WATER-POWER.

The question of conservation has to do with the policy, not only of the governments, federal and provincial, but also of the people at large, with regard to those resources, useful to man, which are supplied by nature in a form easily adaptable to immediate utilization, and particularly with regard to those natural resources, not uniformly distributed, which are limited in extent or in quantity. Among such natural resources are the minerals in the earth, the forests growing upon the earth, and the waters flowing over the earth. Whether applied to any or all of these, a policy of conservation should, manifestly, be directed neither to a locking up or withdrawal from use, on the one hand, nor to an indiscriminate or wasteful utilization, upon the other hand. Economy, in its best sense, should prevail, but an economy which has regard for both the present and the coming generations. These natural resources are placed by nature for the use of man, the man of to-day and the man of the future. Where present and future interests conflict, those of the present are paramount. It is not justifiable unduly to place burdens and restrictions upon the present generation out of regard for those to come after us, nor unduly, by present extravagance, to impose unnecessary burdens upon the future. More than that, neither desires for the present nor for the future should be made the justification or pretext for measures in conflict with the fundamental laws of personal and property rights which are, under our constitutional government, the safeguards of our free institutions.

Conservation, then, should denote the policy of the economical utilization of these natural resources, and of the utmost protection, within the law, of such economy, consistent with the needs of present and of future generations.

The two great, natural sources of energy available are coal deposits and water-powers. The known supply of bituminous coal, while sufficient for a few centuries to come, assuming that the present rate of consumption continues, is in fact limited, as its cost to the consumer gradually increases as the supply diminishes. While the cost of developing water power is considerable, the development of electrical transmission of energy has made water-power development feasible as a business proposition, as against the cost of steam power, to the extent that the amount of water power which is yet undeveloped, but which could be economically developed at the present time, amounts to millions of horse-power. As fuel grows scarcer and as the science of electrical transmission progresses, further water-powers, now merely potential, will be available for the market. It is computed that under average conditions about fifteen tons of coal are required to generate one horse-power a year. The use, therefore, of the water power now unused but economically available, would reduce the annual coal consumption by a remarkable percentage. Thus by the extended utilization of one source of energy, water power, two objects of conservation would be accomplished,—the utilization, without loss, of one natural resource, and the saving from loss of another.

Herein lies the peculiar adaptability of the policy of conservation to the use of water-powers. The three natural resources referred to represent fairly three distinct classes, or kinds, differing in respect of their quality of persistence. The mineral supply, in this case the coal deposits, is limited by its fixed and approximately computable quantity. In the case of timber, while the present supply is limited it, nevertheless, is naturally renewed. Indeed, the non-use of the quantity ripe for use is itself a waste; but, comparatively speaking, timber is a recurring, even if not a constant and undiminishing, natural resource. But water power is constant. The supply is not diminished by use, for in itself it consists in the development and use of two constant factors, viz., supply of water, and a head and fall, through which the weight of the water creates energy developable for practical use.

Every ton of coal used is forever lost as a source of energy. The use of every fifteen tons of coal means that the natural sources of energy have been forever diminished by an amount equivalent to the use of one horse-power for an entire year. To the extent that any quantity of coal is used up for energy before the time when its use is necessary, in place of an equal amount of energy from water power, such use constitutes a waste of energy. On the other hand, the non-use of any quantity of water power, through lack of development and of use of water-powers, the development of which is commercially feasible, means a waste of energy which can never be recouped. So far as such waste of water-power energy is accompanied by the further waste of coal energy, which the water-power energy might otherwise replace, there results a double and continuous loss or waste of the energy available from natural resources and, therefore, of these two natural resources themselves. The primary object of the conservation of natural resources, which is to preserve them from waste, is manifestly doubly opposed by any policy which defeats or postpones the development and utilization of water-power energy.

Because it is inexhaustible and because its use replaces that of another and exhaustible natural source of energy, water power is the most potent of all natural resources, as a subject and agency of conservation. In the case of a limited, exhaustible, and rapidly diminishing supply of a natural resource, such as that of coal deposits, the forces of conservation should be directed to the prevention of use, as far as consistently possible. But the correct view of conservation inevitably leads to the demand that, in the case of water-powers, there shall be encouraged and promoted the greatest and most immediate use possible.

SANITARY SEWER FILTRATION.

Too little is known of the infiltration of subsoil water into sewers and of the escape of sewage en route to the outlet. Undoubtedly there are a good many conflicting conclusions pertaining to the subject, but there are as well numerous instances to indicate that the infiltration of ground water into sewers is costing municipalities large sums in pumping and treating this water at purification and disposal plants. There are systems where newly laid sewerage systems discharge ground water in quantities equal to a considerable percentage of their capacity, before house connections are made.

Reasons that have been advanced for the general delay in acquiring more detailed knowledge and data on ground-water flows centre largely around the historic fact that the combined sewer preceded the separate sewerage system. In the construction of the former, tight joints were not an important item, otherwise, ground and surface water would have had difficulty in finding its way into the system, such a condition rendering it less efficient. Entering upon the design and construction of separate systems, engineers and contractors somewhat included the importance of perfect jointing and the resulting leakage feature has become prominent. An instance is on record at New Orleans of the leakage of ground water into sewers attaining an extent of 1,250,000 gallons per square mile. This infiltration, perhaps not objectionable in storm sewers or drains, is unquestionably so in other sewers and the importance of careful design and workmanship to reduce leakage to the least possible amount is perhaps no greater in any other branch of municipal engineering.

Obviously, the amount of filtration is a function of the head of ground water on the sewer, of the linear measure of joints in the case of pipe sewers, and of the superficial area of the interior of brick or concrete sewers. The volume is usually stated as so much per acre, per square mile, per mile of sewer, per capita or percentage of dry weather flow, but there is little information by which an estimate may be made based on the fundamental considerations mentioned above. There should, at least, be some regulations to apply to work done by contract. This would naturally involve a determination of how much water the sewer might be allowed to carry without materially injuring its usefulness. This determination would depend upon the number and circumference of the joints.

At a meeting of the American Association for the Advancement of Science, Mr. J. N. Ambler incorporated in a paper which he read on this subject a part of his own specifications covering sewer construction. While effecting some very careful work and acting as a powerful deterrent to poor construction, the specification was not regarded by the contractors as unduly severe. Mr. Ambler states in his paper that he once laid a mile of large sewer through exceedingly swampy land passing several streams with the result that not more than a stream ¼-inch deep was flowing from the lower end of the sewer upon completion.

The following is an outstanding part of his specification:—

It is the intent of these specifications that no more leakage of ground water into the sewer be allowed than is admissible with a first-class piece of work, in which care has been exercised to get as near as possible to a watertight result.

To determine the admissible amount of leakage, the length of a joint will be considered as the outside circumference of the spigot end of a pipe.

Leakage not in excess of two gallons per day of twenty-four hours for each foot of circumference of every joint will be considered admissible, the amount of flow to be determined by the engineer's gauging in each section, by means of a notch board.

The contractor agrees that for each 10,000 gallons per day of twenty-four hours by which the total flow of the sewer exceeds what the total flow should be, when figured on the basis already given, a deduction of $100 from the contract price will be made.

This will not apply further than to a total flow resulting from three gallons per day of twenty-four hours, from each foot of joint length, beyond which figure the sewer will be regarded as not in compliance with this contract.

PROTECTION OF UNDERGROUND SURVEY POINTS.

In mining work it has been found that protection against rot of survey points is most important. The work of the mine surveyor largely hinges upon their proper location and upon their not having been disturbed, but in order that the survey stations may possess a longer life of service some method must be adopted to prevent decay or molestation.

If survey plugs are driven flush with the rock they are less subject to rot than when allowed to project. The use of horse-shoe nails has given place in many instances to brass spads. When survey points have to be set in timber, especially in new timber near a face, it has been found well worth while to carry the point down from the spad in the cap to a point on the sill or on a hub in the bottom. The cap and consequently the spad is more subject to movement than the point in the bottom. Furthermore, with the point set in the floor, any movement can be readily detected.

ULTRA-VIOLET RAYS STERILIZATION OF WATER IN AMERICA.*

A FEW weeks ago the contract was awarded by the City of Niagara Falls, N.Y., to the R.U.V. Co., Inc., of New York, for the installation of 35 "Pistol" lamps for the sterilization of water by the ultra-violet rays of the mercury vapor quartz lamp. This is the first municipal installation of the system in America. The capacity of the filter plant in which they are to be used is 16,000,000 gallons per day.

The lamps will operate in banks of seven, and will be spaced 30 inches apart. Each bank will rest in a concrete channel 2 ft. wide, 3 ft. deep and 26 ft. long. Water will pass through the channel at a rate that will allow an exposure of 30 seconds to the ultra-violet rays.

The cost of the installation will be $19,800, which will be augmented by the necessity of rectifying the electric current from alternating to direct. This equipment will cost approximately $2,200. The guaranteed cost per million gallons for maintenance comprises current at 7 cents, and lamp renewals, based on a 2,900-hour life, 60 cents.

The Niagara Falls plant has been using about one grain of coagulant per gallon and five pounds of bleach per million gallons, thus costing about $1.50 per million gallons for chemicals. With the introduction of the new process it is expected that the plant will be made more economical as well as more efficient.

[* An article on water sterilization by ultra-violet rays appeared in *The Canadian Engineer* for June 25th, 1914.—Editor.]

The Dominion Creosoting Company, Limited, of Vancouver, B.C., has received an order for 160,000 creosoted railway sleepers from the Bengal and Northwestern Railway Company of India. The specifications call for best quality, well seasoned Douglas fir to be treated with 12 pounds of creosote per cubic foot under specified temperature and pressure conditions.

PRESENT TENDENCIES IN ENGINEERING EDUCATION

AS DISCLOSED BY THE PAPERS, DISCUSSIONS AND CONVERSATIONS AT THE ANNUAL MEETING OF THE SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION, AT PRINCETON, N.J., JUNE 23-26, 1914.

By C. R. YOUNG, B.A.Sc., C.E.,
Assistant Professor of Structural Engineering in the University of Toronto

THAT the engineering profession has not yet attained a status in keeping with its importance is amply evident from the spoken and written words of its thoughtful members. Duties, often of a judicial character, are performed under conditions inimical to the calm and thorough consideration of all the factors of the problem in hand. The independence of the physician or of the lawyer is enjoyed in much less measure by the engineer. His lack of activity in public affairs must be admitted. As yet, he lacks social consciousness.

Every thoughtful engineer has a vision of what his profession ought to be. Primarily, membership in it should involve the capacity to meet new and unexpected situations promptly and effectively. The engineer must be able to devise, unaided, his own plan of campaign, must forge his own weapons and wield them skillfully and courageously. He must be, as President Hibben put it, a scientist, not a technician; he must know not only the facts but the causes of the facts. Like the great physician, he should, to a large extent, be the maker of the conditions under which he works. More frequently than he now does, the engineer should be called upon to fill responsible executive positions requiring both technical and business training. He should be a loyal supporter of every movement for the betterment of his own profession and not only should he have convictions on public questions based on conscientious study, but he should take the part that the state requires of every good citizen.

The disparity between the engineer as he is and the engineer as he ought to be can be lessened only by a powerful transforming agency. Various opinions are held as to what this is to be. That imperfect education of engineers is responsible for many, perhaps most, of the ills which the profession now suffers, cannot be doubted when one hears the testimony of those qualified to judge respecting the fitness of the engineering graduate for the work of the world as he leaves the college halls. Professor John B. Whitehead, in reporting the results of the investigations undertaken prior to establishing a Department of Engineering in the Johns Hopkins University, states that "the average engineering graduate is wanting in general education, in powers of expression, in imagination and ability to reason." He cites in this connection the conclusions of Professor C. H. Benjamin, dean of the engineering schools of Purdue University, who examined the history, subsequent to graduation, of 3,500 graduates in engineering, particularly with respect to their fitness for professional work and with a view of ascertaining how educational training could be altered with promise of improvement. Dean Benjamin found that the graduate has little knowledge of commerce, business methods and economics, and must devote himself in some way to acquiring further information and knowledge of affairs for several years to come; that the literary side of his education has been too much neglected; and that the graduate is frequently unable to express himself properly in either writing or speaking. Among the educators, engineers, employers, and others consulted by the Johns Hopkins University, there was general recognition of the imperfections that have been mentioned. Professor Whitehead states that complaints of two great insistence on professional training to the sacrifice of fundamental and cultural studies were particularly widespread.

From the papers, discussions and conversations at the Princeton meeting of the Society for the Promotion of Engineering Education it appears that improvements in engineering education are to come principally in connection with (1) the subjects taught, (2) methods of teaching, (3) the teacher, and (4) administration.

The Subjects Taught.—In framing new engineering courses, or in the improvement of existing ones, the modern educator will see to it that whatever is taught is closely related to the entrance requirements of the college, to the probable character of employment of its graduates and to the personal qualities desirable in an engineer. His master-motive will be the student, not the subject.

With a course of given length, the scholarship and general equipment of the graduates will be largely determined by the conditions of entrance. With these fixed, the institution is automatically classified as a trade school, a professional school, or a compound of the two, and the subjects taught must follow.

Effective meeting of the needs of the community demands that the technical college shall carefully and continuously study the shifting field of employment of engineers and train its students accordingly. Not only must the broad departments of engineering likely to absorb graduates, as civil, mining, mechanical and electrical engineering, be considered, but the probable *range* of employment of the average graduate should receive attention. So frequently do graduates in one department find their life work in another department that the student should, in prudence, be equipped for transfer. There are now arising, thanks to the joining of technology to business, an increasing number of positions demanding of their incumbents both technical and business training. Professor C. F. Scott is authority for the statement that one-half of the members of the three principal engineering societies of the United States are in executive positions. But few are, or will be, engaged at wholly technical pursuits and of these only a minority will be so occupied for long. In all probability, a large number of graduates of engineering colleges will in the future be called upon to assume duties of a mixed technical and executive character. Instruction in technical institutions must anticipate this.

For business and professional reasons alone, and quite apart from higher motives, engineering education should aim to develop in the student character, intellectual capacity, well-ordered knowledge of his own field, knowledge of men, address and popularity. In purely technical pursuits the last three are less important than the first three, but for the majority of positions that engineers are called upon to fill, knowledge of men, address and popularity are of the utmost consequence. Their indispensability in the field of the engineering salesman is obvious.

In so far as specific subjects of the curriculum tend to develop these personal characteristics in students they are useful and that group of subjects giving the best balance in equipment is the most desirable.

There is now general agreement among engineer educators that three classes of subjects should be taught: technical subjects, economic subjects and cultural subjects.

Technical subjects, based upon the physical, chemical and mathematical sciences, give to the student that introduction to professional practice required in order that he may become an engineer. The selection must be made to correspond to the probable range of employment of the average graduate and at the same time to enable the undergraduate, in democratic institutions at least, to earn a living and something more during the holidays. Limitations of time require that only those subjects in which the student most needs assistance shall be taught. Many reading or descriptive courses might, with profit, be left entirely to the student. In presenting those subjects which are given a place in the curriculum, the usual situations and problems should be given priority over the unusual. In the writer's opinion, much time is wasted in giving elaborate courses in higher structures to civil engineering students when only a small percentage of them will, as engineers, have anything to do with such structures. Let the problems that 70 or 80 per cent. of the graduates of an institution will be called upon to solve determine what is taught, rather than those with which 20 or 30 per cent. may occasionally be confronted. Fundamentals, not details, should prevail. Both cannot be taught in college and it is obvious which should give way. The attempt to give manual dexterity in field work, shop work or in routine testing is an anomaly in an institution for the training of professional men. Such is the work of a trade school.

Economic subjects, devised to reveal to the student economic laws and business methods, are being introduced for the sake of the increasing numbers who will find their life work in a combination of engineering and business. Attention should be given to organization, management, finance, business procedure, commercial law and accounting. There are, however, in the presentation of these subjects, the same difficulties as have been noted in connection with technical subjects, particularly the tendency to encumber the student with multitudinous details. The advocates and teachers of scientific management are especially culpable in this respect. If there is any science in management, surely it can be presented in a few simple principles and it is these that the student should hear about.

Cultural subjects are now generally regarded by those who have given study to the matter as not only a desirable but a necessary part of an engineering course. To attain the higher reaches of success, the engineer must be an educated and cultured man. No corporation, public or private, cares to trust large problems and delicate negotiations to an ignorant, unpolished representative with one idea, and that a technical one. Even if the student cannot see far enough ahead to cultivate "the durable satisfactions of life," he should realize that the shortest cut to failure lies through neglect of the things that put him at once in touch with educated men in other walks of life, upon whose favor his professional success will depend.

It is possible, of course, to so select the cultural subjects incorporated in the curriculum as to improve not only the general education of the student but his professional equipment as well. Expression, whether it be in speech or in writing, in his own tongue or in a foreign one, ministers to both these ends. An acquaintance with literature opens, as Alfred Noyes has put it, "twenty gates to knowledge." Modern, and particularly current, history widens his horizon and makes him a citizen of the world. Sociology introduces him to public problems to the solution of which he should contribute his best thought and effort. In professional as well as in private conduct, a grounding in ethics is vital to him.

Already many institutions have given place to cultural subjects in their curricula. The Massachusetts Institute of Technology strives to carry instruction in English, in one form or other, throughout the four years. Third-year students must spend 45 hours in the first term and 75 hours in the second term on elective work in general subjects. These are arranged in four general options: Economics, English, Modern Languages and History. Fourth-year students may also be admitted to these options without examinations. Beginning with the next session, Columbia University will require for entrance to its engineering courses a three-year college course comprising instruction in English, Modern Languages, History, Philosophy and Political Science. In the new engineering courses recently established at the Johns Hopkins University, 24 per cent. of the total time will be devoted to general educational and cultural studies, comprising English, Modern Languages, Political Economy, Logic, Ethics and Psychology.

It is thus evident that a multiplication of the points of contact with life is the ideal of many engineering educators. Mr. W. H. Rayner, of the University of Illinois, has given effective expression to this view. Says Mr. Rayner: "I believe that it is more important for a senior to gain a good comprehension of present-day labor problems than to spend six or eight hours per week in detailing a plate-girder bridge; and, as an academic means to equip an engineering graduate for intelligent citizenship, it would be more profitable for him to consider the fact that between 10,000,000 and 20,000,000 people in our prosperous America are near the poverty line, and design measures of relief for them, than to design a gas engine."

Methods of Teaching.—Instruction may be imparted by formal or by informal means. The first is undertaken in lectures, recitations and laboratory investigations. The second arises through personal example, inspiration and advice in personal matters not covered by the curriculum. Increasing recognition is now given to the necessity for informal intercourse with students. Only in this way can the teacher really come to know the student and thereby reach and inspire him.

In formal instruction, the best teachers now apparently strive to (*a*) create and maintain interest in what is taught, (*b*) indelibly fix the fundamentals in the student's mind and (*c*) provide the student with means of self-help.

(*a*) Without interest, the student will carry little away from the class-room or the laboratory. How to develop it is the first problem of the teacher, and evidences are not lacking of earnest efforts to find the solution. For engineering students, there should be at the outset a consuming desire to become engineers and a willingness to make large personal sacrifices in order to do so. To create this desire, the teacher must present engineering in an attractive, if not a romantic, light.

Maintenance of interest is only possible by encouragement and frequent assurance of progress on the part of the instructor. The basing of new principles upon what is already known to the student is to him one evidence of increasing knowledge. The tacit inventory-making involved in tracing the inter-relation of subjects is another.

Apart from this mental stock-taking there is a value in constant relation of the new to the old. It is a fact, as Professor William James has pointed out, that the absolutely new makes no appeal.

In the teaching of theoretical subjects it is now regarded as highly desirable to introduce physical notions whenever and wherever possible. Professors Franklin, MacNutt and Charles, in their paper on "Practical Mathematics," repeatedly express this as their belief. Thus:

"In the teaching of mathematics every effort should be made to appeal to sense material and to the quantitative notions which permeate everyday life; and mathematical principles and relations should be visualized wherever it is possible."

" . . . . the only way to marshall the mind-stuff of a young man for the manufacture of ideas is to introduce the drag net of physical suggestion into every discussion. There is no other way to bring intuitive and sense material into the field of consciousness where it may be organized into a structure of ideas."

Of especial importance in maintaining the interest of engineering students is the correlation of theoretical subjects with practical engineering problems. Professor A. B. McDaniel, of the University of Illinois, has effectively pointed this out in his paper on Coördination in Engineering Instruction." Speaking of the teaching of trigonometry, he says:

"Generally, the speaker has found the student equipped with a vague idea of the trigonometric functions. Beyond the fact that they are certain abstract fractional forms, they mean very little to him. He does not readily see their significance in the solution of problems on paper, and in the field. Especially is he deficient in the ability to visualize these fundamental trigonometric concepts and quickly grasp their applicability. The reason for this is clear. *The subject is taught in an abstract way and not in correlation with the dependent branches of engineering.* Some schools, notably the college of engineering of the University of Minnesota, have endeavored to solve the problem by employing teachers with engineering training for the courses in mathematics. This method has proved to be quite satisfactory and efficient. Unquestionably such teachers vivify the subject, and present it in a concrete manner, having always in mind the future applications of the principles which they are drilling into the minds of the students."

(*b*) The indelible fixing of fundamentals in the student mind requires that the teaching shall largely be confined to fundamentals. Sufficient detail to enable the student to relate the problem to his own experience or to identify it later in practical affairs is salutary. More than this beclouds the central principle. The reduction of the principles taught to the fewest possible adds to clearness. Encyclopedic teaching is no longer in favor. When President Wilson began his teaching career he strove to compress into his lectures the greatest possible amount of information, but he soon discovered that the true ideal of teaching was not the communication of facts but the development of understanding in his students.

Symbolism in mathematics is responsible for the lack of clear understanding of many principles that for convenience are given statement in mathematical formulæ. Thus, Professors Franklin, MacNutt and Charles find that in their experience when a student is asked to state Joule's Law he will say "*aitch equals arr aye square tee*"! and that it is difficult to get him to say that "the amount of heat generated in a particular piece of wire during a given time is proportional to the square of the current in the wire and to the time that the current continues to flow." The aid to be derived in fixing principles in the mind of the student by their expression in words rather than in symbols is indicated by Professor Dugald C. Jackson, of the Massachusetts Institute of Technology, in the following:

"I am strongly in favor of emphasizing the instruction in mathematics, but particularly in calculus, on the side of the interpretation of the meaning of equations into simple terms of English, as the terms of English are those in which one ordinarily thinks, and it is necessary to make such interpretation in order that the logical processes of mathematics may be incorporated with our ordinary processes of thought and analysis."

On the principle that no operation is clearly understood until one performs it one's self, the subject should be drawn out of the student rather than put into him. He should solve his own problems, make his own discoveries and answer his own questions, merely receiving the guidance and suggestion needed to keep him on the trail. It is this method that Dr. E. J. Berg follows at Union College, Schenectady. While ideal, it has the disadvantage of requiring the expenditure of much time on the part of the instructor as well as a large teaching staff.

(*c*) Recognizing that the student must rely wholly upon himself when his college days are over, the judicious teacher will seek to provide him with adequate means of self-help. Primarily, the student must know how to study, but, as Professor George L. Sullivan has shown in his paper "Teaching Engineers How to Study," he usually does not. Increased attention must be given to this matter and an effective method of securing it would be to encourage students, by special recognition, to devise improved methods of study of the various subjects of the curriculum. An experiment of this kind is now being tried at Brown University.

So large a part does judgment play in the work of the engineer that a special effort should be made to develop it in college. Opportunities for choice and decision must be created and wherever possible responsibilities must be placed on the student. Let him fix important features of the problem in hand, although he may have to do it over several times as a result of erroneous assumptions. Require him to seek out his own data from the books, tables and typical plans available. Through the blunders, rather than by the fortunate steps he makes, he will understand the value of judgment and the meaning of responsibility.

Success in dealing with practical situations requires that the engineer shall be able to formulate the scientific problem from a layman's statement of conditions. One of the greatest difficulties of the young graduate is in making a book problem out of the information supplied him or to apply the theoretical principles learned in college to the securing of useful results from a mass of data gathered, perhaps, by himself. To remedy this, practice in formulating theoretical problems from practical statements of conditions and requirements should be given in engineering courses.

The Teacher.—Without able and inspiring teachers no institution can influence the student deeply or for long. Above all other qualifications demanded of one who would guide youth is character. No connivance at sharp practice, "tricks of the trade" or the operations of the disaster-inviting "bluffer" can be permitted. Varied ability, too, is essential. The teacher must possess mental calibre, an unusual facility of expression and tact in dealing with man, especially unruly and, at times, erratic students. Extreme cleverness in an instructor is, however, a handicap. The student's difficulties are not his

difficulties and the discussion will in all probability be carried over the heads of and beyond those who are supposed to profit by it.

Scholarship should be a prerequisite for teaching. Only one who is an up-to-date, first-hand authority on the subject he teaches can win and maintain the confidence of students. This necessitates a certain amount of research and writing. Through such activities the teacher not only extends his knowledge, but maintains a perennial freshness and interest in what is perhaps no more than a narrow specialty. Danger to the effectiveness of the institution as a teaching organization, however, lurks in the effort to carry on a great deal of research or writing. An eminent professor, upon outlining the various researches that he proposed to carry on during the approaching session of college, was asked what he would do with his students. "Neglect them," he replied. Little objection could be raised to investigations respecting the effectiveness of various methods of teaching and much of this legitimate form of research is now being undertaken by engineering instructors. An evil also exists in the practice, happily not widespread, of institutions urging young and immature instructors to write text-books with one eye on the advertising value to be derived therefrom.

No one should attempt to teach engineering subjects without enough experience in engineering to convince his students that he possesses more than book-knowledge of that which he teaches. As an adviser, he must have a knowledge of various fields. sufficient at least to give perspective. Much has been said concerning the engagement of practicing engineers as instructors on "part time." Engineering experience, as against a communicable knowledge of theoretical principles, as a qualification for effective teaching in a technical college, is losing its hold as a fetish. Directing a squad of draftsmen or keeping a contingent of contractors out of each other's way is not precisely the training that is most useful in enabling a man to impart a knowledge of the great fundamentals of engineering science. Teaching is a vocation requiring special fitness and special training quite as much as any other calling. An engineer of vast experience may be quite useless as an instructor. There is too great a disposition on the part of those who are called in from the field to teach to present the subject in a bewildering maze of detail. Their traffic with fundamental principles occurred so long ago that they have half forgotten that such exist. What they give to their students, therefore, are details, short-cuts, approximations and serviceable turns in the practical execution of work in office and field. The maintenance of a private practice of any considerable extent is, so far as its aid to teaching is concerned, of doubtful value. Not even the engineering professor can serve two masters. The advertising value to the institution does not compensate for the loss of personal contact with students inevitable with such an arrangement. So long as the major interest of the teacher is his students, the college will profit by allowing, or perhaps encouraging, private practice, but when academic duties are performed in time not otherwise occupied, the college is the loser.

Personal qualities of a high order are rightfully demanded of a teacher. His sympathies must be wide and his appeal to the student must be many-sided. In enthusiasm, however, is found his greatest source of power. Without it, he will be a failure, no matter what his other qualifications may be. Dean Orton, of the Ohio State University, has expressively put it in his remark that "About all a teacher is good for anyway is to 'enthuse' boys."

Good teachers can neither be obtained nor retained without inducements other than the opportunity for service —compelling though that may be to an idealist. The desire for a salary adequate to the position should be pardoned. Reduction of clerical and routine work to a minimum is highly desirable for one whose chief asset is his freshness and enthusiasm. Appointments, promotions and rewards must be based on capacity for the particular service required. If teaching is the service desired, let rewards be governed by ability to teach and not by demonstrated ability as an engineer, an original investigator or a writer.

Co-operation among teachers will profoundly minister to the effectiveness of instruction. Without it, the results achieved by one may be offset by another. There must be "give and take" in the matter of inter-relation of courses. Mutual help in faculty seminars and conferences is desirable.

Administration.—Since we teach not as individuals but as institutions, constant direction of both staff and students by a central authority is a necessity. For the good of the college and the effectiveness of its teaching no teacher should be permitted to carry an overload. His personal power with students depends, to a remarkable degree, on his enthusiasm, freshness and elasticity, and these cannot be maintained under a burden of overwork. Leisure is the one thing that the teacher should not be permitted to forego. There is, too, such a thing as a student load. The administrative head should assure himself that it, as well as the staff load, is not excessive. Much attention is now being given to such matters as the length, inter-relation and balancing of courses, the length and frequency of lecture, recitation and laboratory periods, the size of classes, the part of the day utilized, and allied problems vitally affecting the student. A halt has been called in the institution of graduate courses in engineering as a result of the indifferent success of the Harvard graduate school, and the action of the Johns Hopkins University in the establishing of a four-year undergraduate course with the provision for graduate work later is indicative of the tendency in this matter. A pronounced reaction against specialization is now in evidence. But little election is allowed in the new course at Johns Hopkins, and many educators are inclined to favor the attitude of such institutions as the University of Pennsylvania, which, for example, requires all students in civil engineering to take the same course.

Indications of Change.—Indications of profound change in the methods of engineering education are not wanting. Dean Gardner C. Anthony, in his presidential address to the Society for the Promotion of Engineering Education at Princeton, declared that the pendulum had reached the extreme position in its swing toward vocational training. The committee on Entrance Requirements of this society put themselves on record as deprecating the acceptance by engineering colleges of more than two Carnegie units of time devoted to manual training. The Johns Hopkins University designedly omitted shop work, foundry work and manual training from the curriculum. The University of Washington has completely revised its courses in the direction of greater attention to cultural studies. The three-year preparatory course for entrance to Columbia has already been mentioned. There appears to be, on every hand, ample evidence of a coming liberalization of engineering education. The ideal of ex-President Charles W. Eliot is more generally accepted than ever before: "Education for efficiency must not be materialistic, prosaic or utilitarian: it must be idealistic, humane and passionate, or it will not win its goal."

A FORM OF SIPHON SPILLWAY.

THE following illustrations are descriptive of a device for regulating the water level in a canal, stream or reservoir, and to provide for the disposal of surplus water in time of flood. It was developed by Mr. G. F. Stickney in connection with his work as designing engineer for the New York State barge canal, on which waterway it has been adopted. It is claimed by the inventor that the device will reduce considerably the size of a structure necessary to dispose of a flow of water, as a dam or spillway, and thus effect a material saving in its cost. Its automatic features contribute greatly to economic operation. In the development of water power in the storage of water for irrigation or other purposes, or in the increase of navigable depth of streams, there are problems such that those interested in the same will find the following descriptive notes of interest:—

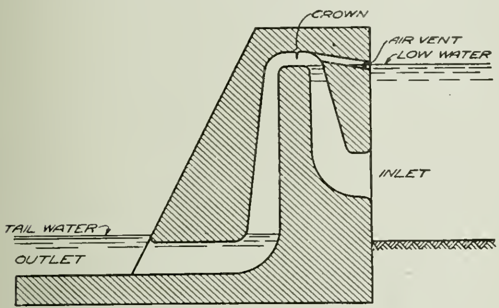


Fig. 1.—Section Through Siphon Spillway.

Fig. 1 is a sectional view of the siphon spillway. It is a closed conduit of an inverted "U" shape extending through a dam where a fall is available, thus utilizing the siphonic principle to induce a high velocity of flow. The siphon is built in the masonry of a dam, and its action is entirely automatic. The flow, when established, is comparable to that through a submerged sluice-gate with a velocity of from 60 per cent. to 80 per cent. of the theoretical velocity due to the head.

Fig. 2.—Upper and Lower Sides of Spillway. The Former Shows Inlets and Air Vents; the Latter, Siphons in Operation.

The crown of the siphon is entirely above low water level. The upstream leg is sufficiently long to bring the inlet well below the water surface so as to avoid the entrance of ice drift, etc. The downstream leg is made as long as is practicable in order to take advantage of all the head available. It is not necessary that the outlet be submerged.

The action of the siphon is controlled by an air-vent which pierces the up-stream wall at the low-water level. When the water above the dam rises the vent is submerged so that no air can pass into the siphon. The water then spills through the crown and the down-stream leg. At a certain depth of overflow the air in the siphon begins to pass out with the flowing water; and, as the air becomes rarified the water rises to a higher level in the crown than the surface of the stream outside. Within a short period of time the crown becomes completely filled with water. The siphon is thus primed and rapid flow established. It will continue until the water surface has lowered to such an extent as to expose the vent sufficiently to admit a volume of air into the crown. Then the siphonic action ceases. A fluctuation of the water surface of from 3 inches to 1 foot, depending on the size of the siphon, is necessary to start and to stop the flow. The limiting height of head which may be utilized to produce flow is 33.9 ft.—the height of the longest column of water which atmospheric pressure will sustain.

Siphons of large capacity may be built with the top of the crown well above the highest water level, but in such cases a simple automatic priming device is necessary and both ends of the siphon must be submerged.

Concerning this device it is notable that there are no adjustable or working parts liable to derangement or deterioration. It is genuinely automatic in action; and it will maintain a water surface which will fluctuate between narrow limits regardless of the flow, thus giving a reasonably constant level. The great volume of water which it will discharge per unit of length is also a notable feature.

Fig. 2 illustrates an installation built for the Tennessee Power Co. on the Ocoee river. The spillway contains 8 siphons, each 8 ft. square in section, 4 of which operate under a head of 19.2 ft. and 4 under a head of 27.2 ft. They have a total capacity of 1,650 cu. ft. per second. A rise of 4 inches starts the siphons.

The inventor claims for the device the following special uses:—

1. To regulate the water surface in a stream above a dam at the highest permissible level, giving the maximum head for power development, the maximum storage, the greatest navigable depth, and reduce the fluctuation of the water surface to a minimum.

2. To provide an outlet from a flume or forebay, where a constant flow is maintained, which will operate with a slight raise in the water surface and will discharge the entire flow, in case of a sudden shutdown of the power plant or a sudden obstruction of the flow.

3. To use in place of gate-valves to discharge water from a reservoir. The crown of the siphon may be placed entirely above the water level, so that no leakage is possible, and the siphon may be arranged to be operated by the manipulation of small hand-valves.

On June 15, articles of incorporation were filed with the Secretary of State for the South-West Pacific Railway Company, which purpose building a railway from Denver, Colo., to San Diego, Cal. The capitalization of the company is given as $2,200,000; and the approximate cost of the construction of the total 2,200 miles of road is placed at $105,000,000. The main line from Denver to San Diego will be 1,021 miles in length, while branches will be constructed from Denver to Salt Lake, and from other points to several mining districts.

A LAND SURVEY PROBLEM.

By J. A. Macdonald, Ottawa, Ont.

VERY little information is to be found in technical journals on land surveying, and there is no journal in America devoted exclusively to this important subject. As land surveying goes on continuously, and as each county supports, ordinarily, at least two land surveyors, it is plain that, in the United States and Canada, there must necessarily be a large number of men interested in this work. In late years, as land survey work grows less, most land surveyors are also civil engineers, or understand that part of civil engineering so far as instrumental surveying goes, though they may not be designers of bridges, tunnels, aqueducts, etc. There are, however, a large number of civil engineers who know little of practical land surveying. The following notes, which relate to a survey of a stone quarry and mill property contain a number of points illustrating several methods which are more or less essential to a practical knowledge of the subject, and should commend themselves as well to every surveyor of experience as they are a model in their way. Fig. 1 is a sketch of the survey to which they pertain, and Table I. gives the field notes themselves. The former, of course, should appear on the right-hand page of the field book, and the latter on the left-hand page.

Fig. 1.

It will be seen in this instance (Table I.) that the tree was sighted from each corner of the survey and its bearing recorded. These lines, when correctly plotted, intersect at one point. If the plot had not closed, then these bearings would have been plotted, as shown in the dotted lines on the sketch, and they would not have intersected at one point, the first line which deviated from the common point indicating that the preceding course had been erroneously measured, either in bearing or distance, or else wrongly plotted. Such bearings taken to a common point, enable us to locate an error either in the field notes or in the plot. The mill is located by bearings taken from corners B and C. The quarry and entrance thereto is located by bearings taken from known points in the lines 3 and 4.

Latitudes and Departures and Their Computation.—There is only one correct way of computing a compass survey, and this is by latitudes and departures. The latitude of a course is the length of a course into the cosine of its bearing. If the forward bearing of a course is northward its latitude is called its Northing, and is reckoned positively, or plus; while if the course bears southward its latitude is called its Southing, and is reckoned negatively, or minus. The Departure of a course is the length of its east and west line, or the length of course into the sine of its bearing. If the forward line is eastward its departure is called Easting, and is reckoned positively; while if its forward bearing is westward its departure is called Westing, and is reckoned negatively.

The Meridian Distance of a point is its perpendicular distance from the reference meridian, in the sketch from the north and south meridian point, and the most westerly point of the survey.

Table I.—Field Notes of a Compass Survey.

The Double Meridian Distance of a course is equal to the sum of the meridian distances to the extremities of the course. The double meridian distances of the two courses adjacent to the reference meridian are equal to their respective departures. The double meridian distance of any other course is equal to the double meridian distance of the preceding course plus the departure of that course plus the departure of the course itself, eastern departures being counted positively, and western departures negatively.

In the computation of area, twice the area of the figure is equal to the algebraic sum of the products of the double meridian distances of the several courses into the corresponding latitudes, north latitudes being reckoned positively, and south latitudes negatively.

Since the departure of a course is its length into the sine, and its latitude, its length into the cosine, of its bearing, these may be computed at once from a table of natural sines and cosines. As it is now customary to read even the needle compass as close as 5 min., the ordinary reverse table is of little use in modern surveying. For land surveying, a 4-place table is sufficiently accurate.

Balancing the Survey.—If the bearings and lengths of all courses have been accurately determined, the survey will "close," i.e., when the courses were plotted to any scale the end of the last course would coincide on the plot with the beginning of the first one, and the sum of the Northings would exactly equal the sum of the Southings (minus latitudes), and the sum of the Eastings (plus) would exactly equal the sum of Westings (minus). All surveyors and draughtsmen know that such exactness is not attainable in practice, and that no plot will close exactly; that neither the north and south latitudes nor the east and west departures will exactly balance. The distribution of these errors of latitude and departure is called "balancing the survey." In Table II. it is seen that the error of latitude is 60 links and the error of departure is 50 links. The distribution of these errors is made as follows:

The ratio of the length of the line joining the initial and final points to the whole perimeter is 17, as found from the field notes. The length of this line is the hypotenuse of a right-angled triangle, of which the errors in latitude and departure are the two sides. Its length is equal to the square root of the sum of the squares of these two errors. This, divided by the whole perimeter, gives the error of closure, which ratio is expressed by a vulgar fraction whose numerator is one, being 1/366 in the example given. For ordinary rolling country the error of closure should not be more than 1 in 500.

A check on the computation of the double meridian distances is found in the fact that when computed continuously in either direction and from any corner, the numerical value of the double meridian distance of the last course must equal its departure.

To Plot a Compass Survey.—Select a point for the initial Station, and pass a meridian through it in pencil. By means of a protractor, mark the bearing and draw an indefinite line from the Station point. On this lay off to scale the length of the course, 5, 10 or 20 chains to an inch, thus establishing the next corner. Through this, by means of a parallel ruler, draw another pencil line meridian, and proceed as before. The bearings of the successive courses may be so combined as to give the deflection-angle, similar to a railway survey, at any station, and these may be laid off from the preceding course as already drawn. Errors are more likely to accumulate in the plot by this method, so that the first is preferable.

Probably the best method of all, but one seldom used, is that by which rectangular co-ordinates of the several corners are computed, and these plotted from a pair of rectangular axes.

Table II.—Form for Computing Areas from Bearings and Distances of the Sides.

Area = 5324 sq. chs. or 532.4 acres.

Error of closure = 1 in 366 =

$$(\text{square root of}) \frac{\sqrt{50 + 60}}{286200} = 0.0027 = 1 \text{ in } 366.$$

A Diesel electric railway motor car accommodating 50 passengers and weighing over 70,000 lbs. has run, since the beginning of the year, over 2,000 miles on the railways of Sweden, usually at a rate of 20 to 35 miles per hour. The Diesel engine burns about 9 lbs. of crude oil per mile. The car is propelled by electric motors furnished with current from a generator driven by the engine.

Many thousands of bricks per day are being manufactured by the different brick companies of Fort William. The demand at present is fair and as the season advances will increase. The Alsip Brick and Tile Company is working to capacity and producing 70,000 bricks per day. The Fort William Brick and Tile Company is turning out some 26,000 brick per day. The Superior Brick Company is manufacturing 35,000 brick daily; while, at the new plant of the Mount McKay Products, Limited, great activity is being shown in the construction of new kilns, although brick making for commercial purposes will not be under way for at least two months.

The Canadian Pacific Railway will shortly have 1,095 miles of double track between Port Arthur and Calgary, leaving only about 165 miles still to be double tracked between these points.

During 1913, 10,000 box cars, 1,227 passenger, sleeping, dining, and other cars, and 156 locomotives of different types were added to the rolling stock of the Grand Trunk system. They included 41 superheated Pacific type of engines, 100 other large locomotives, 15 switching engines, 10 dining cars, 15 sleeping cars, 11 parlor cars, 67 first-class coaches, 500 flat cars, 500 stock cars, and a large number of combination cars. In box cars a preference was shown for 80,000 pounds' capacity. The prices paid for the passenger cars ranged from $10,000 for a first-class car to $25,000 for a sleeper equipped for service. Orders placed by this road for 1914 include 10 mail cars, 500 stock cars, 20 baggage cars, 82 first-class coaches, 5 second-class coaches, 4 dining cars, 5 parlor cars, 5 express cars, 200 fifty-ton flat cars, and 300 forty-ton flat cars.

LOCK ENTRANCE CAISSON, PANAMA CANAL.

A VERY interesting feature of Panama Canal construction is the lock entrance caisson which is to act as a floating gate or dam for closing the entrance of the lock so that any of the chambers may be unwatered for inspection, cleaning, or repairs. The following description of it is from the "Canal Record":—

The width of the lock chamber is 110 ft.; beyond the line of the emergency dams, the approach is widened by an offset of 24 in. on either side. The shoulders so formed, with a connecting horizontal sill across the bottom of the chamber, afford a frame into which the caisson is fitted to dam off the interior of the lock. This is accomplished by floating the caisson against the shoulders and letting water into its hold to sink it on the sill.

Pumps in the interior of the caisson are then employed to unwater the chamber, while the water pressure from the outer side will force the caisson securely against the frame, reducing leakage around the edges. When it is desired to remove the caisson, the lock chamber will be filled with water, relieving the pressure, and the water within the caisson will be pumped out to allow it to be floated away. The general principles of construction are the same as in the caissons for Gatun and Miraflores Spillways, but the requirements and conditions of its use make the design of the lock caisson more complex than that of the spillway caisson.

The caisson is designed for interchangeable use at all locks, and will have a draft when light of 32 ft., to allow its convenient handling through the locks. The lower elevation of the sill at the Pacific end of Miraflores Locks, 50 ft. below mean sealevel, in connection with the tidal fluctuation which raises the surface as high as 11 ft. above mean, requires that the extreme draft of the caisson, when sunk, be 61 ft. Provision for a proper freeboard makes the aggregate depth of the structure 65 ft. The achievement of statical stability at the various depths of immersion, without undue bulkiness or excessive weight in the different parts, makes the design of especial interest.

In form, the bottom of the hull will be convex, the ends pointed, and the sides will slope inward from a maximum width of 36 ft. at about one-third the way up from the keel, to a breadth half as great at the top. A typical transverse cross-section of the structure resembles in outline the vertical section through a pear-shaped carbon-filament electric lamp. The horizontal lengthwise sections vary with the inward slope of the sides; in general, they resemble those of the ordinary vessel of commerce, and may be described as flattened ellipses, blunt at the ends to contain the girders and breasthooks by which the pressure will be transmitted to the vertical sills, or shoulders, on the lock walls. The length between the vertical ends will be 112 ft. 6 in., and the extreme length, including the timber cushions, 113 ft. 10 in.

It is desired that the side walls of the locks shall carry practically all the static load from the caisson when it is supporting the water pressure. Accordingly, there will be a number of horizontal decks and end breasthooks to carry the load to the vertical ends; and a system of vertical framing, built intercostally and extending from the keel to the top deck, will transmit the panel loading to the horizontal decks and breasthooks. The essential features of the structure will be the transverse and longitudinal framing, with bulkheads; the horizontal plate decks, girders, and stringers; the girders at the ends and along the keel; the end breasthooks; and the plating to cover the skeleton in forming the hull proper. These elements will all be made from open-hearth structural steel.

The transverse framing system will consist of nine cross frames, spaced about 12 ft. apart and extending the whole height of the caisson, and intermediate frames, spaced at intervals of about two feet between the main cross frames. All will be built intercostally between the five horizontal decks. Two of the cross frames will be built watertight and designated as "Collision bulkheads," to form trimming tanks at each end of the vessel, for maintaining longitudinal stability and settling the caisson on even keel when it is to be put in use. The seven other cross frames will have apertures in their lower sections to make them serve as swash bulkheads for controlling the water within the caisson by which the depth of immersion will be regulated.

A longitudinal bulkhead will extend the entire distance between collision bulkheads, from keel to operating deck, along the centre line. Its lower part will be sufficiently watertight to form two distinct lengthwise compartments, dividing the free surface of the water ballast and increasing the static stability of the caisson, as against lateral motion.

There will be 5 horizontal decks, built continuously from vertical end to vertical end. The two lower decks, 16 and 25 ft., respectively, above the base line, will be entirely plated over with the exception of openings for hatches and manholes, the hatches being made large enough for the installation or removal of the pumps through them. The operating deck, 37 ft. above the keel, will be entirely plated from end to end, and made absolutely watertight. This deck will support the motors for the pumps, with switchboards, gauge registers, etc. The plate-stringer deck, 49 ft. above the base line, will be an open truss with diagonal bracing for the central two-thirds of its length. The top deck, 65 ft. above the base, will be plated over from end to end, with openings for manholes, skylights, deck cranes, companionways, and scuppers.

Six plate breasthooks will be built at each stem of the vessel, at intervals between the decks. They will serve to transmit the end shears from the decks to the vertical girders. One of these breasthooks, situated 31 ft. above the base line, will have its plating calked to watertightness and serve as the bottom for the end trimming tank. At the same level as the breasthooks will be longitudinal intercostals, securely riveted to the transverse frames and to the sheathing.

The skeleton will be entirely sheathed over with steel plating worked in in-and-out strakes, running longitudinally over the frames, making lap seams and butt joints which are to have double splice plates. At all the horizontal decks, and around the pipe discharge and suction openings, the sheathing will be doubled. Fenders against external impact will be provided between the 25 and 49-ft. levels, by bent plates securely riveted to the sheathing, the space between being filled with poured rosin. Towing rings will be attached along the 37 and 43-ft. levels.

End reaction castings will provide connection of the decks and breasthooks, up to and including the 49-ft. stringer deck, with the vertical girders, for transmitting to the latter the reactions of horizontal forces. They will be made of carbon steel and closely fitted during construction.

Along the exteriors of the ends and keel will be fastened cushions of British Guiana greenheart timber. They will be planed to make even contact with the plated sill and reduce leakage to a minimum. Greenheart timber

is notably durable under water, either fresh or salt, and has been used for the sills of the miter gates in the Canal locks.

Pumping System.—The pumps installed within the caisson are designed to regulate the water ballast, determining the depth of immersion, and to unwater any portion of the locks between the upper and lower entrances. Of all the lock chambers, the only ones which can be cleared of water without pumping are the two in the upper flight of Gatun Locks, because they are the only ones the floors of which are below the level of the water at the lower end of the flight. The floor of the intermediate level at Gatun is 13⅔ ft. below sealevel. The floor at Pedro Miguel Lock is at elevation plus 9, which is 46 ft. below the normal level of Miraflores Lake. The upper of the two levels at Miraflores is 18½ ft. below mean sealevel, which means a minimum depth of water in it of about 8 ft. at low tide of the Pacific. Moreover, the caisson dams will afford the only means of working in the dry on the outward faces of the guard gates, and the sills for the emergency dams.

The main pumping system will consist of 4 vertical-shaft centrifugal pumps, having a 20-in. discharge and a 22-in. suction. The practical test governing its design is that it shall be able to pump out in not over 25 hours all the water in the upper and lower chambers of one flight of Miraflores Locks, between mean sealevel and the top of the sill of the lower chamber (El.—50 ft.), the tidal level to be at El. 0 when the pumping is begun, and the tide rising. The total quantity to be pumped out, including 518,000 ft. for leakage, will be about 10,285,000 cu. ft. The average discharge under these conditions, for the entire period of pumping, would be about 13,000 gal. per min. for each of the 4 pumping units. Two of the pumps are to be arranged for pumping out the caisson when it is to be removed from its position against the sill.

Inasmuch as the sill for the caisson is higher than the level of the floor, suction extension pipes are to be provided to cross the sill on the bottom of the chamber, to allow its complete unwatering. The suction extensions will be lowered by cranes on the deck, and attached from a pontoon, similarly handled.

An auxiliary pump, with suitable pipe connections, will be used to regulate the end trimming tanks, flush the scuppers, and scour the sills.

Electrical Equipment.—The caisson will have no means of auto-propulsion, but will be towed from place to place. Its motors will be for operating the pumps, and their details will be determined by the pump characteristics. Four 2,200-volt motors will drive the main pumps, and one of 220 volts potential will operate the auxiliary pump. Another 220-volt motor will drive a ventilating fan. Current will be received at 2,200 volts from chambers in the lock walls, through four flexible cables, and a three-phase transformer is to be provided for the 220-volt motors, and for the lighting equipment. A switchboard will be installed in the operating room, which is on the operating deck, 37 ft. above the base line.

Miscellaneous Parts.—There will be four portable cranes on the top deck, to handle various loads. Each must be capable of raising another at a radius of 14 ft., by 2-man power. The pontoon for making the suction extension attachments will be stowed on the top deck and handled by cranes. A deck capstan, hand-operated, will be provided at each end of the top deck. It must be able to withstand a pull of 10,000 pounds.

Two ventilators, 16 in. in diameter, with hoods of U.S. Navy standard type, will be placed on the top deck, for ventilating the operating room. One, discharging a short way below the 49-ft. deck, will have a multivane exhauster, motor-driven. Twelve 2-in. air vents, to allow the escape of air and gases from the interior compartments, will lead to the top deck. Two skylights, 8 by 16 ft., will be set in the top deck, symmetrical with the axes of the caisson. The covers will be made in two parts, for portability, and a hand-operated device will be provided for raising and lowering them. The skylights will be watertight against a hose discharge under 50 pounds pressure.

Fixed ballast, composed of pig iron punchings and concrete, is to be placed in the bottom of the hull to a normal thickness of about a foot and a half. The pig iron will at all points be at least six inches from the sheathing. Two 70-ft. lengths of anchor chain will be provided for mooring the caisson when it is not in service, and chain lockers for them will be built of reinforced concrete at the ends of the 37-ft. deck.

Programme of Construction.—Only one caisson is being built at present, though it is expected that two will be provided for the operation of the canal. The first is to be completed about September, 1914, and towed to the Isthmus for test at the lower end of Miraflores Locks. The test may suggest modifications; if not, the second caisson will be constructed like the first. The patterns tor all the castings in the structure will become the property of the Isthmian Canal Commission on acceptance of the caisson, and will be delivered with it. Fabrication and erection of the first caisson are being supervised at the plant of the contractor by Mr. Lewis A. Mason, assistant engineer, who was associated with Mr. Henry Goldmark, designing engineer, in working out the design, plans, and specifications.

A LARGE CENTRAL HEATING PLANT.

About 22,000 tons of coal is the annual consumption of the central heating plant of the University of Wisconsin, at Madison, Wis. Only 10% of the total fuel is chargeable to power uses. All power exhaust, together with low-pressure live steam, is used for heating. At present 42 buildings are heated from the central plant, including practically all of the University buildings and the United States Forest Products Laboratory. The distribution system includes 2 miles of tunnel and 1 mile of conduit. The maximum pipe size is 16 in.; on this a total thickness of 3 in. of 85% magnesia insulation is used. The heating pressure is 5 to 10 lb., and no difficulty in maintaining pressure at the receiving end has been experienced.

The world's production of copper, during 4 years, as given in a recent issue of the "Engineering and Mining Journal," is as follows, quantities in metric tons:—

Country.	1910.	1911.	1912.	1913.
United States	492,712	491,634	563,260	555,990

SUMMARY OF TESTS OF BOND BETWEEN CONCRETE AND STEEL.

The usefulness of reinforced concrete as a structural material depends on the strength and permanency of the bond between the concrete and the reinforcing metal, and for this reason bond resistance has received much attention from engineers and experimenters. It is said that Thaddeus Hyatt made tests to determine the bond between concrete and iron bars as early as 1876. During the past decade numerous bond tests have been reported. These tests have been characterized by a lack of uniformity in the form of the test specimen and in the methods of conducting the tests, as well as by the wide variations in the values reported for bond resistance. In nearly all the tests thus far published values of maximum bond resistance only have been given. These test results and the discussions called forth by them have furnished the basis for a great variety of opinions as to the value of bond resistance. Many explanations of the source and nature of bond resistance have been given. Various methods have been advocated for increasing bond resistance and numerous devices have been employed for this purpose.

Present practice is fairly standardized as to the bond stresses to be used in designing, but a rational basis for the stresses used is lacking and there is a great diversity of practice in the methods of calculating these stresses. There are many phases of bond action which are not now understood. It is evident that the distribution of bond stress in reinforced concrete members under load and the nature and value of bond resistance under given conditions may well be the subject of experimental investigation.

The tests reported in a bulletin, entitled "Tests of Bond between Concrete and Steel," recently issued by the Enginering Experiment Station of the University of Illinois, were undertaken with a view to securing additional information on the nature of the bond resistance of reinforcing bars in concrete, to determining values of bond resistance for a wide range of conditions, and to studying bond action in specimens of different forms. Tests were made on pull-out specimens and on reinforced concrete beams. In both forms of specimen attention was given to obtaining accurate measurement of the slip of bar through the concrete as the loading progressed. In many of the beam tests the slip of bar at various points along its length was measured for different loads. In the discussion of bond resistance the load-slip-of-bar relation has been utilized to a considerable extent. These measurements are useful in indicating the distribution of bond stress. They are particularly significant in the beam tests. In a few of the beam tests the distribution of bond stress was studied by measuring the changes in the stress in the longitudinal reinforcement throughout the length. The values found for bond resistance and the relative bond resistance found in beam tests and pull-out specimens are also interesting features of the investigation.

The pull-out tests consisted in applying load to a short reinforcing bar embedded in a block of concrete. The concrete block was generally 8 in diam. and 8 in. long, with the bar embedded axially. In certain groups of tests these dimensions were varied. The size of bar used varied between ¼ in. and 1¼ in. The pull-out tests covered a wide range and included effect of dimensions of specimen, effect of form of bar, effect of conditions of storage, effect of age and mix, using both plain and deformed bars, effect of different methods of loading, bond resistance of concrete setting under pressure, effect of reapplied loads, comparison with the bond resistance of reinforced concrete beams, etc. The deformed bars used included most of the forms in use at the time the work was begun, but it should be noted that the tests with deformed bars were intended to bring out the action of the deformed bar as contrasted with the plain bar and not to determine the value of particular forms of bars.

A special effort was made to determine the behavior of beams subjected to high bond stresses. The beams tested were 8 by 12 in. in section with an effective depth of 10 in. The span length was generally 6 ft.; a few beams were tested with span lengths of 5 to 10 ft. All beams were tested with two symmetrical loads, generally at the one-third points of the span. With the exception of six tests, the longitudinal reinforcement consisted of a single bar of large diameter placed horizontally throughout the length of the beam. Both plain and deformed bars were used.

The tests were made in the laboratory of Applied Mechanics of the University of Illinois, and formed a part of the investigations of reinforced concrete and other structural materials which are being conducted by the Illinois Engineering Experiment Station. These tests cover the experiments which were designed with special reference to a study of bond between concrete and steel during the period of 1909-1912. This work was done by Duff. A. Abrams, Associate in Theoretical and Applied Mechanics, under the direction of A. N. Talbot, Professor in Charge of that Department. The tests covered a wide range of conditions and the results have a significant bearing on the nature of bond resistance, the action of bars of different forms under bond stress, and the behavior of beams subjected to high bond stresses. The load-slip determinations have given definite information on the nature and distribution of bond resistance. The following is a resumé of the principal observations and conclusions which have been stated and discussed in the text. Paragraphs 2 to 34 refer primarily to the results of the pull-out tests:—

(1) Bond between concrete and steel may be divided into two principal elements, adhesive resistance and sliding resistance. The source of adhesive resistance is not known, but its presence is a matter of universal experience with materials of the nature of mortar and concrete. Sliding resistance arises from inequalities of the surface of the bar and irregularities of its section and alignment together with the corresponding conformations in the concrete. The adhesive resistance must be overcome before sliding resistance comes into action. In other words, the two elements of bond resistance are not effective at the same time at a given point. Many evidences of the tests indicate that adhesive resistance is much the more important element of bond resistance.

(2) Pull-out tests with plain bars show that a considerable bond stress is developed before a measurable slip is produced. Slip of bar begins as soon as the adhesive resistance is overcome. After the adhesive resistance is overcome, a further slip without an opportunity of rest is accompanied by a rapidly increasing bond stress until a maximum bond resistance is reached at a definite amount of slip.

(3) The true relation of slip of bar to bond stress can best be studied by considering the action of a bar over a very short section of the embedded length. The difficulties arising from secondary stresses made it impracticable to conduct tests on bars embedded very short lengths. The desired results were obtained by varying the forms of the specimens in such a way that the effect of different combinations of dimensions could be studied.

(4) Pull-out tests with plain bars of the same size embedded different lengths furnish data which suggest

the values of bond resistance over a very short length of embedment, or indicate values of bond resistance which are independent of the length of embedment. Tests with bars of different size which were embedded a distance proportional to their diameters give the true relation when the effect of size of bar is eliminated. Two series of tests of this kind on plain round bars of ordinary mill surface gave almost identical values for bond resistance after eliminating the effect of length of embedment and size of bar, and we may consider that these values represent the stresses which were developed in turn over each unit of area of the embedded bar as it was withdrawn by a load applied by the method used in these tests. These tests showed that for concrete of the kind used (a 1:2:4 mix, stored in damp sand and tested at the age of about 60 days) the first measurable slip of bar came at a bond stress of about 260 lbs. per sq. in., and that the maximum bond resistance reached an average value of 440 lbs. per sq. in. If we conclude that adhesive resistance was overcome at the first measurable slip, it will be seen that the adhesive resistance was about 60 per cent. of the maximum bond resistance. This ratio did not vary much for a wide range of mixes, ages, size of bar, condition of storage, etc.

(5) Sliding resistance reached its maximum value for plain bars of ordinary mill surface at a slip of about 0.01 in. The constancy in the amount of slip corresponding to the maximum bond resistance for a wide range of mixes, ages, sizes of bar, conditions of storages, etc., is a noteworthy feature of the tests. With further slip the sliding resistance decreased slowly at first, then more rapidly, until with a slip of 0.1 in. the bond resistance was about one-half its maximum value.

(6) Pull-out tests with plain round bars show end slip to begin at an average bond stress equal to about one-sixth the compressive strength of 6-in. cubes from the same concrete; the maximum bond resistance is equal to about one-fourth the compressive strength of 6-in. cubes. These values were about the same for a wide range of mixes, ages and conditions of storage. In terms of the compressive strength of 8 by 16-in. concrete cylinders these values would be about 13 per cent. for first end slip and 19 per cent. for the maximum bond resistance.

(7) The tests indicate that bond stress is not uniformly distributed along a bar embedded any considerable length and having the load applied at one end. Slip of bar begins first at the point where the bar enters the concrete, and the bond stress must be greater here than elsewhere until a sufficient slip has occurred to develop the maximum bond resistance at this point. Slip of bar begins last at the free end of the bar. After slip becomes general, there is an approximate equality of bond stress throughout the embedded length.

(8) Small bars gave a bond resistance somewhat higher than the large bars during the early stages of the test. This was probably on account of greater irregularity of section and alignment of the smaller bars. The maximum bond resistance was not materially different for bars of different diameters.

(9) Computations based on the elastic properties of the materials indicate that in the pull-out tests the tensile deformation in the bar had a much greater effect on the amount of bond stress which permitted a given slip of bar than had the compressive deformation in the concrete block in which the bar was embedded.

(10) Rusted bars gave bond resistances about 15 per cent. higher than similar bars with ordinary mill surface.

(11) The tests with flat bars showed wide variations of bond resistance and were not conclusive. Square bars gave values of unit-stress about 75 per cent. of those obtained with plain round bars.

(12) T-bars gave lower unit bond resistance than plain round bars, but gave about double the bond resistance per unit of length that was found for the plain round bars of the same sectional area.

(13) With polished bars the bond resistance is due almost entirely to adhesion between the concrete and steel. Numerous tests with polished bars embedded in 1:2:4 concrete and tested at 60 days indicated a maximum bond resistance of about 160 lbs. per sq. in., or about 60 per cent. of the bond resistance of bars of ordinary surface at small amounts of slip. This value agrees closely with tests reported elsewhere, and apparently represents the value of the tangential adhesion between any clean steel and concrete of this quality. The sliding resistance of polished bars was very low.

(14) Tests with polished bars with wedging and non-wedging tapers showed that adhesion was broken for both types of bar at about the same bond stress as in the polished bars of uniform section.

(15) The tests with polished bars with wedging taper showed that after the adhesion was broken a considerable movement of the bar (as much as ¼ in. with the smallest tapers) was required before the bond resistance again reached the amount which was at first carried by the adhesive resistance. The amount of movement necessary to restore the bond stress to the value of the original adhesive resistance was inversely proportional to the amount of taper. This indicates that a definite normal compression must be developed in the surrounding concrete before a longitudinal component equivalent to the original tangential adhesion is produced.

(16) It was noted in the tests with plain bars that sliding resistance was due to inequalities of the surface of the bar and to irregularities of its section and alignment. The projections on a deformed bar give an exaggerated condition of inequality of surface or irregularity of section. Adhesive resistance must be destroyed and the usual sliding resistance largely overcome and the concrete ahead of the projections must undergo an appreciable compressive deformation before the projections on a deformed bar become effective in taking bond stress. The tests indicate that the projections do not materially assist in resisting a force tending to withdraw the bar until a slip has occurred approximating that corresponding to the maximum sliding resistance of plain bars. As slip continues a larger and larger portion of the bond stress is taken by direct bearing of the projections on the concrete ahead.

(17) In determining the comparative merits of deformed bars, the bar which longest resists beginning of slip should be rated highest, other considerations being equal. The bond stresses developed at an end slip of 0.001 in. furnished the principal basis of comparison for the different types of deformed bars. At an end slip of 0.001 in. 12 sets of deformed bars of ¾-in. and larger sizes embedded 8 in. in 1:2:4 concrete, tested at about 2 months, developed an average bond resistance of 318 lbs. per sq. in., 4 per cent. higher than the corresponding value for plain bars. At this stage of the test, two sets of deformed bars gave practically the same bond resistance, five sets gave lower values, and five sets higher values than the plain rounds. At an end slip of 0.01 in., corresponding to the maximum bond resistance of plain bars, the average bond resistance of the 12 sets of deformed bars was 445 lbs. per sq. in., 10 per cent. higher than plain rounds. At this stage of the test two sets gave about the same values, two sets gave lower values, and eight sets gave higher values than the plain bars. The hooping used in these specimens had a marked effect in

increasing the bond resistance, even at small amounts of slip.

(18) The concrete cylinders of the pull-out specimens with deformed bars were reinforced against bursting or splitting, because it was desired to study the load-slip relation through a wide range of values. The bond stresses corresponding to an end slip of 0.1 in. are the highest stresses reported for the deformed bars. In only a few tests was the maximum bond resistance reached at an end slip less than 0.1 in. It should be recognized that, in general, the bond stresses reported for deformed bars at end slip of 0.05 and 0.1 in., could not have been developed with bars embedded in unreinforced blocks. These high values of bond resistance must not be considered as available under the usual conditions of bond action in reinforced concrete members. In the tests in which the blocks were not reinforced, evidence of splitting of the blocks was found at end slips of 0.02 to 0.05 in.

(19) The normal components of the bearing stresses developed by the projections on a deformed bar may produce very destructive bursting stresses in the surrounding concrete. The bearing stress between the projections and the concrete in the tests with certain types of commercial deformed bars was computed to be from 5,800 to 14,000 lbs. per sq. in. at the highest bond stresses considered in these tests. For bars having projections of different heights and spacing, the bearing stresses on the projections at the highest bond stresses considered were inversely proportional to the bond stress which had been developed by the bar at an end slip of 0.01 in., the slip at which the projections were beginning to be effective. These considerations show that the ratio of the area of the projections measured at right angles to the bar to the superficial area of the bar in the same length is the proper criterion for judging of the effective bond resistance of a deformed bar. In some forms of bar the bearing stresses must have been much higher than the values given above. The large slip and the high bearing stresses developed in the later stages of the tests show the absurdity of seriously considering the extremely high values that are usually reported to be the true bond resistance of many types of deformed bars.

(20) Round bars with standard V-shaped threads gave much higher bond resistance at low slips than the commercial deformed bars. The average bond resistance at an end slip of 0.001 in. was 612 lbs. per sq. in. The maximum bond resistance was 745 lbs. per sq. in. These were the only deformed bar tests in which failure came by shearing the surrounding concrete.

(21) In a deformed bar of good design the projections should present bearing faces as nearly as possible at right angles to the axis of the bar. The areas of the projections should be such as to preserve the proper ratio between the bearing stress against the concrete ahead of the projections and the shearing stress over the surrounding envelope of concrete. Failure by shearing of the concrete should be avoided. The tests indicate that the areas of the projections measured at right angles to the axis of the bar should not be less than, say, 20 per cent. of the superficial area of the bar. A closer spacing of the projections than is used in commercial deformed bars would be of advantage. Advocates of the deformed bar would do well to recognize the fact that in a deformed bar which may be expected to develop a high bond resistance, a certain amount of metal must be used in the projections which probably will not be available for taking tensile stress.

(22) The 1-in. twisted square bars gave a bond resistance per unit of surface at an end slip of 0.001 in., only 88 per cent. of that for the plain rounds. Following an end slip of about 0.01 in., these bars showed a decided decrease in bond resistance, and a slip of 5 to 10 times this amount was required to cause the bond resistance to regain its first maximum value. After this, the bond resistance gradually rose as the bar was withdrawn. Some of the bars were withdrawn 2 or 3 in. before the highest resistance was reached. The apparent bond stresses at these slips were very high; but, of course, such stresses and slips could not be developed in a structure and could not have been developed in the tests had the blocks not been reinforced against bursting. Such values are entirely meaningless under any rational interpretation of the tests.

(23) The load-slip curves for twisted square bars are similar to those for polished bars with wedging taper. The twisted bar is essentially a combination of the wedging and non-wedging taper. As the bar is drawn through the concrete the wedging tapers are drawn more firmly against the concrete ahead, while at the same time the non-wedging tapers are separated from the concrete with which they were originally in contact. The drop in the load-slip curves after an end slip of about 0.01 in. shows that the separation of about one-half of the surface of the bar from its original contact and the continued sliding of the flatter portions of the bar, until a large slip has occurred, have a greater influence in reducing the average bond resistance than the increased bearing of the wedging tapers has in raising the bond resistance. The results found with the twisted square bar do not justify its present widespread popularity as a reinforcing material.

(24) The tests with plain round bars anchored by means of nuts and washers and with washers only showed that the entire bar must slip an appreciable amount before these forms of anchorage come into action. Anchorages of the dimensions used in these tests did not become effective until the bar had slipped an amount corresponding to the maximum bond resistance of plain bars. With further movement the apparent bond resistance was high, but was accompanied by excessive bearing stresses on the concrete.

(25) The load-slip relation for bars anchored by means of hooks and bends was not determined. The high resistance given in these tests was probably a result of the bearing stresses developed in the concrete ahead of the bends.

(26) Tests on specimens stored under different conditions indicate that concrete stored in damp sand may be expected to give about the same bond resistance and compressive resistance as that stored in water. Water-stored specimens gave values of maximum bond resistance higher in each instance than the air-stored specimens; the increase for water storage ranged from 10 to 45 per cent. The difference seemed to increase with age. The presence of water not only did not injure the bond for ages up to three years, but it was an important factor in producing conditions which resulted in high bond resistances. However, it was found that specimens tested with the concrete in a saturated condition gave lower values for bond than those which had been allowed to dry out before testing. The bars in specimens which had been immersed in water as long as three and one-half years showed no signs of rust or other deterioration.

(27) Specimens made out-doors in freezing weather, where they probably froze and thawed several times during the period of setting and hardening, were almost devoid of bond strength.

(To be continued.)

Coast to Coast

Toronto, Ont.—The Toronto Hydro-Electric Commission sustained a deficit of $1,600 for the past month.

Calgary, Alta.—A report has been presented by the city commissioners to the Calgary city council showing the surplus for 1913 for the Calgary Electric Railway to be $177,000.

Winnipeg, Man.—Another report, submitted recently by J. G. Glassco, superintendent of the Winnipeg light and power department, indicates a surplus amounting to $81,897.45 for the year ending April 30, 1914.

Winnipeg, Man.—In the und rakings which Winnipeg has planned for 1914, there will be involved an expenditure of $10,000,000. In addition to this, the Greater Winnipeg Water District board will spend $2,000,000.

Montreal, Que.—It is reported from headquarters at Montreal that the G.T.R. Railway Company is now carrying passengers over an all-rail route from Fort William, Ont., to Prince George, B.C., a distance of 1,729 miles.

Port Arthur, Ont.—A recent statement made by the public utilities commissioner of Port Arthur shows that in Port Arthur there are now 2,224 street lights. Addition to the city's street lighting system is being made continuously.

London, Ont.—A report from London announces that another gas gusher has been struck close to the great Fairbanks gusher recently struck; and that the new well is flowing at a rate of 500,000 feet per day. The drill had only reached the depth of 1,800 feet.

Maple Creek, Sask.—The Coste-McAuley syndicate has filed for the gas and oil rights on 80,000 acres of land situated from 60 to 65 miles north of Maple Creek. It is in this area that the company will bore for the gas, with which it hopes to supply the cities of Saskatchewan.

Ottawa, Ont.—A report from Ottawa advises that construction work on the National Transcontinental Railway has reached a stage of practical completion. All that remains to be done is some additional ballasting and filling and the erecting of a few stations, which are to be completed by October 1.

Saskatoon, Sask.—A new system of electric lights is being tested at Saskatoon. High power nitrogen filled lamps are being suspended from the tops of trolley poles; and, should these prove more efficient and more economical, it is intended to place the lamps on most of the main thoroughfares of the city.

Regina, Sask.—The city council of Regina has approved the programme of this year's civic construction work recently recommended by the city commissioners, and has passed the by-laws necessary to legalize the flotation of treasury bills to the extent of $1,250,000, of which $500,000 is to be issued immediately.

Hamilton, Ont.—Hydro-Electric street lighting was inaugurated at Hamilton on July 1. It is estimated by the city works department that lighting under hydro management will cost $98,000 per year, or $49,000 per half-year during the time that the lights wou'd be mostly in service. The department has expropriated $58,000 for the half-yearly expense.

Fort William, Ont.—Construction work has started on the big turning basin in the Fort William harbor, 5 miles up from the mouth of the Kaministiquia River. Two clam shell dredges are at present engaged in taking out loose earth; and in about two weeks' time the large dipper dredges of the Great Lakes Dredging Co., will also be employed. The construction of the turning basin is a large undertaking. Over 35 acres of solid earth will have to be removed before the basin is finished; and it will take some 2 years to complete the work.

Calgary, Alta.—An announcement was made last week by City Engineer Craig of Calgary, to the effect that actual construction work on the new bridges proposed at Calgary will commence within a month or 6 weeks. About 6 weeks ago, the by-laws providing for the bridges were passed; and since that date, the engineer's department has been employed on the necessary surveys. Construction will begin at the Louise Street bridge, since more time will be needed to complete the surveys for the Centre Street structure.

St. John, N.B.—Recently a shipment of steel for the new bridge being constructed by the Dominion Bridge Company over the reversible falls, is reported as having arrived in St. John; and the preliminary work of placing the first piece in position is proceeding under the supervision of Engineer Springer. The large granite blocks upon which the new pier will be erected have been placed on the bed of concrete; and this part of the contract will be completed very shortly. The steel work will then be advanced rapidly.

Victoria, B.C.—A recent announcement from Victoria states that satisfactory progress is being made with the construction of the concrete tank which will be a part of the northwest sewer system, and into which sewerage will be drained from the area lying north of the Burnside Road and thence pumped into the system which will carry the sewerage across the Victoria Arm and across to the outlet at Macaulay Point. The tank is being made especially strong to support the roadway beneath which it is being constructed.

Ottawa, Ont.—The construction of both the bridge across the Rideau Canal to Ottawa East from Pretoria Avenue and the bridge across the Rideau River at Billings' Bridge, is being delayed. In the former instance, the officials of the Ottawa Electric Railway will not consent to run cars over a low level lift bridge, the plans for which are now being prepared by the city engineer at a cost of $120,000; while, in the latter, the county has refused to bear half the cost of construction, and an agreement has yet to be reached as to the division of cost between the city and county.

Vancouver, B.C.—Officials of the engineering department of the Canadian Northern Pacific Railway have announced that track-laying will be resumed on that road from Kamloops to a point 28 miles west where the right-of-way crosses the Thompson River. The track construction will be delayed at the Thompson River until a bridge has been completed across it, when another section of the road will probably be built and the uncompleted portion of the work between Cisco and Kamloops somewhat diminished. The steel for the bridge across the Thompson has already been fabricated, and as soon as the rails reach the river, work will be commenced and rushed ahead on the erection of this structure.

Medicine Hat, Alta.—In the course of a few weeks Medicine Hat will have a most up-to-date and modern telephone system, differentiating from the present one in that it will be large enough to accommodate several times its capacity. For some time contractors have been at work on the installation, a new building, for this purpose only, being part of the plans. Contractors are engaged in the construction of the building and also on 125,000 feet of underground conduits; and it is expected that September will see the city served with the latest automatic telephone system. Some 2,000 of the new phones have already arrived for installation, there being room for 10,000 if required in the near future. Every part of the city will have adequate connection; and no poles will be used except in the lanes.

Winnipeg, Man.—An expenditure for the month of July amounting to $168,470, has been passed by the administration board of the Greater Winnipeg Water District. Items of expenditure have been placed as follows: salaries and wages, $13,000; supplies and equipment, $3,000; railway ties contract, $32,300; steel rails, $59,000; steel splice bars, $3,310; railway construction, $54,000; residences for divisional engineers, $2,150; switches, frogs, and track accessories, $1,710. It is estimated that an expenditure of $500,000 will be passed for the month of August, though the total outlay is placed at $522,580.29 Plans for the aqueduct line beyond range 7 will be completed and work on them is now being advanced rapidly. This will conclude the determination of the exact line to be followed east as far as the Whitemouth River, which will be over half the way to Indian Bay at Shoal Lake. The route will not go in a straight line but will have numerous angles and curves as has the sanctioned plan from the Transcona reservoir site to the end of range 7, 24 miles east of the city.

PERSONAL.

CAMPBELL M. HUNTER A.M.Inst.C.E., F.R.G.S., of the firm of Thompson and Hunter, geologists specializing in petroleum investigations, is investigating oil possibilities in the Province of Alberta.

LUCIUS E. ALLEN, A. B., C.E., consulting engineer of Belleville, Ont., sails for Europe on July 11th, for the purpose of making an investigation and study of Continental methods and materials used in good roads and pavements.

H. T. CROSBIE, town engineer of Yorkton, Sask., read a paper at the recent municipal convention in Moose Jaw, entitled "Engineering Advice to Villages About to Enter the Town Estate." Mr. Crosbie dealt with the subjects of water supply, sewerage system, electric light, sidewalks and boulevards and town planning.

A. N. JOHNSON, M.Am.Soc.C.E., has resigned as State Highway Engineer of Illinois to accept a position with the Bureau of Municipal Research, New York City. Mr. Johnson graduated in civil engineering at the Lawrence Scientific School, Harvard University, in 1894. He was an instructor at Harvard in 1895 and 1896, and then for two years was Assistant Engineer of the Massachusetts Highway Commission. From 1898 to 1905, Mr. Johnson was State Highway Engineer of Maryland. For a year he was Chief Engineer of the United States Office of Public Roads, Washington, D.C., and since 1906 has been State Highway Engineer of Illinois.

OBITUARY.

The death occurred in Toronto recently of Chas. R. Rundle, for many years prominently engaged in contracting work.

CANADIAN SOCIETY OF CIVIL ENGINEERS.

The following engineers were elected to membership in the Canadian Society of Civil Engineers at a meeting of the Council in June:—

Duncan McMillan, district engineer's office, Canadian Northern Railway, Victoria, B.C.; Robt. H. Parsons, superintendent of municipal electric light, power and pumping plant, Edmonton, Alta.; A. K. Robertson, chief engineer, McAlpine, Robertson Co., Vancouver, B.C.; C. B. Thorne, chief engineer, Riordon Pulp and Paper Co., and manager Hawkesbury branch.

At the same election the following were transferred from the class of associate member to that of member:—

Geo. E. Bell, western manager, Dominion Bridge Co., Limited, Winnipeg; Wm. M. Edwards, consulting engineer and professor of municipal engineering, University of Alberta; E. A. James, consulting engineer, Toronto.

At a previous meeting, April, the newly-elected members were G. C. Clarke, chief engineer, Fraser, Bruce and Co., New York City; Ernest Davis, hydrographer, Water Rights, Department of Lands, British Columbia Government, Victoria, B.C.; Geo. R. Heckle, managing director, Walker and Co., Ambursen Hydraulic Construction Co. and Reinforced Concrete Pile Co., Montreal; H. E. M. Kensit, city commissioner, Prince Albert, Sask.

The transfers from class of associate member to that of members consisted of C. B. Brown, prin. asst. engineer, eastern lines, Canadian Pacific Railway, Montreal; R. J. Gibb, sewer and waterworks engineer, Edmonton, Alta.; J. H. Holliday, district engineer, Transcontinental Railway, L'Islet, P.Q.; W. Hollingworth, deputy city engineer, Hamilton; Chas. M. Morssen, president and consulting engineer, Atlas Construction Co., Montreal; F. H. Peters, commissioner of Irrigation and chief engineer, Department of the Interior, Irrigation Office, Calgary; C. W. P. Ramsay, engineer of construction, Canadian Pacific Railway, Montreal; H. P. Rust, prin. asst. engineer, Viele, Blackwell and Buck, consulting engineers, New York City.

At a March meeting Messrs. E. A. Cleveland, of Cleveland and Cameron, Vancouver, B.C., and Fred C. Kunz, consulting engineer, Philadelphia, Pa., were elected members.

COMING MEETINGS.

UNION OF CANADIAN MUNICIPALITIES.—Annual Convention to be held in Sherbrooke, Que., August 3rd, 4th and 5th, 1914. Hon. Secretary, W. D. Lighthall, Westmount, Que. Assistant-Secretary, G. S. Wilson, 402 Coristine Building, Montreal.

WESTERN CANADA IRRIGATION ASSOCIATION.—Eighth Annual Meeting to be held at Penticton, B.C., on August 17, 18 and 19. Secretary, Norman S. Rankin, P.O. Box 1317, Calgary, Alta.

AMERICAN PEAT SOCIETY.—Eight Annual Meeting will be held in Duluth, Minn., on August 20th, 21st and 22nd, 1914. Secretary-Treasurer, Julius Bordollo, 17 Battery Place, New York, N.Y.

CANADIAN FORESTRY ASSOCIATION.—Annual Convention to be held in Halifax, N.S., September 1st to 4th, 1914. Secretary, James Lawler, Journal Building, Ottawa.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown, Indianapolis, Ind., Secretary.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—11th Annual Convention; 5th American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau St., New York, N.Y.

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

WATER SUPPLY FOR CITIES AND TOWNS

AN OUTLINE OF THE PROBLEMS CONNECTED WITH WATERWORKS CONSTRUCTION AND VALUABLE HINTS AS TO THEIR SOLUTION.

By BERNARD E. T. ELLIS, C.E.,
Oborn and Ellis, Consulting Civil Engineers, Toronto and Hamilton.

AMONG the problems which attend the establishment of a water supply for a community the first, and often the most important, is its source, particularly in the case of towns and cities that are not so favored by nature as to be able to secure an ample and safe supply from adjacent lakes or rivers, but have to resort to wells, collecting grounds, etc.

The first step the engineer is called upon to decide is the selection of a suitable watershed and site for the proposed works, including the dam and reservoir. Since we depend solely upon rain for our supply of water, after these selections have been made it is necessary to find out exactly how much rain actually falls on the contemplated watershed drained by the stream which is to feed the impounding dam. To do this, rain gauges must be fixed on the watershed and from these an estimate made of the rainfall. After comparing them with any existing rain gauge records which have been kept over a number of years in close proximity to the proposed site, the engineer should be able to strike a fair average of the rainfall. The longer the period taken, the better and more satisfactory average results will be obtained. From these records an estimate of the quantity available for storage can be calculated allowing, of course, for losses on the average rainfall due to evaporation, percolation, and absorption, which allowance can only be estimated from previous experience on similar gathering grounds, and practical experience of the engineer. After computing the available supply for storage, the available yield in gallons per day is arrived at. An excellent check on the amount—a really better method to obtain the actual supply—lies in the use of stream gauges. They should be placed, wherever possible, in the feed channel supplying the impounding dam, and, when fitted with an automatic recorder, render the operation a simple and accurate test for the actual yield.

In most cases part of this supply will have to be liberated to supply rivers, etc., for compensation water (usually fixed at ⅓) and this must be deducted before deciding upon the average available daily supply.

The size of the impounding dam should be next settled. The late Thomas Hawkesley's well-known formula, which gives the number of days' storage required, taking for safety the mean annual rainfall for the three driest years, is recommended. Then, after levelling and contouring the site, the engineer can determine the height and dimensions of the dam to impound the required number of gallons. The actual construction of the dam will depend largely on local conditions, especially as to material of which it will be constructed, but the ground should be carefully examined, trial holes sunk, plans prepared showing all levels, etc., and geological formation before the actual locality and line of the proposed structure can be definitely settled.

In this paper it is not proposed to enter into the actual design of the dam and the many calculations required as the subject cannot be treated properly in the limited space, but on its stability the engineer is very often confronted with serious difficulties, and the most important points for his careful consideration will be the foundations, stability of walls, and a properly designed overflow to take off the flood water. A dam may fail by overturning, crushing, sliding, shearing, or by rupture due to tension, and to safely guard against all these causes of failure the section of the wall must be such that the lines of resultant pressure, both when the dam is full or empty, must fall within the middle third of any horizontal joint, in order that the maximum pressure on the foundation will never exceed certain fixed limits of safety. The friction between any horizontal layers, into which the dam may be divided, and also between the main walls and their foundation must be sufficient to prevent any sliding taking place. The ideal and safe cross-section of wall is the one which is constructed of sufficient dimensions to safely withstand all these pressures. After they have been properly calculated, the method adopted by the author in calculating the required sections for the design of the walls is by mathematics, and on completing same, he re-checks graphically, so that the line of pressure must fall within the middle third.

A considerable economy can be made if the site of the valley across which it is proposed to construct the dam is narrow, by making the dam curved and reducing the section, but the author does not recommend, from a stability standpoint, a greater radius than 300 feet being actually constructed. One of the main points, frequently overlooked, and upon which the stability of the dam and safety of the system so largely depend, is the provision of a sufficiently large overflow to amply take care of all likely flood water, as without such the works may be seriously damaged and unnecessary trouble and expense incurred which, at little first cost, could easily be provided for. From the author's own observations and experience he advises a 3 to 4-ft. length of weir to every 100 acres of watershed, fixing the maximum height, in all cases, to which the water is allowed to rise above the crest of the weir at 1 ft. 6 in. to 2 ft.

Purification of Water.—The methods adopted to purify water for domestic consumption are æration, subsidence, precipitation, straining, and filtration.

Aeration or oxidation is sometimes adopted to get rid of certain impurities in the water, such as dissolved sulphuretted hydrogen, exposure to the atmosphere in thin sheets or sprays, has the effect of also softening hard waters, by releasing the loosely combined carbonic acid and precipitating the carbonate of lime. This process is very rarely adopted, the chief objection being vegetable growth, but the action of oxygen in the atmosphere on water in rivers or channels, certainly gradually oxidizes the organic impurities, and in time renders them innocuous and the water more palatable.

Subsidence.—This procedure generally takes effect in storage reservoirs and depends solely on the specific gravity or fineness of the matter in suspension being deposited.

Precipitation.—Water, especially when obtained from bore holes (see later) is often hard and sometimes it is of such a nature that after standing it becomes slightly discolored, due generally to deposit of iron. Now that the question of an ample and suitable water supply plays such an important part in our present-day manufacturing industries, it is essential from this standpoint, as well as from the domestic one, that the supply should be softened and purified to be beneficial for all concerned. Without entering into any details of any individual water-softening process, the general outline of the cheapest and universal methods and materials adopted in most cases, may be briefly given. Caustic lime is one of the most economical precipitants and the *modus operandi* is to add a certain quantity of lime to a measured volume of water in a tank or vessel, to form lime water. The clear fluid is then drawn off by a float pipe into another tank and mixed with the water to be softened. The result is the formation of carbonate of lime, which is precipitated along with the carbonates already in solution. In some plants it is an advantage to discharge "purified" generated carbonic acid gas into the main delivery pipe from the softening tanks. If, at the expiration of the time allowed for settling, there are any particles of lime left in the water, whether visible or otherwise, they unite with the carbonic acid gas and form a soluble carbonate which is taken up by the water and does not make any appreciable effect on the hardness of the softened water.

Straining and Filtration.—Straining water through fine screens of brass or copper set in wooden frames has proved satisfactory, and in some cases the author recommends their use in reservoirs, as, when properly supervised and cleansed by a jet of water, they arrest and intercept large quantities of floating suspended matter. Gravity or sand filters have been adopted in the past, owing to the general opinion that the slow gravitation of water through layers of sand, polarite, spongy iron and other media removes the suspended matter and purifies the water better than any other system, and the author under this head intends to illustrate the many advantages obtained by the installation of suitable mechanical filters in preference to the gravity type, especially in cases of large cities. A mechanical plant does not require the extensive area of a gravity bed; consequently there is a great saving in purchasing suitable land. A million gallons per day can be treated on gravity filters on an area of approximately 2,000 sq. yd., whereas the same quantity could be mechanically treated on a space of 60 to 70 sq. yd. This is a considerable saving, especially in works of any magnitude, such as required for large cities. Again, whatever a filter bed extracts it retains and the better the filtering material the sooner it becomes clogged and requires cleansing. Therefore, ease and rapidity of cleansing should play an important point before the engineer decides on the class of filters he should adopt.

The gravity beds, when downward filtration is adopted, requires the constant attention and removal of the top layer of sand, containing the perceptible suspended matters. If the sand is costly and has to be washed, an expensive sand-washing machine is centrally installed which necessitates a cleansing gang continually employed to wash the beds in rotation. On large filtration areas this is a very costly maintenance item.

The cleansing of the mechanical filters is simply accomplished by upward or reversed flow of water, aided by the complete agitation of the filtering media by revolving arms, and the greater the amount of agitation within the bed of filtering material, the more rapid and effectual is the cleansing. The actual time taken in cleansing one of these filters varies from 3 to 5 minutes. For several obvious reasons the filtered water should only be used for cleansing purposes, as the impurites of unfiltered or raw water would collect at the bottom for the time being, and would have to be removed before considered fit for use.

A mechanical filtration plant capable of dealing with 5,000,000 gal. per day should take approximately 1½ hours to clean, using about one gallon to every 300 gallons of filtered water. Cleansing in mechanical filters for successful results should be accomplished every two days, which goes to prove that the filter is doing efficiently that which it is intended for. Another big advantage of mechanical filtration over sand filtration lies in the compactness of the plant, which facilitates better and cheaper maintenance, also a more complete and concentrated control over the feed pipes to the service reservoir.

It has been found and adopted in practice that the introduction of aluminum sulphate is very beneficial from two important aspects: (1) It acts as a coagulant causing minute particles to unite and become one large particle; (2) being converted into aluminium hydrate, a gelatinous insoluble mineral matter is formed on the filter bed, being impervious to micro-organisms, and having the power to extract coloring matter, adds materially to the filtering media, as the coloring is often due to dissolved vegetable matter and cannot be arrested in the finest filtering material unless in conjunction with precipitated aluminum-hydrate. This would not be feasible or workable in cleansing operations for gravitation or sand-bed filters.

There are several different mechanical filtration plants from Great Britain and the United States well represented on the Canadian markets, and the author advises any local authority who contemplates the installation of mechanical filters to place the scheme in the hands of an expert water engineer who can get out the necessary data and specifications for such an installation, and is in a better position to judge technically the merits and cost of such installations represented by the different companies who are invited to tender.

Service Reservoirs.—Service reservoirs are supplied direct from the impounding reservoir, or where filtration is necessary from the filter beds. Their use in water supply systems is to regulate the variation in daily consumption, and during accidents or break-downs to supply sufficient storage to meet the supply requirements. Their size, or storage capacity, depends on local conditions of the scheme, such as the distance from source of supply, single or duplicated feed pipes (especially important in case of a pumped supply). As a general rule, 2 to 3 days' storage capacity should meet all emergencies.

The site of reservoir should be at a sufficient elevation to give the required pressure on the mains and as close

as convenient to the district to be supplied. The actual construction of it depends on local conditions, both from a material and design standpoint. The author favors concrete construction with puddle clay backing and entirely covered in with arch construction, well ventilated and having at least 2 to 3 feet of earth filling above the roof to keep the water as cool as possible. The tank should be subdivided into at least two portions for cleansing purposes. The reservoir should be provided with ample arrangements for inspection and cleansing and the inlet, outlet and overflow pipes placed in the best position the local demands and requirements call for. After passing through the reservoir, the water should flow through a meter house constructed at the head of the main distribution pipes to the city and correct records kept by means of a meter recording automatically the daily consumption and delivery of water into the city at all hours of the day.

Wells.—A difficulty often arises in finding near a large town a suitable gathering ground. In such cases the engineer directs his attention to a source of supply from wells, if possible. In selecting the site and position of bore-holes, the engineer, if not conversant in practical geology, should engage the services of an expert geologist before finally selecting and commencing on a scheme. The preliminaries mentioned previously as regards rainfall calculations should be carefully and accurately taken and records kept. The construction for the bore-holes present very few engineering difficulties and is accomplished by the several drilling and deep-well boring outfits. The author has had experience in both the "free-falling tool" and the "slack rope" method, and can recommend both as worth consideration, the local conditions governing the final selection. Perhaps details the writer has at hand of the actual construction of a well and bore-hole for a large city in Great Britain will be of interest, as it gives an excellent idea of the usual procedure. The well was first constructed 8 feet inside diameter, 24 feet deep with 14 inches of best hard blue brick lining filled in behind with cement grout. The floor consisted of 18 inches of cement concrete. A circular cast iron standpipe, 29-in. bore 9 feet long with flanged end to which was fixed during boring operations two similar lengths bolted on with special short valve casting to facilitate the testing of the yield of the bore-hole at certain stages. The bore-hole for approximately 110 feet was 28 in. in diam. and lined with 25-in. bore steel tubes, the annular space being filled in with concrete and so lined to prevent the contamination by impure surface water. The boring was continued from the lining tubes with a 14-in. circular hole to the rock strata, a distance of approximately 600 feet, when the water-bearing strata was penetrated sufficiently for the following tests of the probable yield of water to be made. The previously mentioned valve at the top of the stand-pipe was closed and the brick well emptied of all water, carefully measured, and the water admitted by opening the valve on the standpipe. The time taken in filling the well was accurately measured as the water rose to the surface of the ground. This level was then taken as the rest level and surface pumping was continued to lower it. From these results the actual yield of water flowing into the well per hour was ascertained by hydraulic formula. The head on the valve being known, the yield in gallons per 24 hours could readily be calculated. In this particular case the above was considered sufficient to warrant the installation of the pumping and machinery plant. The actual yield from the bore-hole was almost 750,000 gal. per day.

Distribution.—It is always the aim of the engineer to install a gravitation system, not only from an initial outlay standpoint but also owing to maintenance cost. Providing the selected site for supply reservoir is situated at such an elevation as to give the minimum pressure for supply purposes, both for domestic and trade use, this can be adopted; but should it not be available, pumping machinery will have to be installed. It requires careful thought in designing a complete and suitable pumping plant of sufficient capacity to supply the maximum demand at all times and at the most economical cost, having in mind local conditions and requirements. The author has visited waterworks plant where considerable saving has been accomplished by means of syphons. A great deal of costly excavation can be saved by adopting syphons providing for practical working purposes the difference of elevation between the summit and level of water from which the supply is to be drawn does not exceed 25 feet (34 feet theoretically).

The syphon should be provided with an air pump attachment on the longer leg, and in all cases for proper and satisfactory results, sluice valves and cocks must be placed in proper positions.

Water is conveyed generally under pressure from the source of supply to the consumer and pipes are mostly used. They have been constructed in cast iron, wrought iron, steel, wood, and reinforced concrete. Whichever material is adopted the pipes should be properly calculated for diameter and thickness to give the delivery and strength required. The thickness of metal in pipes requires careful consideration and good judgment on the part of the engineer, as after calculations have been made, sufficient allowance must be made for imperfect workmanship, shocks in handling and laying, weight of earth and traffic, also the great strain to which pipes are subjected on the sudden closing and opening of valves. It is the author's practice in calculating the required thickness from formula to withstand the water pressure, to allow a high factor of safety to take care of the above-mentioned additional strains, and in no case using less than ⅝-in. in thickness whatever the calculations work out at.

A margin on the diameter should be allowed for possible corrosion. In specifying cast iron pipes, they should be cast vertically and dipped when hot into a hot bath of a solution consisting of asphalt, resin, pitch and linseed oil. A percentage of test bars 3 in. x 2 in. x 3 ft. 6 in. should be cast at the same time and tested for tensile strength and deflection. The following tests by Sir Frederick Bramwell, strikingly illustrate the increase in strength and density obtained by re-melting the metal before finally running:

Samples.	Tensile Strength per sq. in.
1st sample	7.5 tons
2nd sample, after 2 hours longer fusion	8.3 tons
3rd sample, after 1¾ hours longer fusion	10.8 tons
4th sample, re-melted with fresh pigs	11.0 tons
5th sample, after 4 hours longer fusion	18.5 tons
Maximum of 5th sample	19.6 tons

The strength at the spigot end is increased by casting an additional 6 in. or more beyond the finished length of the pipe, this having the effect of compressing the metal and permitting ash and air bubbles to rise into same, which extra length is finally cut off in the lathe and the pipe finished off to required dimensions. All pipes should be tested by oil or water (preferably the former) in a testing machine up to at least twice the pressure they will afterwards be subjected to before leaving the foundry.

Wrought iron and steel pipes have of late found favor amongst engineers, especially for large mains, because of their greater tensile strength and lightness over cast iron giving them many advantages in cases where weight and

strength are the main objects, but owing to the thickness and rapid corrosion of wrought iron and steel pipes the author thinks cast iron will be hard to displace for general use, as they are cheaper and more easily made Their greater thickness allows for corrosion, which overcomes to a certain extent one of the main difficulties in the upkeep and maintenance of water mains.

Pipe Jointing.—Cost and local ground conditions play an important point in settling the type of joint to be used, but the local custom of selecting spigot and socket joints in all horizontal positions (except for very high pressure pipes) and flanged joints where pipes are fixed vertically are so universally adopted that any description is not necessary. The author has used with success the turn and bored joint and can safely recommend same in bad situations, providing the pipes are laid in a straight line and an ordinary spigot and socket lead joint inserted every ninth or tenth pipe to allow for expansion in variable temperatures.

The laying of distributing pipes and mains presents very little difficulty, requiring engineering skill, especially in open ground. The only occasion where the work becomes intricate is in handling and laying large pipes in the centre of cities having their usual network of underground mains which have to be considered. On all pipe lines washout chambers should be built within reason, and especially at every depression, so that scouring out process may be easily accomplished, and an air valve placed at every high point to allow the imprisoned air to escape. Pipes should be laid true to line, grade, and on a good solid foundation, with particular care and attention paid for sufficient collar holes to facilitate and ensure the proper caulking of the joints. The mains, after being laid, should be subjected to proper tests and every length, when completed, should be closed by means of a blank socket, drilled and tapped to receive the connection pipe from the pressure pump, and a water pressure gauge showing the pressure registered in feet of water and lbs. per sq. in., with valves for safety, and lowering the pressure. An economical arrangement for testing the pipes is to commence laying, wherever practicable, from the source of supply, say reservoir, to the site of distribution.

All defects can be easily detected in the trench by careful observation and close attention to the indicator or pressure gauge, especially when pumping ceases. The most familiar defects are from weeping joints, split or cracked pipes and pinholes. The position of defect was marked on pipe, the pressure lowered, leakage made good, and the section re-tested. Weeping joints are generally easily put right by re-caulking. A split or cracked pipe requires more labor and attention, and in most cases its removal and replacement is the only satisfactory remedy. This can be accomplished in one of the following ways: (1) Burning out lead; (2) cutting out lead joint; 3) splitting off the socket; (4) replacing the whole pipe; (5) cutting the pipe, providing the defect is not too serious, the cracked portion taken out and a short piece cut to the required length inserted and jointed up by thimbles or sleeves. Pinholes in otherwise sound pipes may be drilled, tapped and plugged with brass or gun metal plugs.

Corrosion or rusting of pipes conveying water, both externally and internally, are serious items in the life of pipes supplying water as, although when properly coated with patent solution, corrosion is greatly reduced. But in time, unless properly inspected and removed, it takes effect, and although the danger of weakening the pipes is small, the real trouble lies in the contraction of the bore of the pipes, which diminishes their discharging capacity and reduces the working head.

Fire Service and Meters.—In conclusion the author would like to mention in connection with water supply for cities and towns—especially those in Canada—the absolute necessity of providing in all waterworks schemes an abundant supply to meet all the demands when called upon to save the destruction of lives and valuable property. This can only be successfully accomplished by the engineer making ample provision in the preparation of the scheme he is called upon to design; and by remedying the shocking waste of water in our cities through careless consumers who do not value or realize the expense a proper waterworks system entails to properly maintain out of the city's funds.

The advantage of having a powerful stream of water to be easily put into requisition to retard or prevent conflagration of buildings can be readily understood.

A little extra cost, if necessary arrangements are provided. in the original design of the waterworks, but may, as afterthoughts, prove an expensive addition.

The writer strongly recommends for use in case of fire, a surplus storage capacity over and above that required for general purposes, such storage to be of sufficient elevation to allow water being forced above the tops of the highest buildings in the cities, and also the arrangement and dimensions of •the mains and distributing pipes to be capable of permitting the maximum fire supply when the demand for water for other purposes is at its greatest. In order to render a fire service efficient, hydrants should be placed at the most convenient and important points on the system to ensure a maximum efficiency. They should be in sufficient number and, above all, easily accessible, but not in danger of frost.

The available head at any given point on the system is calculated by deducting the loss of head due to friction in the pipes from the statical head at that point. It can plainly be seen that such results only hold good on a thoroughly watertight system, and it is imperative for hydrant purposes to maintain pressure. The laying and testing of mains should have the strictest attention of the engineer.

With reference to the prevention of waste, this important point must sooner or later be taken up seriously by Canadian cities, especially where pumping is the means of supply. The author strongly favors the insertion of water meters on the distribution services as an excellent prevention against extravagance and thoughtless excess in consumption. There are certainly advantages and disadvantages, the latter applying especially to the cheaper class of dwellings, for such a step might mean reversing the conditions as they exist at present and economy being substituted for undue extravagance at the expense of cleanliness and health. On sanitary grounds this would be a great objection, but at any rate the writer strongly advocates the adoption of meters for trade and manufacturing purposes, and also the serious consideration of meters on residential property with modifications to offset the disadvantage mentioned above. There are two types of meters, the "positive" and the "inferential." The former records by clock mechanism on similar principle to that of a cylinder and side valve of a high-pressure steam engine, water alternately filling and emptying a vessel of known capacity. The latter mechanically registers the flow by recording the revolutions made by a wheel with vanes or discs attached, on the principle of the water-wheel or turbine in a small chamber. The engineer should select the one which combines accurate results with varied flows, simple and easy repairing, and does not interfere with loss of head in supply pipe.

SUMMARY OF TESTS OF BOND BETWEEN CONCRETE AND STEEL.

(Concluded from last issue.)

(28) Pull-out tests made at early ages gave surprisingly high values of bond resistance. Plain bars embedded in 1:2:4 concrete and tested at 2 days did not show end slip of bar until a bond stress of 75 lbs. per sq. in. was developed. Bond resistance increases most rapidly with age during the first month. The richer mixes show a more rapid increase than the leaner ones. The tests on concrete at ages of over one year showed that the bond resistance of specimens stored in a damp place may be expected ultimately to reach a value as much as twice that developed at 60 days.

(29) The load-slip relation of leaner and richer mixes was similar to that for 1:2:4 concrete. For a wide range of mixes the bond resistance was nearly proportional to the amount of cement used. This relation did not obtain in a mix from which the coarse aggregate had been omitted.

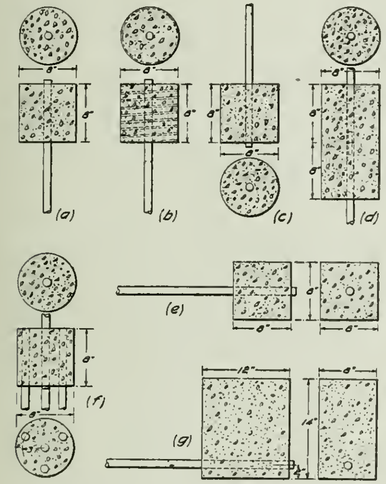

Fig. 1.—Types of Pull-out Specimens Used in the Tests.

(30) When the application of load was continued over a considerable period of time, or when the load was released and reapplied, the usual relation of slip of bar to bond resistance was considerably modified. The few tests which were made indicate that the bond stress corresponding to beginning of slip is the highest stress which can be maintained permanently or be reapplied indefinitely without failure of bond. The effect of continued and repeated load, impact, etc., may well be the subject of further experimental study.

(31) Little difference was found in the pull-out tests whether the load was distributed over the entire face of the block or over a narrow ring at the centre of the block or around the edge of the face of the block.

(32) Specimens molded in a horizontal position gave lower bond resistance than those molded in a vertical position; when settlement of the bar with the settlement of the concrete was entirely prevented, the bond resistance was reduced to about 60 per cent. of that found for similar specimens which were molded with the bars in a vertical position. Plain bars tested by being pulled in the same or the opposite direction from the settlement of the concrete during setting gave about the same bond resistance, but in the tests of certain deformed bars this was not true.

(33) The term "autogenous healing" is used to designate phenomena observed in pull-out tests and in compression tests of concrete cylinders in which the hardening of the concrete was interrupted by loading the specimen at early ages to its ultimate resistance. Up to an age of one year the bond resistance of specimens stored in damp sand was not affected by as many as four loadings at intervals during the period of storage up to the ultimate resistance. For specimens stored in air and tested in the same way, the bond resistance was less than for damp-sand storage, but the tests showed a steady increase in bond resistance with each loading up to three months. Specimens which had been stored in air for two months before the first test and in water thereafter showed a decrease in bond with each subsequent loading, although the bond resistance in the last test was fairly high. The presence of water apparently permits the continuation of the hydraulic action of the cement for several months after the mixing of the concrete.

(34) Bond resistance of plain bars is greatly increased if the concrete is caused to set under pressure. With a pressure of 100 lbs. per sq. in. on the fresh concrete for five days after molding, the maximum bond resistance was increased 92 per cent. over that of similar bars in concrete which had set without pressure. The greater density of the concrete and its more intimate contact with the bar seems to be responsible for the increased bond resistance. Light pressures gave an appreciable increase in bond resistance. With polished bars the effect of pressure was slight.

(35) As might have been expected, the compressive resistance of concrete setting under pressure was increased in much the same ratio as the bond resistance. At the age of 80 days the initial modulus of elasticity in compression for concrete which set under a pressure of 100 lbs. per sq. in. was about 37 per cent. higher and the compressive strength was increased by about 73 per per cent. over that of concrete which had set without pressure. The density of the concrete, as determined by the unit weights, was increased about 4 per cent. by a pressure of 100 lbs. per sq. in. on the fresh concrete. The increase in strength and density was relatively greater for the low than for the high pressure. A pressure continued for one day, or until the concrete had taken its final set and hardening had begun, seems to have produced the same effect in increasing the strength and elastic properties of the concrete as when the pressure was continued for a much longer period.

(36) Concrete cylinders tested in compression at age of 80 days after having been loaded to failure at 7 days gave compressive strengths nearly as high as those tested for the first time at the same age. Retests of cylinders which had set under pressure gave similar results.

(37) Beams of comparatively short span reinforced with bars of large size were used in order to develop high bond stresses and give bond failures. Most of the beams failed in bond; a few failed by a combination of bond and diagonal tension or by tension in the steel.

(38) The usual method of computing the bond stress in a reinforced concrete beam does not take account of all the phenomena of bond action. Slip of bar due to beam bond action and the presence of anti-stretch slip may be expected to greatly modify the distribution of bond stress over the length of the bar, and otherwise to affect resistance to beam bond stresses. However, the

nominal values for bond resistance, computed by the usual formula, form a useful basis for comparison in beams in which the dimensions and general make-up are similar.

(39) Slip of bar was a phenomena in all beam tests in which careful slip observations were made. These load-slip relations give important indications as to the bond stress developed at points along the length of the beam.

(40) Slip was first observed in the middle region of the span at loads producing a tensile stress in the steel of about 6,000 lbs. per sq. in. In this region the shear is zero, and hence beam bond action, as usually understood, is absent. As the load was increased, slip of bar progressed through the outer thirds toward the ends of the beam at a rate nearly proportional to the increase of load. After slip occurred at the ends, the outer thirds of the length of the bar moved toward the middle of the span relative to the adjacent concrete. Slip of bar was probably partly responsible for the opening of outer cracks, since slipping was observed in the outer thirds of the beams before the cracks became visible.

of the bar, was about 75 per cent. of that for similar beams reinforced with plain round bars of similar size.

(44) Beams reinforced with twisted square bars gave values at small slips about 85 per cent. of those found for plain rounds. At the maximum load, the bond-unit stress with the twisted bars was 90 per cent. of that with plain round bars of similar size.

(45) In the beams reinforced with 1⅛-in. corrugated rounds, slip of the end of the bar was observed at about the same bond stress as in the plain bars of comparable size. At an end slip of 0.001 in., the corrugated bars gave a bond resistance about 6 per cent. higher and at the maximum load, about 30 per cent. higher than the plain rounds.

(46) The beams in which the longitudinal reinforcement consisted of three or four bars smaller than those used in most of the tests gave bond stresses which, according to the usual method of computation, were about 70 per cent. of the stresses obtained in the beams reinforced with a single bar of large size. The progressive opening of cracks with increase in load was well shown in these tests. These beams showed cracks nearer the ends than usual. The distances of the outermost

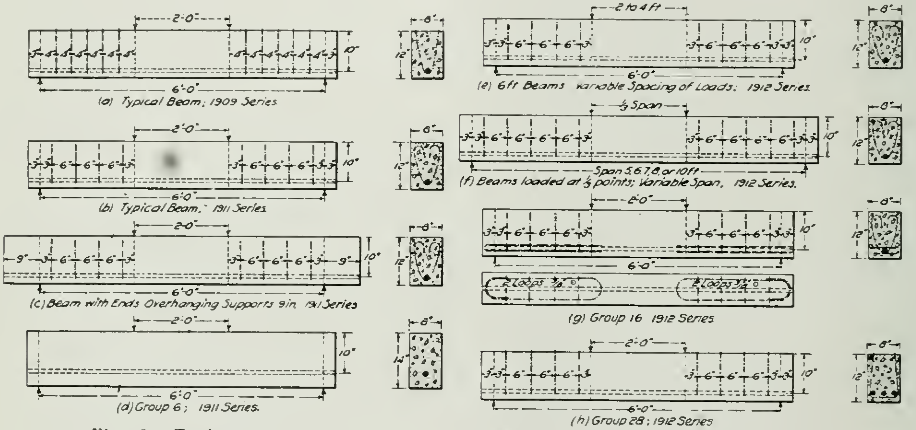

Fig. 2.—Typical Forms of Reinforced Concrete Beams Used in the Tests.

(41) The mean computed values for bond stresses in the 6-ft. beams in the series of 1911 and 1912 were as given below. All beams were of 1:2:4 concrete, tested at 2 to 8 months by loads applied at the one-third points of the span. Stresses are given in pounds per square inch.

	Number of tests.	First end slip of bar.	End slip of 0.001 in.	Max. bond stress.
1 and 1¼-in. plain round	28	245	340	375
¾-in. plain round	3	186	242	274
⅝-in. plain round	3	172	235	255
1-in. plain square	6	190	248	278
1-in. twisted square	3	222	289	337
1⅛-in. corrugated round..	9	251	360	488

(42) In the beams reinforced with plain bars end slip begins at 67 per cent. of the maximum bond resistance; for the corrugated rounds this ratio is 51 per cent., and for the twisted squares, 66 per cent.

(43) The bond unit resistance in beams reinforced with plain square bars, computed on the superficial area

cracks from the ends of the beams suggest that the unbroken length of embedment has an important bearing on the maximum loads which the beams may be expected to carry before failing by bond. It seems probable that the lower computed bond stresses in these tests are due to errors in the assumptions made as to the distribution of bond stress and not to actual differences of bond resistance in the bars of different size.

(47) The tests on beams with the loads placed in different positions with respect to the span gave little variation in bond resistance during the early stages of the tests. The maximum bond resistances increased rapidly as the load approached the supports. These tests indicate that the variation in the maximum bond stresses must be due to the presence of other than normal beam action.

(48) Nearly all the beams tested on span lengths of 7 to 10 ft. failed by tension in the steel and did not develop the maximum bond resistance, although high bond stresses were obtained. The bond stress corresponding to first end slip of bar did not vary much with the span length.

(49) The bond stresses developed in the beam tests indicate that with beams of the same cross-section the bond stresses are distributed in the same way during the early stages of the test in beams varying widely in span length and loading. During the later stages of the test, the distribution of bond stress seems to depend largely upon the conditions of stress in the concrete through the region of the span where beam bond stresses are high. The distribution of bond stresses in beams of different cross section apparently varies with the relative dimensions of the beam and the reinforcing bars.

(50) The use of auxiliary tensile reinforcement in the outer thirds of the beam served to modify the distribution of bond stress during the early stages of the test, but did not have any influence on the maximum bond resistance. While the auxiliary bars seemed to prevent the opening of outer cracks, the tests indicate that interior cracks which did not appear on the surface of the beam may have opened to an extent that permitted the same distribution of bond stress as was found in other tests.

(51) Increasing the thickness of the concrete below the reinforcing bars beyond the depth usually employed caused a very large increase in the resistance to bond and web stresses. The added stiffness of the beam and the increased flexural strength through the outer thirds of the span, prevented the formation of cracks in these regions. In the other beam tests such cracks were found to interrupt the continuity of bond action and to be an important factor in producing lower average bond resistances.

(52) Increasing the length of overhang of the ends of the beam beyond the support did not increase the resistance to web stresses as indicated by the opening of outer cracks, but it had an influence on the bond resistance. The bond resistance at first end slip was greater in the beams with the longer overhang. The maximum bond resistance was materially increased by the additional overhang.

(53) In the reinforced concrete beams it was found that very small amounts of slip at the ends of the bar represented critical conditions of bond stress. For beams failing in bond the load at an end slip of 0.001 in. was 89 per cent. to 94 per cent. of the maximum load found in beams reinforced with plain bars, and 79 per cent. of the maximum load for similar beams reinforced with corrugated bars. As soon as slip of bar became general, other conditions were introduced which soon caused the failure of the beam.

(54) The bond stresses developed in a reinforced concrete beam by a load applied as in these tests varies widely over the region in which beam bond stresses are present. High bond stresses are developed just outside the load points at comparatively low loads. The load which first developed a bond stress nearly equal to the maximum bond resistance in the region of beam bond stresses produced a stress near the support which was not more than about 15 to 40 per cent. of the maximum bond resistance. As the load is increased, the region of high bond stress is thrown nearer and nearer the support, and at the same time the bond stress over the region just outside the load point becomes steadily smaller. This indicates a piecemeal development of the maximum bond stress as the load is increased. The actual bond stresses in certain tests varied from less than one-half to more than twice the average bond resistance computed in the usual manner.

(55) Slip of bar in a reinforced concrete beam has a marked influence in increasing the centre deflection during the later stages of loading.

(56) The comparison of the bond stresses developed in beams and in pull-out specimens from the same materials is of interest. Such a comparison should be made for similar amounts of slip. In the pull-out tests the maximum bond resistance came at a slip of about 0.01 in. for plain bars. The mean bond resistance for the deformed bars tested was not materially different from that of the plain bars until a slip of about 0.01 in. was developed; with a continuation of slip the projections came into action and with much larger slip high bond stresses were developed. The beam tests showed that about 79 to 94 per cent. of the maximum bond resistance was being developed when the bar had slipped 0.001 in. at the free end; hence the bond stress developed at an end slip of 0.001 in. was used as a basis of the principal comparisons in the pull-out tests. However, it is recognized that, under certain conditions, the stresses developed at larger amounts of slip may have an important bearing on the effective bond resistance of the bar.

(57) The pull-out tests and beam tests gave nearly identical bond stresses for similar amounts of slip in many groups of tests, but it seems that this was the result of a certain accidental combination of dimensions in the two forms of specimens and did not indicate that the computed stresses in the beams were the correct stresses. However, it is believed that a properly designed pull-out test does give the correct value of bond resistance, and gives values which probably closely represent the bond stresses which actually exist in a beam or other member as slipping is produced from point to point along the bar. The relative position of the bar during molding may be expected to influence the values of bond resistance found in the tests.

(58) A properly made pull-out test on a specimen of correct design is a valuable aid in determining the bond resistance of reinforcing steel in concrete, if due consideration is given to the load-slip relation. The tensile stress in the bar should be kept well below the elastic limit. Best results will be obtained by using a relatively short embedment. An embedment of 8 diameters is recommended.

(59) A working bond stress equal to 4 per cent. of the compressive strength of the concrete tested in the form of 8 by 16-in. cylinders at the age of 28 days (equivalent to 80 lbs. per sq. in. in concrete having a compressive strength of 2,000 lbs. per sq. in.) is as high a stress as should be used. This stress is equivalent to about one-third that causing first slip of bar and one-fifth of the maximum bond resistance of plain round bars as determined from pull-out tests. The use of deformed bars of proper design may be expected to guard against local deficiencies in bond resistance due to poor workmanship, and their presence may properly be considered as an additional safeguard against ultimate failure by bond. However, it does not seem wise to place the working bond stress for deformed bars higher than that used for plain bars.

It is expected that Lord Kitchener, British Consul-General, will bring to England details of the plans for the barrage on the White Nile, about 37½ miles above Khartum, which are now being prepared by the Egyptian authorities. This great work is to form a necessary auxiliary to the Assiut barrage and the Esnch barrage, the present successful drainage schemes of Northern Egypt. It is expected that within 2 or 3 years, the area in the delta will have been reclaimed; and then the new barrage will be needed urgently. Commencement on the work will probably be postponed for another year, since the receipts from revenue will be low this year in Egypt; and the scheme is estimated to cost about $4,000,000,000.

TENDENCIES IN TRACK CONSTRUCTION.

At a joint meeting in Boston of the American Society of Mechanical Engineers, the Boston Society of Civil Engineers and the American Institute of Electrical Engineers, papers on present tendencies in railroad work were read and discussed. One of these, presented by A. B. Corthell, Chief Engineer, Boston and Maine R.R., had to do with track construction, and reviewed its development during the past half century or more. The Journal for July of the first-mentioned Society publishes an abstract of Mr. Corthell's paper, to which we are indebted for the following:—

The first steel rails made in America were rolled at Danville, Pa., in 1845. Other rollings were made in the same year by the Boston Iron Works, the Trenton Iron Works, the New England Iron Co. and the Phœnix Iron Co. The first Bessemer rail made in the United States was rolled in Chicago in May, 1865; the first Bessemer steel rails to be produced on a commercial order were rolled in Jamestown, in August, 1867. The introduction of the Bessemer process thoroughly revolutionized the art of rail manufacturing, and the ultimate effect on railway building and commercial development of our country can hardly be over-estimated.

Attempts were made about 1870 to roll a combination rail with steel head and iron web and base, but the rapid reduction in price of all-steel rails rendered this process of no economic value, for while steel rails in 1872 sold for $140 per ton, in 1882 the price had dropped to $35 per ton. This cheaper production made possible the heavier rail of recent years, also the larger locomotives, greater capacity cars, and correspondingly greater economy in railroad operations. It is interesting to note in this connection that there seems to have been a fixed relation between the weight of rail in pounds per yard and the weight of locomotives in tons, for when we had 60-lb. rails in general use, we had 60-ton locomotives, and with the 100-lb. rail came 100-ton locomotives; roughly speaking, in 70 years the weight of rails has increased 70 lb., or 1 pound per year.

Not many years ago the designing of rail sections had become a fad. Most engineers were called upon to get up a new standard design, and nearly all roads had their own standard sections. As a matter of record, the rail mills at one time had no less than 188 different patterns and 119 patterns of 37 different weights per yard. The situation was investigated by the American Society of Civil Engineers, and in 1893, after more than three years' deliberation, the Society reported upon standard sections for rail from 40 to 100 pounds, varying in weight in 5-lb. increments. This report was accepted by the Society and recommended to the railroads for adoption during the year 1901. Rails of the above type of sections constituted fully 75 per cent. of all the rails rolled in American mills.

In 1901 the report of the American Railway Association recommending the use of 33-ft. rails was adopted. In October, 1907, a preliminary report was submitted accompanied by two series of proposed standard rail sections, and in 1908 the report recommended types A and B. Since October, 1907, several mills have rolled rails substantially in accord with the new sections, both A and B, and it has been demonstrated that these sections can be finished in the mill at a lower temperature than the A.S.C.E. sections. A finer-grained and better-wearing rail should be secured. However, great care must be exercised in the mills to see that the rails are actually rolled at the lower temperature.

During the year 1913 there has been laid on the Boston and Maine Railroad 500 tons of 85-lb. frictionless rails in curves of 5½ deg. and over, with which it is hoped to lessen materially the flange wear on high rails, which on sharp curves is always considerable. Actual experiment shows that curve resistance is a great deal lessened by the use of this rail. The theory offered for the action of the so-called frictionless rail is based on the means that it offers the outer wheel on each axle to become dominant over the inner one, and the inner wheel to slide laterally to release the outer wheel flanges as they are forced against the outer rail. The outer wheel is traversing a greater distance through a curve than the inner one, but is making the same number of revolutions. On this account, a compensating slide of the outer wheel or a spin of the inner one must occur. The frictionless rail allows this necessary spin to occur at the inside rail.

No subject concerned with track appliances has been more discussed than that of the joint fastening. The evolution of joint fastenings has advanced through three stages: first, the chair which maintains the ends of the rail in alignment and serves as a bearing; second, the fish-plate, which afforded the rail some support under the head, but greatly improved the matter by stiffening the junction of the rails vertically; and third, the angle-bar, which combines the features of the fish-plate and flange, and effected a great improvement in both the vertical and horizontal stiffness of joint fastening; the plain angle-bar is very simple, easily applied and cheap in first cost.

The conditions, which bear some relation to the wear of splice-bars, are the extent of bearing surface and the hardness of the metal. In the new 85-lb. rails and smaller sizes, the question arises whether the plain angle-bar meets with the ideal requirements of the splice-bar in the two important respects, strength, and the wear in the immediate vicinity of the joint, which affects the close union of the parts. We know that angle-bars are not strong enough because they bend and take a permanent set in service, and occasionally one breaks. The supported joints which we have had in use are the Fisher, the Continuous and the Weber joints.

For bolts to fasten the joints to the rails, the most efficient are those having the so-called grip thread. This bolt is made of a soft steel, and the threads are cold-pressed in a manner to upset the metal so as to reduce the diameter of the bolt but slightly at the bottom of the thread. The threads are ratchet shape and under-cut 5 deg. on the bearing side. In the nut the bearing side of the thread is at right angles to the axis of the aperture, so that when it is screwed tight against the splice-bar the threads of the bolt give to the extent of which they are under-cut and the metal will be pushed completely to the outer recesses of the nut-threads, so as to hold the nut against turning off. The nut is square, with the corners chamfered next to the wearing surface, which gives an approximately circular bearing. On the bearing side the nut is recessed the depth of a thread and to a diameter somewhat larger than that of the threaded bolt, thus housing and protecting the many threads against injury by the chafing on the splice-bar.

The first tie-plates were used to prevent rails from cutting into and destroying the ties. Gradual development has added other features, such as the top shoulder, spike-hole, bottom claws and ribs, all tending to make the tie-plate not only a tie protection, but a more valuable rail-brace. Economy of material compels a minimum of weight consistent with strength, and one of the most important considerations is to obtain a tie-plate which will unite firmly with the tie; otherwise it will pound the tie and wear it under rail vibration and afford no lateral resistance to the spreading of the rails. As

such a requirement cannot be had by a plate with a smooth underside, practically all tie-plates are now made with under projections in the shape of claws, which enter the wood crosswise of the grain, or of the flanged or rib type, which enter the wood longitudinally with the grain. In the former case the lateral displacement of the plate is resisted by an abutment against an end section of the fibres. The standard Boston and Maine tie-plate has four flanges which enter the grain of the tie longitudinally, running the width of the plate. The latest tie-plate shows the two longitudinal flanges and two smaller transverse flanges on the bottom, a heavier shoulder and a better portioning of material.

Wooden ties have been almost universally used by the railroads of this country, and are still used as best practice. Steel ties and ties of concrete construction have been made, and are used to some extent with varying success. For wooden ties, the hardwood tie of oak, chestnut and hard pine are used mostly for main line traffic, and the softer woods, such as cedar, for branch lines of light service. The standard Boston and Maine tie is 6 in. thick by 8 in. wide and 8 ft. long. The average life of a chestnut tie is seven ears, and hard pine ties eleven years. The life of a tie can be lengthened by the use of tie-plates and preservatives.

There is indication of no radical change in the present track materials or methods in the immediate future. The rail may be heavier and more spikes, tie-plates and braces added, but the general design will be the same. The changes in turnouts and yards will be most marked; longer switch leads, wider spacings of track, heavier rail and more careful maintenance are already necessary in a great number of our yards, due to the increased loads in power and rolling stock. In the Pennsylvania Terminal in New York City we find part of the tracks laid on stone ballast and some part on a solid concrete base, with creosoted ties bedded therein and anchored by bolts to the concrete.

CONSTRUCTIONAL ACTIVITY IN MONTREAL.

The iron and steel trade in Montreal is greatly interested in the various reports given out from time to time by the big producing firms of the country. The statement of the Nova Scotia Steel and Coal Company for June was regarded as quite encouraging, compared either with a year ago or with the previous month. The figures are as follows, outputs being given in tons:—

	June, 1913.	May, 1914.	June, 1914.
Ore mined	47,200	38,903	44,000
Ore shipped	......	70,129	60,000
Coal mined	67,088	69,349	71,600
Coal shipped	......	61,677	90,000
Pig iron	7,220	......	7,000
Steel ingots	7,147	6,668	10,600
Ingots rolled	......	......	3,770

From the above figures it would seem that the company maintained its output in a satisfactory manner. The activity was evidently greater in June than in May, and the statement is made that the output of steel ingots reached a new high record. This result is somewhat surprising when it is remembered that it was generally considered that outputs of steel companies were very low in June. The trade is looking forward to other companies' reports.

It has developed during the past week or so that orders for structural steel have been running light and it is stated that the principal bridge companies are laying off draughtsmen and other employees. On the other hand, it is asserted that the cement companies are more actively employed, and that they are doing a better business than a year ago. The same is asserted for the brick factories, while other lines of industry send in somewhat similar reports.

INITIAL STRESSES IN STRUCTURAL STEEL.

THE importance of investigation into the subject of initial stresses in steel for structural purposes has assumed a prominence in recent years that is well justified when one is led to observe the low elastic limits, evidently due to initial stress, which tests made on rolled steel shapes have disclosed. Engineers who have noted fractures in fabricated steel work that are indicative of disproportioned stresses and strains are generally inclined to lay the blame upon internal initial stresses. The subject has been well treated by Mr. J. R. Worcester before the Boston Society of Civil Engineers, and from his paper we reproduce the following interesting discussion:—

For many years it has been recognized that where steel is heated locally by forging, there is likely to be produced a region between the heated and unheated portion where the metal is brittle and can be broken by a blow or shock. A striking example of this defect came under the writer's observation recently in the case of some 2-in. diameter steel truss-rods which had been upset. One of these, in unloading from a wagon, had its upset end broken off with a granular fracture. On testing the other rods, by striking the ends with a sledge, it was found that several broke in the same manner, while the remainder could not be broken. A chemical analysis of the fractured ends gave the following result, which is consistent with good metal: carbon, 0.408 per cent.; sulphur, 0.045 per cent.; phosphorous, 0.065 per cent.; and manganese, 0.38 per cent. Although not so certainly established as in other cases, it is quite probable that this fracture was induced by internal stresses caused by the local heating.

A similar defect in I-bars was noticed, soon after the introduction of steel into their manufacture, and led to the universal adoption of annealing furnaces long enough to anneal the whole bar at one time after forging. This practice has recently been proved by Mr. A. H. Emery to be of no benefit, as far as can be determined by tensile tests, as it decreases both the elastic limit and the ultimate strength, while no decrease in strength appears to follow from the local heat treatment, under direct tension as applied in the testing machine. It does not necessarily follow, however, that the annealing may not be a desirable precaution as a safeguard against shock.

Admitting, then, the prevalence of initial stresses, it is interesting to consider their origin with a view to guarding against them where possible. When their origin is in some form of heat treatment it is generally possible to overcome them by annealing, although this may not be the only or the best method. When they are confined to members used in direct tension they may not be of serious import, because, on the application of stress to the member, the effect is to increase the initial tensile stresses already existing, reducing or neutralizing internal compressive stresses. As the applied load increases, a point is soon reached where the fibres carrying most of the tension reach the elastic limit and begin to stretch, after which a redistribution of stress occurs, spreading the stress equally over all the fibres.

A familiar example of this is in the case of a copper wire which may be coiled or crooked with internal stresses. We all know how, if such a wire is stretched beyond the elastic limit all crooks immediately disappear. So with a steel member, if in tension it is in stable equilibrium, and a minute stretch can usually occur without harm to the structure.

With compression members, however, the case is radically different. In these, the first applied load, if con-

flicting initial stresses exist, tends to throw the whole member out of alignment. It is in unstable equilibrium, and the more it bows the greater the danger.

One of the causes of initial stresses is cold straightening of metal before assembling. Cold straightening is, in reality, cold bending, and the following investigation is an attempt to determine the limits of internal stress which may be produced by cold bending.

It is well known that material as it comes from the hot bed is almost always more or less out of line, and that in order to straighten it the most effective and simple method, and the one generally used, is to bend the member, in the direction opposite to the initial curvature, enough so that when it springs back under its elasticity its alignment will be true. The effect of this bending beyond the straight line and allowing the elasticity to bring it back to the correct point is to strain the outer fibres on each side beyond the elastic limit. The elastic recovery reverses the stress in the extreme fibres which have been overstrained, and leaves a condition of stress within the section similar to that shown in Fig. 1.

This means that starting from one edge of the section we find at first a tensile fibre stress extending a certain distance in constantly decreasing intensity until it reaches a point of zero stress, or a secondary neutral axis, beyond which the stress becomes compressive, increasing to a maximum at a point, the distance of which from the outer fibre is the same as that which limited

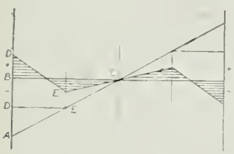

Fig. 1.

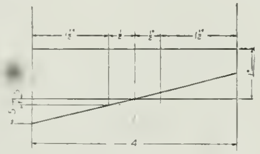

Fig. 2.

the field of metal stressed above the elastic limit by the bending. From this point the compressive stress diminishes to the axis of the section, beyond which it becomes tensile again, increasing to a certain point from which it again decreases, changing to compression at another secondary neutral axis and increasing in compressive stress until the opposite extreme fibre is reached.

By considering Fig. 1 we see at once that with a symmetrical rectangular section we have two fields of tensile stresses and two fields of compressive stresses represented by triangles, and we find that certain assumption may be made with regard to these fields which serve to fix their amounts. In the first place, considering the effect of the bending, if the material was not strained beyond the elastic limit, the stresses on each side of the neutral axis would have been represented by a single triangle ABC. If, however, the stress AB is greater than the elastic limit of the metal, this triangle would be truncated by a line DE parallel to the cross-section and distant from it an amount represented by the elastic limit of the material. When the bending stress is relieved, the line DEC assumes a new position $D'E'C$, the distance from D to D' and from E to E' being proportional to the distance from the neutral axis. This proportionality is one of the determining elements. Another is the fact that the total tensile stress multiplied by the distance of its centre of gravity from the neutral axis must equal the compressive stress multiplied by its axial distance. This is a necessary condition of equilibrium.

Lest it be argued that the line DEC does not agree with the stress-strain diagram, it should be borne in mind that in considering the elastic distortion we are dealing with an extremely minute deformation. Between adjacent planes of cross-section it is really infinitesimal, and any finite stretch would be so small as to produce practically no increment in stress. This consideration is valueless on account of its imaginary character. We might, therefore, without invalidating the argument, assume that we are considering the angle between two planes of cross-section separated by a finite distance, as, for instance, 1 in.

Suppose, for example, a bar 4 x 1 in. bent edgewise, to a radius of curvature such that one-quarter of its width along the neutral axis is still elastic and the remainder, on each side, is overstrained. Referring to Fig. 2, the stretch S, at the limit of the elastic portion,

will be about $\frac{30{,}000}{30{,}000{,}000} = 0.001$ in. The stretch of the extreme fibre S' will be

$$0.001 \times \frac{1.5}{0.5} = 0.003 \text{ in.}$$

The assumption is that the elongation of $S' - S$ will not cause an appreciable increase in stress after the metal has reached the elastic limit, i.e.,

$$S' - S = 0.003 - 0.001 = 0.002 = 0.2 \text{ per cent.}$$

If the gain in strength between the elastic limit and the ultimate strength is accompanied, as it frequently is, by a stretch of 30 per cent., and we assume that the rate is proportional, this stretch of 0.02 per cent. would mean an increase of stress of about

$$\frac{0.02}{30.0} \times 30{,}000 = 200 \text{ lbs.}$$

But, the characteristic of stress-strain diagrams is that there is a sudden yielding accompanied by a very considerable stretch, with no increase in stress; in fact, there may be a slight decrease in stress. It is evident that, in assuming any sharp angle in the diagram, there is a slight error, as the corner should be rounded. It would be more exact to say that the lines assumed are tangent to the curves, but the effect of this rounding may be disregarded without invalidating the theory. Referring to Fig. 3, the above assumptions may be expressed algebraically as follows:—

$$x_1 + x_2 = a \quad \ldots \quad (1)$$

$$\frac{x_1}{y} = \frac{x_2}{z} \quad \ldots \quad (2)$$

$$y + e = u + e - w \quad \ldots \quad (3)$$

$$\frac{v + e}{e} = \frac{a + b}{b} \quad \ldots \quad (4)$$

$$\frac{w}{z} = \frac{a + b}{b} \quad \ldots \quad (5)$$

$$y\frac{x_1}{2}\left(a + b - \frac{x_1}{3}\right) = (b + x_2)\frac{z}{2}\left(\frac{b + x_2 + b}{2}\right)\frac{2}{3} \quad \ldots \quad (6)$$

Solving these equations, we obtain these values for y and z in terms of a, b and e:—

$$y = \frac{2\,(a + b)^2}{a\,(a + 2b)}\,e\,; \quad z = \frac{2\,(a + b)^3}{a^2\,(2a + 3b)}\,e.$$

Letting $a + b = 1$, we find that the equation for y, assuming a as a variable, is a parabola with its vertex at the neutral axis of the section with a value of $\frac{1}{2}e$, the parabola passing through the origin (see Fig. 4). This equation is

$$y = \left(a - \frac{a^2}{2}\right)e, \text{ or } 2a - a^2 = \frac{2y}{e}.$$

Expressing this result in words, it amounts to this: If a rectangular bar is bent so that it has any permanent set, the internal maximum fibre stress may be obtained if we know to how great a depth the outside portion of the section has been stressed beyond the elastic limit. The amount of this internal stress can never exceed one-half the elastic limit, and between o and $\frac{1}{2}e$ it varies according to the abscissas of a parabola of which the axis is the neutral axis of the section.

We may determine the depth to which fibres are stressed beyond the elastic limit if we know the radius of curvature and the thickness or depth of the section.

We know from mechanics that $\frac{1}{r} = \frac{e}{Ed}$, in which r is the radius of curvature, e is the elastic limit of the material, E is the modulus of elasticity, and d, the distance

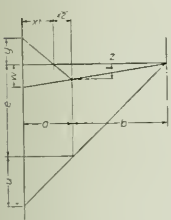

Fig. 3.

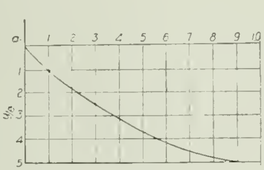

Fig. 4.

from the neutral axis to the extreme fibre. Using 30,000 for e and 30,000,000 for E, this formula becomes, $r = 1{,}000\,d$. In other words, the distance from the neutral axis to the fibre which is strained just to the elastic limit will be 1/1,000 of the radius of curvature; hence, if we know approximately the radius of curvature, we can tell at once what part of the thickness of the section is not overstressed, and, subtracting this from one-half the total thickness, we can find a. Taking a practical example of this, we should obtain the following results:—

Assume a bar 3 x 1 in. to be somewhat crooked edgeways and to be straightened in a press. Let us assume that in straightening it is curved to a radius of 12 ft., a very moderate assumption.

The width of metal not overstressed would be

$$\frac{12 \times 12}{1{,}000} = 0.144 \text{ in. each side of the neutral axis.}$$

a would, therefore, $= 1.5 - 0.144 = 1.356$ in.
or, on the basis of $a + b = 1$, $a = \frac{1.356 \times 1}{1.5} = 0.9$.

From the diagram, Fig. 4, we find that under these conditions, y, the initial fibre stress amounts to $0.495\,e$, tension on one edge and compression on the other, or approximately 15,000 pds. per sq. in. This means that in a bar which is quite straight and wholly "innocent" in appearance there may exist a compressive stress along one edge of 15,000 lbs. per square inch, while along the opposite edge is a tensile fibre stress of an equal amount; in other words, an inherent tendency to bend out of line on the least "provocation." This condition cannot be detected by any of the usual methods of inspection, but might be suspected if we knew its history.

It will be noted that the above analysis applies only to a rectangular section. In the case of an irregular section, such as an I-beam, it is evident that if the bending is in the plane of the web, a lesser stress in the extreme fibre will produce equilibrium on account of the decreased area of the section in the parts nearer the neutral axis. On the other hand, if the bending is at right angles to the web, the converse is true, and the extreme fibre stress will be greater proportionally, and may easily approach nearer to the elastic limit. The same is true of a bar with a circular cross-section.

Let us now consider the practical effect of these internal stresses. Referring again to Fig. 1, we see that if we apply an axial stress to a member which is already subjected to this condition of internal stress the effect will be to produce a condition as shown by Fig. 5. In this case we see at once that the areas of stress will be unbalanced, so far as the rotating moment is concerned.

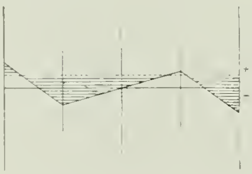

Fig. 5.

The effect of this unbalanced condition will be to produce a tendency to spring out of line. If the axial stress is in tension, this tendency is offset by the axial stress itself, and even in case the extreme fibre stress exceeds the elastic limit, a slight yielding of these fibres soon distributes the stress more uniformly, and so no serious results can occur. But if the axial stress is compressive, the tendency to spring is very serious and immediately throws the strut out of equilibrium, so that the bad effect of the internal fibre stress is accentuated. If the elastic limit is passed, the buckling may even continue to the point of failure.

Mr. Worcester did not enlarge upon applications of the above theoretical considerations. His paper, nevertheless, shows the tremendous importance of eliminating cold straightening so far as possible from the shop treatment of metal which goes into compression members.

On June 19, Kingston dock, Glasgow, Scotland, was completely destroyed by fire, entailing damage to the extent of \$1,250,000. The original cost of the dock was \$750,000; but extensive alterations and improvements have been in progress during the past year. The collapse of the quays carried with them huge cranes, thousands of feet of iron girders, and rooms of sheds. In addition four schooners, laden with seal oil and other products, were destroyed.

According to M. Hans, Dempwolff, of the staff of the Prussian Government Railway, and a recent visitor to Canada, a large scheme is now being considered in Berlin for electrifying the suburban and interurban railway systems, which are run on elevated tracks as in a number of the leading American cities. The cost of the work would involve the expenditure of something like 150,000,000 marks (\$30,000,000.) The German Government, he remarked, was experimenting with electric locomotives, and was trying out Deisel engines on its lines.

WHARNCLIFFE HIGHWAY BRIDGE, LONDON, ONT.

By F. M. Brickenden.

THE city of London, Ont., with its population of 48,000 is situated on the River Thomas. The location with respect to the main river, and particularly its north and south branches, is such as to require a considerable number of highway bridges to convey the traffic from one part of the city to another. A new bridge, to be called the Wharncliffe highway bridge, is at present under construction. It is the first to cross the main river, and is one the need of which has been felt for a number of years, particularly since the annexations of London South and London West, both of which were until a comparatively short time ago municipalities outside the city. The site is shown in Fig. 1. It is about ¼ of a mile downstream from the forks of the north and south branches of the Thames.

Before its municipal development London West was a low-lying piece of land, and has had to be protected on the river side by a breakwater. London South, however, in the vicinity of the bridge site, is on an elevated strip of land. Further, owing to the directions of the currents produced by the junction of the two branches of the river, and taking into consideration the ice brought down in the spring, assisted by the fact that the two centre lines of the Wharncliffe roads in London South and London West do not coincide, it was found necessary to design the bridge on a skew. The angle of the substructure was accordingly set out at 113° 29′.

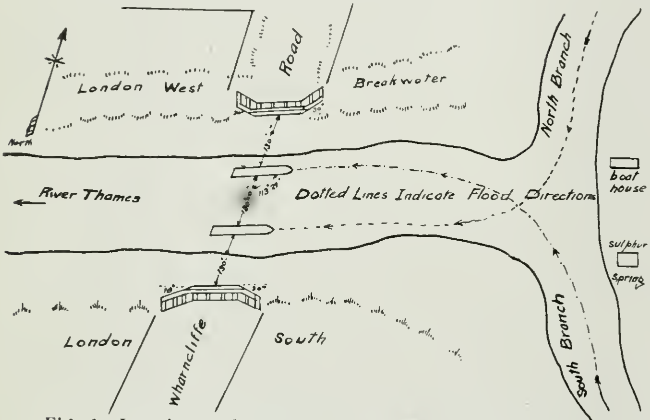

Fig. 1—Location and Layout of the Wharncliffe Highway Bridge, London, Ont.

Excavation.—Underlying the bridge site is what is known locally as London South white clay. This clay is used is another locality for the purpose of making white brick. It is of such a nature as to puddle readily upon mixing with water. Because of this considerable difficulty was experienced in excavating for the south abutment of the new bridge. Clay slid into the excavation on several occasions. The work was started in August last, and the contractors adopted the pick-and-shovel method of removing the clay to a depth of approximately 20 ft. For a part of the time a team and slush scraper were employed. As the clay developed drying cracks on exposure, blasting with black powder was found ineffective when tried.

When the excavation had attained a depth of about 10 ft. a 10-in. cast-iron water main was encountered, necessitating, of course, its removal and relocation to one side of the bridge site. The pipe was found to lie directly under the entire length of the proposed bridge. As the river reaches a depth of about 3½ feet, at low water mark, a special arrangement was necessary to place this 300 feet of water main on the bottom without breaking the caulking. The entire river length was accordingly placed on the bents, each about 9 ft. high. It was then hung from the threaded rods by a wire. The rods projected through the top of the bents and then held by wrenches. To lower, 28 men were placed, one at each bent, and on a given signal, each gave his wrench one turn, thus lowering the whole as a unit. The excavation of the south pier footing was simply sheet-piled, and on reaching the bottom 30 hardwood piles were driven and cut 9 in. up from the bottom level. For the north pier a wood caisson was built, and between the outer and inner parts the intention was to fill with earth and sink to a firm foundation. This was done, but considerable trouble was experienced because of the pressure of the water on the outside of the cofferdam, forcing through the light filling material used in sinking the framework. This was pumped out by means of a centrifugal pump, driven by an 8 h.p. gasoline engine (a small, power diaphragm pump was used in pumping out the other pier excavation). This foundation, although of very good quality white clay, was filled with 30 piles driven to refusal.

The 30 piles for the south pier were driven by means of a horse-driven capstan, lifting about 1,500 lbs. to the height of 18 ft. This operation took an average of 111 seconds from blow to blow. For driving the remaining 30 piles a small hoisting apparatus was connected up with the 8 h.p. engine by a chain, and from the hoisting-drum a cable was fastened directly to the hammer of the pile-driver, so that after raising the hammer it fell, drawing out the cable and ready to start again. The operation of this method consumed at best but 11 secs. from blow to blow, although much time was wasted, in that the leaders used were unsuitable.

The excavation for the north abutment was through the West London breakwater, about half being taken out by means of team and scraper, and the remainder removed by shovel.

Both the abutments were laid out with the short centre line as the line of the bridge-seat on the coping. This line located, the counterfort walls were at right angles to the face, so that the angle turned assisted in the layout of these forms. The angles of the wings were all turned with the transit. The layout of the south pier was simply by direct means, but, as the north pier was entirely in the water at its lowest, the method used for it was different. A wire was stretched along centre line, with the centre point marked equidistant from pier and abutment. The skew was first set by measuring along a triangle applied to the caisson and scaled off the plan. This was checked by measuring along sides of a parallelogram from shore, and later having a stage placed on the cofferdam when the angles were checked with the instrument.

It may be mentioned that the city of London controls the height of the water in the Thames by their

waterworks dam, four miles down the river; so that the level of the water was reduced 3 ft. during pier construction last fall and this spring.

Reinforcing.—The building of the counterforted abutments gave rise to several noteworthy conditions. For example, when the supporting walls or counterforts were being formed, they were battered up from a base-slab, which was 12 ft. in thickness at the bottom, and 57 ft. or 52 ft., according to the abutment, to the top of the ballast wall. At the points of wings and main wall the counterforts are 2 ft. thick, double the width of the remainder. The inclined reinforcing was hooked at the rear of the base reinforcing and ran up 3 in. from the back of the counterforts to the top. The rods used were of three sizes, ½ in., ¾ in., ⅞ in., all square. The base-slab was reinforced by having rods ¾ in. diam. placed across the whole of it, parallel at right angles to the face. To this all the vertical and inclined rods were hooked, thus making the base serve as an anchorage against overturning. Besides the inclined ⅞-in. rods in the counterforts, 3 pairs of ½-in. rods of different lengths were placed vertically, so that they ran to the inclined rods of the latter, and were hooked to them.

Parallel to the base and running 3 in. from the face, other rods were placed up to the bridge-seat. In front of these and in a vertical position were other ½-in. rods, to which were hooked the small, horizontal rods of the counterforts. In the bridge-seat were a number of short ¾-in. rods, laid parallel to the short diameter, and wired to these were several long ½-in. rods, horizontal and parallel to the face.

The ballast wall was reinforced by having short ¾-in. vertical rods, attached to long ½-in. horizontal rods, along the entire length of the wall.

Piers.—The north foundation forms and cofferdamming were radically different from that of the south, which consisted of a sheet piling only. The portion nearest the shore was shallow and easily kept dry, even when the river rose somewhat above the lowest water level obtainable for the work. A ring of clay around the excavation formed a barrier to the water. The seepage water was, as stated, removed by a power diaphragm pump.

The forms for the pier were of simple construction except the nosing. It had to be specially detailed to suit the cut-waters, which were only rolled as regular right angles rather than specials. The detail showed the nosing running back from the ⅞-in. cut-water angle at right angles to nose-point, or at a tangent to its curvature. The amount of curvature did not change, but the tangent or right angle of the nosing varied for each 2 ft. of rise, leaving the joint between tangent and curve vertical and imperceptible. This nosing then required a special form, built up in shapes roughly represented by the letter "U." These fitted over the cut-water angle, holding the form boards in place. The boards were placed vertically, being strongly wired to the 2 x 6-in. uprights which were outside the U-shaped forms.

Generally, the scantling was placed 18 in. apart and wired every 2 ft. with No. 9 galvanized, medium hardness, wire. All forms were oiled with a heavy oil, acting as a filler. Openings of any size were plugged with hard soap.

The north pier occasioned the placing of two cofferdams, one being heavily timbered, with an outer and inner shell. The caisson principle was tried, and this first floated into position and sunk. It required a great deal of filling, followed by many days of pumping before the excavation could be started in the river bottom.

Owing to the lateness of the season there was much uncertainty about the weather. The floods, carrying ice, washed the whole cofferdam away, filling in the work done during the early winter with river muck and debris. To get this in shape again for concrete a different method was used to get the old excavation cased in again, and watertight. A framework was built of 2 x 6's, covered with tongue-and-grooved lumber, and stiffened by corner-braces. The lower, or downstream end, was left uncovered. The boarding reached a height of 6 ft., this being sufficient for the depth of the low water then in the river. This was floated over the piling, which had survived the onslaught of the ice, and was sunk into place, the open end being sheet-piled. Around the whole cofferdam were placed sand-bags and loose sand. This, with the aid of the centrifugal pump, reduced the water again to a workable depth.

Concrete.—The abutments were concreted first. The base of each was concreted for 6 in. and the base reinforcing placed. Concrete was then poured to the level of the base of the vertical walls and top of base plinth. The upper reinforcing was held in position by a framework.

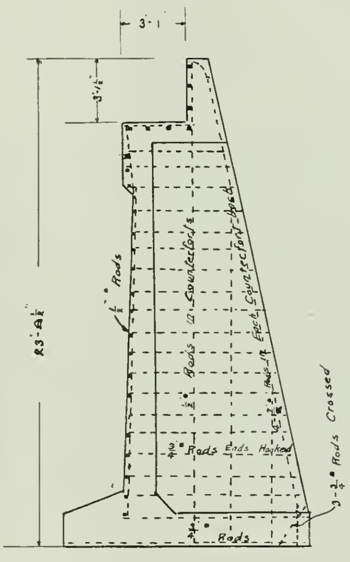

Fig. 2—Section of Counterfort, North Abutment.

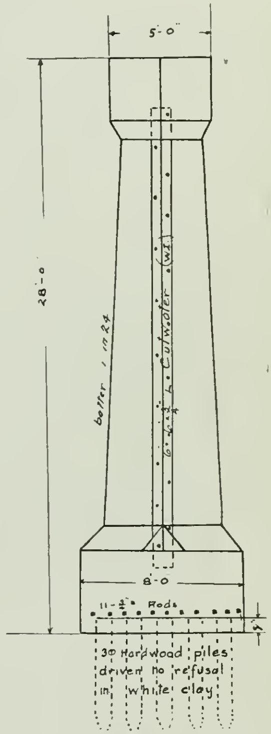

Fig. 3—Typical Pier Section.

After placing the forms the concrete was placed to the coping to allow the bridge-seat reinforcing to go in place, then continued to the base of ballast wall. The long, horizontal rods were then wired to the short uprights, allowing the completion of the remainder.

The placing of concrete for the pier was more difficult. The abutments only required a few lengths of semi-circular troughs, with a bent-end and a small hopper, while the piers required about 150 ft. of troughs, supported on a trestle-work that carried also a plank walk, for workmen.

When the piers rose to about one-third their height, a series of stages were erected at the form end of the chutes, upon which were men who passed up the concrete from one level to another to its position in the pier.

About 700 cu. yds. of concrete were placed, three mixtures being used; bases in water, 1:6 + 25 per cent. cement; ordinary, 1:6; nosing piers, 1:4.

No plaster coat was added to the faces. They were carefully smoothed and a wash applied, making all of the concrete of uniform color.

Steel.—The contractors for substructure and superstructure were both agreeable upon request to leave the drilling for the rag-bolt holes in the seats till a direct bearing-plate on abutment fixed directly off the connection-plate.

The portals are skewed, so that the ends of the end floor beams are sawn at flanges. The angle connections are special to suit 113° 29′ and 66° 31′. The remaining floor beams are placed at right angles to the bottom chord. The stringers are also cut obliquely at the ends of span to fit over the skew beams. The bottom laterals are angles, with legs 2½ x 2½ in., except end panels, which are 4 x 4 in., being rivetted at the centre. The top struts are built of 7-in. channel, edged to web of 6-in. channel, and hung from their connection at the top panel joint. The top laterals are 2½ x 2½ in.

The knee braces attached to the posts and top struts give greater stability from wind stresses which are rather excessive in this valley. The portals are arranged with angles and channels on edge, giving a neat appearance. The sidewalk consists of cantilever brackets having 10-in. I-beam stringer in centre for floor, a channel with angle on upper flange for curb of walk. A latticed railing is on the outside of the walk and inside of the upstream truss.

Erection.—The erection presented a few difficulties, mostly in the placing of the falsework in water—the

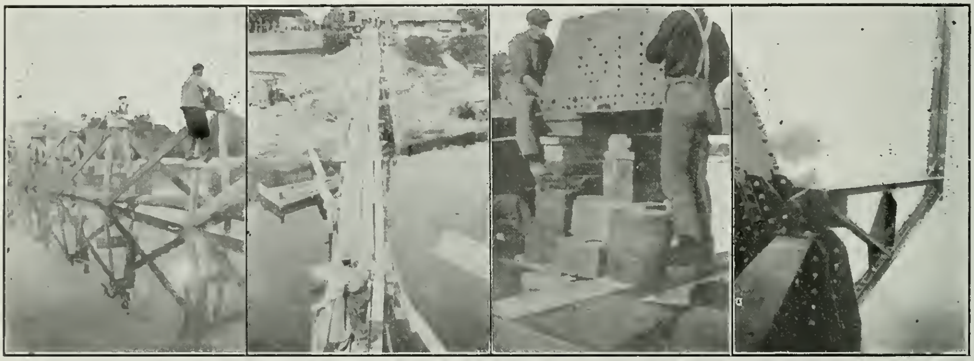

Fig. 4—Views of Bridge Construction—Method of Placing 10-in. C.I. Water Main—Chute for Transporting Concrete to Piers—Rivetting a Bottom Chord Splice—Sidewalk Cantilever Adjustment.

after the steel was erected and centred; the rag-bolts of the cut-water angles were concreted in with the nose. The steel of the bridge consists of three spans, all portals skewed, and the downstream side carrying a cantilever sidewalk (bracketted at each panel joint). The bridge spans are through rivetted trusses. The steel is being erected by what might be called the "Armstrong" method. An idea of the size of the connections and splices may be formed by the fact that the whole structure will require about 7,000 rivets, field-driven. The structure rests on three types of bearings. The south, or expansion end, is of a roller type, resting on a bearing-plate and supporting a slotted plate from the connection of end-post and bottom chord; five rollers to each corner, each roller of 3½ in. diam. The plate is held in position by 2-in. rag-bolts. The bearing-plates all rest on sheet lead, which serves to prevent the action of the free alkali on the steel plates. The bearing casting for the fixed end is a casting over 4½ in. thick. It is partly cast hollow in pockets on the underside, thus reducing the weight, but retaining sufficient strength to resist compression. It rests directly on bearing-plate. The third style used is height which the falsework bents had to rise above the water, compared to the depth of the river, gave no great amount of buoyancy in raising the heavy timberwork. Besides this difficulty, the falsework of the first span, though placed through the ice, had two bents washed out by a flood following the first week of erection, requiring much patience to take lines across the river by means of a rowboat and fasten them there. The erection of the second span being entirely over water, was more noteworthy. The depth of the water was about 7 ft., so that it was not convenient to work a "gin" pole in the river. A built-up "stiff-leg" was placed, projecting over the southerly pier and stayed back to the steel already erected. A bent was built up on shore of 12 x 12 in. material, braced, capped and towed under a hook operated by a pair of "three" blocks swinging from the "stiff-leg." To the end of the loose, threaded line a second pair of "three" blocks was attached and laid out by which the gang of men were able to raise the bent to almost its proper position.

By moving this arrangement to the top of each bent as raised, the eight bents required were speedily placed in their position and braced.

The bottom of the river at this point is gravel over clay, and, as there was no settlement of the falsework, the bents upon being placed were connected longitudinally over the caps by 3 and 4-in. lumber.

In the centre a runway was made by laying down the I-beam upon the centre pair of longitudinal timbers. This double runway was to accommodate the movement of the steel from the storage to its position in the span by means of a cart with a tongue and looped axle arrangement, whereby the steel when attached to the axle could be raised clear of the ground, and by balancing its connection was easily shoved along by a few men. The longest of the heavier top chord sections, 40 ft. in length, was moved this way.

After placing 12-in. I-beams to serve as a runway over the falsework, the bottom chord was next brought into position and rivetted at its splices. This was necessary and expedient at this juncture, because the chord was built up of 2 angles, edge to edge, at end panels, and 4 angles in the middle of the span to take up the greater stresses existing there. This in position, with its vertical connections at the panels, and 2 diagonals, hangers, or end-posts, would have made the splice rivets impossible to drive when all was erected.

Floor System.—The floor system consists of 24-in. I-beams across at all panel joints, about 20 ft. apart, except the ends of the span, or skew beams, which are both 20-in. I's. Because of the oblique angle, 66° 31′, the permanent connection between the lugs and end-post base is made with turned bolts and lock washers. Centered over this beam system, 12-in. I-beams form the stringers, those over the end skew-beams having to be

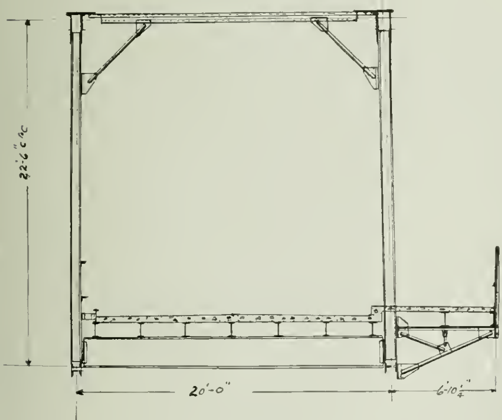

Fig. 5—Section of Bridge at a Centre Panel Joint.

of special length. The stringer opposite to the sidewalk, on the upstream side of span, has a channel on its top flange which forms, with back inwards, the curb of the roadway.

On raising the end-posts, a block and line were attached to the top of the hanger by which the end-post could be hauled into position and bolted at the top to the hanger and to the lower chord at its low end, resting on the bearing-plate of pier. A "traveller" was made of 8 x 19-in. timbers, with upright legs, high enough so that the projecting ends of cap-piece, suspending two sets of blocks, would not come in contact with the top chord or verticals till they were above their position, and could easily be lowered into the position when ready for bolting. The same block method was used as in raising the bents, these pieces were raised by the double three blocks, requiring about 10 men on the line.

Posts or verticals were all placed previous to raising the diagonals. To place them the "traveller" rig had to be shifted by means of pinch-bars, the bottom of both uprights moving along the same thickness of plank. The guy-ropes were held by fastening them around the various

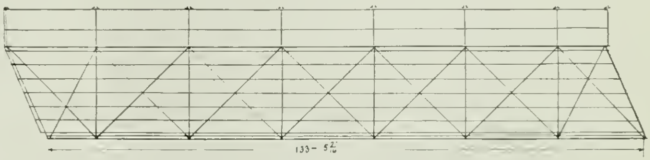

Fig. 6—Floor System.

erected members. In the case of the most distant top chord, these ropes had to be taken across the river and there fastened to a post on the breakwater. This method applied also to the extreme posts of the span.

Laterals and Struts.—Rivetting was done by hand, the outfit consisting of 3 men and a heater. Top and bottom laterals, knee-braces and struts of portals are erected as the rivet gang reaches the connection. The same can be said of the cantilever sidewalk brackets, which were held out by block and line, then set in position by the coupling-up pins and bolted. Only such of these as were needed to resist wind stresses were placed at the time of erection on the falsework.

The floor is to be reinforced concrete roadway of 18 ft. clear width, and the sidewalk 6 ft. The total length of floor is 409 ft. 1 in. This conforms to the Ontario Government specifications for a 15-ton bridge.

The substructure was built by the firm of Bain and Ross. The steel is supplied and erected by the Hamilton Bridge Company. The work is being done under the direction of Mr. W. N. Ashplant, the City Engineer.

Among large buildings at present under construction at Saskatoon, Sask., are a large store and office block, a cold storage warehouse, a distributing warehouse for the Prairie City Oil Company, a business block for the Canadian Townsite Properties, Limited, a new sedimentation basin, and an additional students' residence at the University of Saskatchewan. The interior storage elevator for the Dominion Government also is expected to be completed for this season's harvest. While the new bridge across the Saskatchewan River at Twenty-Fifth Street, being erected at a cost of about $500,000, is to be completed by the fall of 1915.

The Taku Railway and Navigation Company has filed in the land office at Juneau, Alaska, right-of-way and terminal plans for the proposed railway line up the Taku River from a point on Taku Inlet to the Canadian-Alaska boundary. About two miles of side cut rock work on the lower end is encountered. The line for the most part is tangent and free of short or sharp curves. It follows the flat in the valley almost the entire distance and tranverses three tracts of good timber. The grade is said to be considerably less than 1 per cent. The terminal is located on the south side of Taku Inlet just opposite Windom Glacier, which has been dead for some time. The Inlet is narrow at this point and not over 40 feet in depth; and the feasibility of bridging the canal at this point and continuing the line to Juneau has been discussed and is believed by engineers to be practicable. F. J. Wetrick, of Wilhelm and Wetrick, who made the survey for the American line of the railway, is now making a preliminary survey on the Canadian side to Atlin.

SASKATCHEWAN REGULATIONS GOVERNING WATER AND SEWERAGE WORKS.

THE Bureau of Public Health of the Province of Saskatchewan has just issued some important regulations governing the preparation and submission of plans and information with reference to the installation and extension of waterworks, sewerage and sewage disposal systems. These were prepared by Mr. R. H. Murray, A.M.Inst.C.E., engineer to the Bureau, under the direction of Dr. M. M. Seymour. Public Health Commissioner, and form an excellent system of standardization of such proposals, Saskatchewan being the first province of the Dominion to issue regulations of this nature. They were compiled primarily to facilitate the preparation and examination of plans and information pertaining thereto, and supplement the provisions of sections 21, 22 and 23 of the Public Health Act.

Respecting the plans and data required for provisional and final certificates, the following constitute the requirements of the Commissioner for Waterworks systems and extensions: Engineer's report; estimates of cost; general plans; analysis of proposed source of supply, and affidavit covering the same; detail drawings, specifications and affidavits covering both.

For sewerage and sewage disposal systems and extensions the same items apply with the exception of the analysis of proposed source of water supply. In the case of storm sewerage systems and extensions, affidavits will be required to cover general plans, also.

If the information and data submitted with reference to any proposed system or extensions are satisfactory and complete in the first instance, the Commissioner may issue his provisional and final certificates together.

Waterworks Systems and Extensions.—A report shall be submitted prepared by the engineer acting for the municipality giving information under the following heads, in so far as such are applicable to the proposed works:—

Population—The present population and the rate of increase during each of the past five years; available data justifying a future increase of population and probable increase in next ten years.

Maximum population which system will provide for if fully developed.

Population provided for by proposed system.

Area and topography of municipality.

Estimated water consumption per capita per twenty-four hours.

Alternative sources of supply (if any) and if investigated.

Source of supply recommended.

Present available supply of water and how determined.

Estimated supply of water under full development.

Quality of water.

Any present sources of pollution of source of supply.

Measures recommended to prevent future pollution of source of supply.

Nature and construction of intake or collection works.

Wells—The number, depth, size and construction of wells; the nature of the ground through which they are sunk; the construction of collecting galleries.

Watercourses—Minimum dry weather flow, approximate watershed area. If continuous winter flow; reduction in available supply during winter.

Catchment areas—Approximate area of watershed, character of watershed surface with reference to probable run-off, population, arable and stock farming and all available data having reference to rainfall.

Natural lakes—Approximate area of watershed, average depth of lake, area of lake, if overflow is continuous, approximate annual overflow, nature of watershed relative to population, arable and stock farming, and all available data having reference to rainfall. Population on shores winter and summer. If surface is used for traffic in winter.

The capacities and character of pumps; duplication of machinery and energy.

Sedimentation—The size and construction of basins.

Filtration—A full description of the proposed plant including the type of filter, the nature of filtering media, the maximum rate of operation of each unit of the plant; the method of cleansing filtering media; the nature and amount of coagulent or disinfectant estimated to be necessary.

Provision for future extensions.

Provision for measuring and recording amount of water supplied to municipality.

Provision made for storage and capacity of reservoir, stand pipes, etc.

Size of force or gravity mains.

Distribution system, especially with reference to cut-off valves, sluice valves, hydrants and through circulation; minimum size of pipes and minimum depth of trench; character of subsoil.

Pressure available for domestic and fire purposes.

Particulars as to any provision made for turning water other than the domestic supply into mains for fire protection purposes.

Provision to be made for inspection of construction.

Control and operation.

In the case of extensions to an existing system, the report shall, in addition to describing the nature of the proposed extensions, deal with as many of the above matters as are thereby affected.

Estimates of Cost.—A statement prepared by the engineer shall be submitted showing the estimated cost of the proposed system or extensions. The estimated cost of all pipe lines shall be shown in schedule form as follows: (See Schedule A, page 183.)

The estimated cost of all other sections of the work (e.g., land, intake, headworks, pumps, reservoir, hydrants, valves, etc.) shall be shown separately at the end of the schedule. The estimated operating costs per annum shall also be given.

General Plans.—The following plans shall be submitted:—

(*a*) Plan of Municipality.—A general plan of the entire municipality to a scale of not greater than 200 and not less than 500 feet to an inch. This plan shall show:

1. The municipal boundary.
2. All streets existing or proposed.
3. The approximate location of all habitable buildings not served with water at the date of application.
4. The surface elevations at all existing or proposed street intersections.
5. The elevation of the highest point in the municipality.
6. The location and size of all existing and proposed water mains.
7. The location of stand pipes, valves, hydrants and all appurtenances.

(*b*) Location Plan.—A plan to a suitable scale showing the site of the municipality, any outside territory affected, and the following:

1. The source of supply, intakes, wells, filters, pumps, reservoir and any special features.

2. The route of gravity or force mains.

3. The following elevations shall be shown: (*a*) The low, mean and high water levels of the watercourse or lake at the intake. (*b*) The highest known flood elevation of the watercourse or lake. (*c*) Surface and water elevations at standpipes, reservoirs and principal points in the system. (*d*) Surface elevations showing any irregularities of route with reference to the hydraulic gradient.

This plan is not required in the case of extensions to a distribution system.

Analysis of Proposed Source of Supply.—A sample of the water from the proposed source of supply shall be taken not more than six weeks previous to the date on which application is made to the Commissioner of Public Health for his certificate of approval. The sample shall be subjected to chemical analysis and bacteriological examination. A copy of the result of such analysis shall be submitted to the Commissioner of Public Health. The commissioner may require any number of samples extending over a stated period of time, if necessary.

The above shall also apply to each application for approval of extensions to an existing system, the sample being taken from the existing mains, should there be no proposed change in the source of supply.

An affidavit shall accompany any report of water analysis stating that the report of analysis and examination submitted is a true copy of the report supplied by the analyst, and that the water analyzed and examined was taken from the proposed source of supply. The date on which any sample was taken shall also be stated in the affidavit.

Detail Drawings.—Detail drawings shall be submitted to a scale which shall clearly indicate the design of all sections of the proposed system or extensions, including all wells, collecting galleries, intakes, filters, settling basins, reservoirs, conduits, standpipes, siphons, blowoffs, pumps, machinery buildings and other appurtenances.

In the case of a gravity supply, a profile of the route of the pipe line shall be submitted, showing surface elevations, the hydraulic gradient of pipe line, and air and sluice valves.

Specifications.—Specifications shall be submitted covering all work to be undertaken in the proposed system or extensions.

All detail drawings and specifications shall be accompanied by affidavits stating that the drawings and specifications so submitted are those to be used and followed in the construction of the proposed system or extensions.

Sanitary Sewerage Systems and Extensions.—A report shall be submitted, prepared by the engineer acting for the municipality, giving information under the following heads, in so far as such are applicable to the proposed works:—

1. Population—The present population and the rate of increase during each of the past five years. Available data justifying a future increase of population and probable increase in next ten years.

2. Maximum population which system will provide for if fully developed.

3. Population provided for by proposed works.

4. Area and topography of municipality.

5. Water consumption in municipality per capita per 24 hours.

6. The character of the sewage (with reference to surface and roof water, trade wastes, etc.)

7. Estimated maximum rate of flow expressed in gallons per hour.

8. Estimated normal dry weather flow expressed in gallons per 24 hours.

9. The general nature of subsoil throughout the municipality.

10. Precautions to prevent infiltration in water-bearing strata.

11. The minimum grades of all sizes of sewers.

12. Provision made for flushing and the intervals of flushing.

13. Character of pipes and joints to be used.

14. Type of sewage lifts to be adopted.

15. The maximum distance between manholes.

16. Ventilation of system.

17. Storm overflow discharges and any points of discharge other than the sewage disposal plant.

18. The areas of the municipality which cannot drain by gravity into proposed system. The proposed method of providing drainage for such areas in the future.

19. Provision to be made for inspection of construction.

20. Control and operation.

In the case of extensions to an existing system, the report shall, in addition to describing the nature of the proposed extensions, deal with as many of the above matters as are thereby affected.

Estimates of Cost.—A statement, prepared by the engineer, shall be submitted showing the estimated cost of the proposed system or extensions. The estimated cost of all pipe lines shall be shown in schedule form as follows: (See Schedule B, page 183.)

The estimated cost of all other sections of the work (e.g., manholes, inspection chambers, sewage lifts, etc.) shall be shown separately at the end of the schedule. The estimated cost of operation per annum shall also be given.

General Plans.—The following plans shall be submitted:—

(*a*) Plan of Municipality.—A general plan of the entire municipality to a scale of not greater than 200 and not less than 500 feet to an inch, this plan shall show:

1. Municipal boundary.

2. All streets existing or proposed.

3. The approximate location of all habitable buildings not connected with sewers at the date of application.

4. The surface elevations of all existing or proposed street intersections.

5. The location, size and direction of flow of all existing and proposed sewers.

6. The location of all existing and proposed manholes, lampholes, flush tanks, sewage lifts, sewer outlets, overflows and other appurtenances.

7. Any areas from which it is proposed to pump the sewage; these should be indicated by light coloring or shading.

(*b*) Contour Plan.—A contour plan of the municipality to a suitable scale.

Detail Drawings.—Detail drawings shall be submitted to a scale which shall clearly indicate the design of all parts of the proposed system or extensions, including all manholes, lampholes, flushtanks, siphons, pump wells, inspection chambers, buildings, iron work, machinery and other appurtenances. Transverse sections of all sewers over 24 inches in diameter shall be submitted.

Profiles of all sanitary sewers shall be submitted. The following scales are suggested for general adoption:

Vertical 10 feet to an inch
or 20 feet to an inch
Horizontal 80 feet to an inch
or 100 feet to an inch
or 200 feet to an inch

Profiles shall show all manholes, lampholes, flush-tanks, siphons, river and railway crossings, the size and grade of sewers, the elevation of sewer invert and ground surface at all manholes and changes of grade; elevation of river or stream beds crossing the line of sewers.

Specifications shall be submitted covering all work to be undertaken in the proposed system or extensions.

All detail drawings and specifications shall be accompanied by affidavits stating that the drawings and specifications so submitted are those to be used and followed in the construction of the proposed system or extensions.

Storm Sewerage Systems and Extensions.—A report shall be submitted, prepared by the engineer acting for the municipality, giving information under the following heads, in so far as such are applicable to the proposed works:—

1. Precipitation—All available data having reference to the maximum precipitation in the municipality, particularly with reference to short periods of heavy precipitation.
2. Nature of ground surface—The areas paved and unpaved, and in the case of the latter, the degree of porosity of the ground.
3. The area and mean slope of each district draining to a trunk sewer or point of discharge.
4. The data and assumptions upon which the computation of the size of sewers is based.
5. The estimated maximum volume of flow (in cubic feet per second) at each point of discharge, and the estimated increase when the system is fully developed.
6. The character of pipes and joints to be used.
7. The nature of coating (if any) to be used on the outside of pipes.
8. Any connections which it is proposed to make with the sewers, other than for surface water.
9. Provision to be made for inspection of construction.
10. Control and operation.

In the case of extensions to an existing system, the report shall, in addition to describing the nature of the proposed extensions, deal with as many of the above matters as are thereby affected.

Estimates of Cost.—A statement, prepared by the engineer, shall be submitted showing the estimated cost of the proposed system or extensions. The estimated cost of all pipe lines shall be shown in schedule form as follows: (See Schedule C, page 183.)

The estimated cost of all other sections of the work (e.g., manholes, catch basins, etc.) shall be shown separately at the end of the schedule. The estimated cost of operation per annum shall also be given.

General Plans.—A general plan of the entire municipality shall be submitted to a scale of not greater than 200 and not less than 500 feet to an inch; this plan shall show:

1. Municipal boundary.
2. All streets existing or proposed.
3. The surface elevations of all existing and proposed street intersections.
4. The location, size and direction of flow of all existing and proposed storm sewers.
5. The location of all existing and proposed manholes, catch basins and connections to the storm sewerage system, also all points of discharge and natural watercourses.
6. The extent of street paving.
7. The areas draining to each trunk sewer or point of discharge (these may be shown by distinctive coloring or shading).

Detail Drawings.—Detail drawings shall be submitted to a scale which shall clearly indicate the design of all parts of the proposed system or extensions, including all manholes, catch basins, valves, etc. Transverse sections of all sewers over twenty-four inches in diameter shall be submitted.

Specifications.—Specifications shall be submitted covering all work to be undertaken in the proposed system or extensions.

All plans, general plans, detail drawings and specifications shall be accompanied by affidavits stating that the plans, drawings and specifications so submitted are those to be used and followed in the construction of the proposed system or extensions.

Sewage Disposal Works and Extensions.—A report shall be submitted, prepared by the engineer acting for the municipality, giving information under the following heads, in so far as such are applicable to the proposed works:—

1. Population—The present population and the rate of increase during each of the past five years. Available data justifying an increase of population and probable increase in next ten years.
2. Maximum population which system will provide for if fully developed.
3. Population provided for by proposed works.
4. Water consumption in municipality per capita per 24 hours.
5. Estimated maximum rate of flow of sewage arriving at works, expressed in gallons per hour.
6. Estimated daily flow of sewage arriving at works.
7. The number of connections already made to sanitary sewerage system.
8. The character of the sewage (with reference to surface and roof water, trade wastes, etc.). Any excess over domestic sewage shall be estimated in gallons per hour under: (*a*) Roof water; (*b*) surface water; (*c*) infiltration water; (*d*) trade waste water.

   In the case of trade discharge the character of the waste shall be given.
9. The distance and location in relation to the works of any wells or underground source of water supply. In the case of the final effluent discharging into a watercourse or lake, it shall be stated whether such watercourse or lake is, or eventually becomes, a source of domestic supply or is used for watering cattle.
10. Minimum volume and velocity of stream or river into which the final effluent will be discharged.
11. Area of land acquired for sewage disposal purposes.
12. Character of subsoil through which sewerage system is laid, with particular reference to the presence of sand.
13. Character of treatment processes to be adopted.
14. Type of sewage lifts to be used at sewage disposal works.
15. Provision for dealing with sewage in the case of failure of sewage lifts.
16. Type of screens and provision for the removal of screenings.
17. Preliminary precipitation of mineral particles—velocity of flow in detritus tanks.
18. Type of sedimentation tanks, capacity and velocity of flow in tanks, inclination of base of tanks.
19. Method of drying sludge and final disposal.
20. Capacity of dosing or siphon chamber.
21. Type of filter beds; character, area and depth of filter media. Rate of filtration. Method of distribution over surface of media.
22. Retention of humus.
23. Disinfection of effluent.

24. Provision against frost.

25. Location of bypasses.

26. Provision for measuring and recording flow of sewage.

27. Future extensions.

28. Provision for grading, surfacing, etc.

29. Control and operation.

In the case of extensions to existing works, the report shall, in addition to describing the nature of the proposed extensions, deal with as many of the above matters as are thereby affected.

Estimates of Costs.—A statement prepared by the engineer shall be submitted showing the estimated cost of the proposed works or extensions. The estimated cost of each section of the work (e.g., land, pipe lines, sedimentation tanks, filter beds, mechanical appliances, buildings, etc.) shall be shown separately. The estimated cost of operation per annum shall also be given.

General Plans.—The following plans shall be submitted:—

(*a*) Location Plan.—A location plan to a suitable scale showing:

1. The location of the works in relation to the site of municipality.

2. The route of the main outfall sewer.

3. The layout of the various units of the sewage disposal works, including all drains, pipe lines, etc.

4. The area of land to be utilized for sewage disposal purposes.

5. The lake, watercourse or subsoil, into which the final effluent will be discharged.

6. Elevation of high, mean and low water in watercourse or lake.

7. Highest known flood elevation of watercourse.

8. Elevation of effluent drain at point of discharge and of outfall sewer at entrance to works.

(*b*) Sketch Plans.—Preliminary sketch plans shall be submitted to a scale which shall indicate the type and capacity of the various tanks, filter beds, etc.

The principal elevations and measurements of the various parts of the works shall be indicated on these plans. Such preliminary plans shall give sufficient information to enable the commissioner to arrive at a conclusion as to the efficiency of the proposed processes of treatment and design, and structural details may be omitted therefrom. Sketch plans need not be submitted if the detailed drawings required by section (4) accompany the application.

Detail drawings shall be submitted to a scale which shall clearly indicate the design of all parts of the proposed works. Longitudinal and transverse sections of all tanks and filters shall be shown.

Profiles of all pipe lines and drains shall be submitted drawn to a suitable scale.

Specifications shall be submitted covering all work to be undertaken in the proposed system or extensions.

All detail drawings and specifications shall be accompanied by affidavits stating that the drawings and specifications so submitted are those to be used and followed in the construction of the proposed works or extensions.

In addition, there is a set of general regulations applicable to the above respecting dimensions of drawings, samples, records, etc. A penalty is attached covering violation of the regulations.

Schedule A.

Location	Between	Size of pipe	Character of pipe whether steel, cast iron, etc.	No. of existing buildings requiring water	Average depth of trench	Length in feet	Cost of pipe laid complete per lin. foot	Total cost

Schedule B.

Location	Between	Size of pipe	Character of pipe whether fire-clay, concrete, etc.	No. of existing buildings requiring drainage	Average depth of trench	Grade %	Length in feet	Cost of pipe laid complete per lin. foot	Total cost

Schedule C.

Location	Between	Size of pipe	Character of pipe whether fire-clay, concrete, etc.	Average depth of trench	Grade %	Length in feet	Cost of pipe laid complete per lin. foot	Total cost

Some of the building contracts of engineering importance which are at present in progress at London, Ont., are the construction of two public schools at about $50,000 each, the Dominion Savings building at $200,000, the Wellington Street Methodist Sunday School, $12,000, a building for the Ford Motor Company to be used for the assemblage of cars and for a warehouse, $50,000; the reconstruction of the Princess Avenue School, $30,000; a large addition to the St. Joseph's hospital, and the reconstruction and enlargement of the Collegiate Institute

Recent reports state that the Illinois Central Railway has placed orders with the Pressed Steel Car Co., the American Car and Foundry Co., and the Standard Steel Car Co., for 2,000 cars, which will make a total of 5,000 purchased by that railway in June. Other orders reported are one from the Wabash Railway Company for 60 locomotives from the American Locomotive Co., and one from the Seaboard Company to the same engine builders for 30 locomotives. June has proven to be a considerably better month for steel manufacturers than did either April or May.

REPAIRING LEAKS IN AN 8-INCH MAIN 40 FEET UNDER WATER.

About two years ago a water main of 8-inch cast iron pipe with lead caulked flexible joints was laid across Galveston Channel, which is the waterway lying along the wharf front at Galveston. It extended from the wharf front, where it connected with the city water main, to the pile dike on the north side of the channel, a distance of 1,400 feet, thence was laid in a shallow trench along the dredge spoil bank. The portion across the channel was laid in a trench 40 to 100 feet wide, dredged to a depth of 41 feet across the entire width of the channel, which was then about 30 feet deep for 500 feet of its 1,400 feet width. Cast iron pipe was used with flexible joints of the ordinary ball-and-socket type, which allowed a deviation from a straight line of about 12°. The ordinary lead caulking was used with yarn packing. The greater portion of the line was laid by caulking up and lowering one pipe at a time, the line of pipe being carried on an inclined trough from the barge nearby to the bottom of the trench and the barge being fleeted forward as the line lengthened. Soon after the laying was completed and water had been turned into the main, leaks began to develop due partly to the method of laying and to the uneven character of the bottom, which caused such a great deflection at each joint that the lead caulking was squeezed out, and to the fact that the line

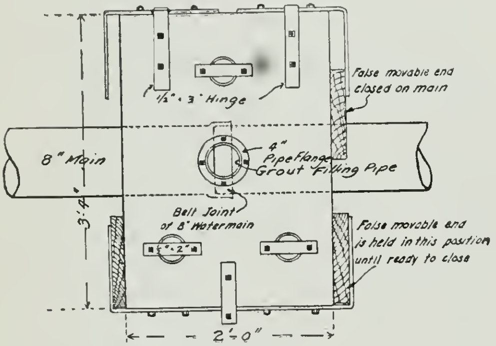

Fig. 1.—Top Plan of Form Used in Repairing Water Main.

was caught by a ship's anchor before completion. Efforts were made to recaulk the leaky joints by the aid of a diver, but these efforts were unsuccessful as it was found the pipe was deflected at these points to such an extent as to close the caulking space on two sides. After considerable thought and investigation, a method of stopping the leaks was evolved which has proven entirely successful. The method is described by Mr. N. T. Blackburn in the July-August issue of Professional Memoirs of the U.S. Army Corps of Engineers, as follows:

The method was simply the placing of a wooden box form around each joint and filling this form with neat Portland cement grout. Each form was supported on three 3-inch pipes, 14 feet long, driven down through holes in the forms into the underlying clay so as to form a pile foundation and prevent any settlement at the joint due to extra weight.

The form, shown in detail in the accompanying drawings, is 3 feet 4 inches square by 2 feet deep, hinged at one edge so that it opens diagonally. In the top is a 4-inch hole with a pipe flange for connecting a 4-inch pipe extending to the top of the water, and through which the grout was poured from the barge into the form. To the front of the lower half was fastened a chain which helped close it and held it closed afterwards, one link being let over a hook attached to the upper half and screwed up until form closed tight. In either side, where main passed through, a square hole 18 inches by 18 inches was left in order that the form would close no matter if the joining pipes were at their greatest possible angle, either vertical or horizontal. A movable section consisting of two pieces, 2 inches by 12 inches by 3 feet, each cut out in the form of an 8-inch semi-circle to take half of the main, closed around the main, tightly covering and at the same time entirely closing the 18-inch square holes. These false ends work outside of the form and are held in position by iron straps under which they can move in any direction against its side. Three holes large enough to take 3-inch pipe were bored through the top and bottom of the form for the piling. They were so bored that two piles would go on one side of the main and one on the other. After the pipe piles were driven down through the form flush with the top, a one-half inch iron plate was laid over the top of the pile and bolted to the form to carry the weight until the cement set around the piling.

The trench in which the main lies had been partly refilled with clay thrown into it by a dredge and by the natural deposit of sand, mud, and silt carried in by the cross currents and tides. This filling was partly removed with a 20-inch suction dredge, but fear of disturbing the main kept the dredge from working closer than about 4 feet of its top. After the dredging was done the water was cut off the main, air pressure put on and leaks were located by the air bubbles coming to the surface of the

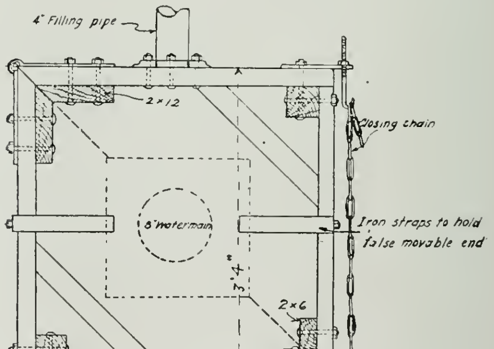

Fig. 2.—Side Elevation of Form.

water. All leaks of any consequence were marked by dropping a weight into the hole blown through the mud over a leak by the air and carrying a line ashore from the weight. It was not safe to use buoys for marking the leaks, as they were liable to be carried away by ships and all leaks had to be located and marked before repairs were commenced as the air pressure had to be taken off the line and kept off until the cement was thoroughly set.

The plant used consisted of a derrick barge and a barge with an 8-inch belt-driven sand pump. A diver was in constant attendance.

The method of placing the form and filling with grout was as follows: The barges were anchored at the leak and the overlying sand and mud first pumped off the pipe. Then to the flange coupling on the form was connected a 45-foot length of 4-inch pipe. Three rope lines were fastened to the front of the lower jaw of the form, one to the end of the closing chain and one near each side. The diver then took all three of these lines down around under the main and back up on the barge where a man was stationed at each line. Then, as the form was lowered away by the derrick with a line from the 4-inch pipe, the men took in on these lines and the lower half of the form, which dropped open when the form was picked up, was guided into place under the main. By lowering the upper half the form was closed. The piling was then set in the holes provided in the form and were driven flush with the top and the iron straps bolted over them. A jet was then put into the form through the 18-inch square openings and any mud in the form driven out and the joint thoroughly washed off. A piece of raveled, loose rope yarn was then tied securely around the leak to keep the cement

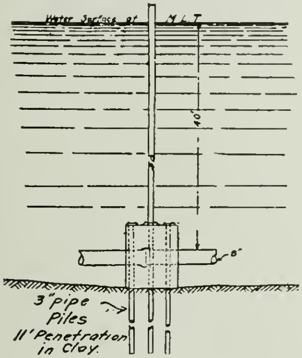

Fig. 3.—Form in Place.

from entering the main. The false forms over the ends of the form were then driven into place around the pipe and the form was ready for cement. The cement was mixed with salt water to a thickness that would just pour through a funnel into the 4-inch pipe leading down into the form. It was found necessary to pour it slowly in order to give it time to settle. Displaced water went out of the form through the holes around the piling in the top of the form. When the form was filled, the nuts on the bolts in the flange union fastened to the form were taken off and the 4-inch filling pipe removed, and the job was finished.

On the last leaks which were closed, pouring the cement through the pipe was abandoned owing to too much lost time in waiting for it to settle. The pipe, however, was still used to lower the form and to hold the form in position until piling were driven. After this it was taken off and the cement, which was mixed as thick as possible, was lowered down to the diver in buckets and poured into the form through the hole at which the pipe had connected.

Where the soft mud and silt was so bad that it could not be kept out of the form, a 4-inch centrifugal pump with a flexible suction end was used to clean out the form after it was in place and all closed, the mud being pumped out through the cement filling hole while a jet alongside stirred it up. In the work of closing these leaks it was found necessary to have the pipe and inside of the form absolutely clean, so that the cement would adhere to the pipe. It was found necessary to take the form off the first leak and do the work all over again, as mud had been pocketed in the grout.

When repairs were completed, all cement was allowed to set a week. About 40 pounds of air pressure was then put on the main and kept on for over an hour. During this time not a single air bubble could be seen and the water meter showed the leaks had been stopped.

Four leaks were repaired and the entire work was executed in about four weeks, including the time of assembling plant, dredging, building forms, etc. By actual time a form was lowered and fastened around the pipe in forty-five minutes. To close the false end gates of the form required fifty minutes. To drive the piles required from one to one and a half hours, depending on how hard the driving was. To mix the cement and fill the form required one hour and fifteen minutes. The total cost of the repair work, closing four leaks, was $2,300.

CARE OF RAILWAY BRIDGES.*

BRIDGE work is a perpetual and continuous job like track and all other classes of railroad work, but the kind and amount of the different varieties of the work changes with the seasons. In the winter surveys should be completed and plans made for future work, and maintenance should be kept up at the least possible expense. Light construction work should be dropped while heavy construction work on abutments, piers, and mass concrete can be pushed to advantage, especially in localities where the ice is strong enough to be of assistance in handling the work, and also where low water is necessary.

In the spring all bridges should be closely inspected and the necessary repairs ordered. Various methods for making inspections are in vogue. The general inspection may be annual or semi-annual, and be added to by periodical local inspections. When semi-annual, the fall inspection is made with a view of seeing that everything is in shape for the winter and to decide on the construction or heavy maintenance work to be considered and investigated for the next season's operations, while the spring inspection is for the purpose of planning and starting the work to be done in the immediate future.

On many roads the bridge engineer makes the general inspection of the large bridges and permanent work, while the inspection of the smaller temporary or wooden structures is left to the local officers. On at least one of the large western roads this process is reversed and the bridge engineer inspects the temporary structures yearly, leaving the permanent structures for the local officers. Possibly it would be well for bridge engineers to combine the two methods and inspect all bridges.

The maintenance and construction forces should be built up and work started as early in the spring as possible so that the beginning of summer will see the work well under way. All pile drivers, machinery and tools should be overhauled and repaired; material ordered, delivered and unloaded, and complete preparations made so that once work is started it can be pushed ahead without delay. A definite programme in the delivery of material to each bridge or each job of work should be outlined and insisted on so that there need be no delays waiting for material, and it should be so arranged that gangs can fully complete each job and then go to the next job without any delay.

*Railway Age Gazette.

The summer is the season for doing the systematic work of repairing, renewing, filling or replacing with permanent structures every bridge on the line as it may need. The work is done by gangs of various sizes which may be either permanent or extra gangs as the work may demand. The pile driver is generally handled by a regular gang, although the method of having each bridge gang educated so that it can also handle the pile driver is sometimes advocated. However, as each road tries to get along with a minimum number of pile drivers so that it is desirable to keep them working at their maximum efficiency at all times, this latter method is of doubtful economy.

On account of the scarcity of foremen and of labor and the advantage of getting work done immediately with as little travelling as possible the combining of the bridge work with section work, signal work and other maintenance work is beginning to be advocated. There are many strong arguments in favor of this and should it be found successful it is likely to reorganize our entire maintenance system and methods. The past 15 years have witnessed very radical changes in the construction of permanent waterway openings due to the use of concrete and steel, and the future will be likely to add to these and thereby also change our methods of maintenance.

As temporary bridge structures are replaced by steel and concrete the amount of maintenance work is very materially decreased. Bridge gangs are replaced with carpenter gangs, painters' gangs, plumbing gangs, etc., as development of the country necessitates. The building up of towns and cities makes it necessary to do much more work around the station grounds than formerly, and the quality and kind of work varies with the nature of the public improvements. Sewers, pavements, permanent platforms, water supplies, plumbing, electric lighting, electric power and other features of latter day progress make it necessary for the railroads to employ specialists who can best handle the necessary work.

Small jobs of construction work and indeed all construction work that it is possible for them to handle should be done by the regular maintenance organization, but large construction jobs require a separate organization which should be flexible as to size and which can be moved from place to place as exigency requires.

Permanent structures in the past have been largely put in by contractors, mainly for the reason that the railroads have not had the necessary equipment for handling the work. However, as they have become larger and permanent work has become more general, it is now becoming customary for the railroads to do their own masonry and steel erection work. Whether they save money in all cases by doing this is questionable, when the cost of the equipment with interest and depreciation is taken into consideration. Undoubtedly where construction work is continued from year to year requiring permanent forces, outfits and machinery, they save the contractor's profit, but in many cases the amount of work and the inexperience of the men makes the cost more to the railroad company, although this fact may not be evident on the surface of their accounts.

During the summer months all the bridge work should be pushed to completion as rapidly as possible, so that in the fall all that remains to do will be to get every bridge and opening in shape for the winter. This not only means that its strength and condition should be cared for, but that the waterways themselves, including the channels and ditches, should be clean and free from obstructions, so that there will be a free flow of water to and from the openings, that the openings may fulfil the purpose for which they were constructed.

As most of the railroads in this country were constructed in a time when timber was cheap, many pile and trestle bridges and timber culverts were built which are being replaced more or less rapidly with permanent structures. This has been accelerated of late years by the use of concrete and the consequent cheapening of the permanent openings. The life of the timber bridges has also been lengthened in many cases by the use of creosoted timber. This material is especially applicable in cases where the bridge decks have to be replaced oftener than the piles, and many years are often added to the life of the bridge by the use of a creosoted deck which may be filled in and ballasted.

When the original timber bridges were built, but little attention was paid to the size of opening required to properly carry the water, so long as it was large enough.

With permanent structures this is not a sufficient rule on account of the greater cost, and the size of openings should be proportioned to the use required of them. This makes necessary complete surveys and investigations of the bridge, its drainage area and outlet. These surveys should be made or started as early in the fall as possible, so that time may be had for considering each bridge and designing the necessary structure, culvert or pipe for the opening in order that the material may be ordered and delivered in time for the next summer's building.

In considering the amount which can profitably be spent for replacing temporary with permanent structures, the first cost of the temporary bridge should be taken together with such an amount as will, when put at interest at current rates, provide for its maintenance and periodical replacement at such times as it may wear out. A common wooden pile bridge can be replaced by a permanent reinforced concrete pile bridge on a ratio at present-day prices of about 3 to 1, while there are many cases of bridges or trestles which can be replaced by reinforced concrete culverts, boxes or pipes for even less than the cost of a wooden structure. The use of reinforced concrete for many railroad structures is growing rapidly and merits the full investigation of every railroad engineer. Pipes, culverts, boxes, highway bridges, subways and overcrossings, arches, trestles, bridges and retaining walls are now being permanently and cheaply constructed of this material, to say nothing of buildings, tanks, coal chutes and other uses for which it is being rapidly adopted.

RAILROADS OF BRITISH COLUMBIA.

It is estimated that during 1913, 650 miles of new railway, not including double-tracking, were laid in British Columbia, of which 285 miles are credited to the Grand Trunk Pacific, 212 to the Canadian Northern, 75 to the Kettle Valley Railway, 65 to the Canadian Pacific, 19 to the Esquimalt and Nanaimo Railway, 18 to the Pacific and Great Eastern, 5 to the Victoria, Vancouver and Eastern, and one-half mile to the Western Canada Power Co. There were also 66 miles of double-tracking, 59 of which is credited to the Canadian Pacific, and 7 to the Victoria, Vancouver and Eastern.

It is announced in the Scientific American that earthquake construction has now reached a very practical stage in the seismic districts of Italy, where all new buildings are being erected under strict supervision with regard to their ability to resist earthquake shocks. Professor Omori, the Japanese authority, has estimated that 99.8 per cent. of the deaths in the great Messina earthquake of 1908 would have been prevented if the buildings had been properly constructed.

A METHOD OF FIGURING REACTIONS FOR CONTINUOUS BEAMS.

By I. F. Morrison, S.B.,
Lecturer in Structural Engineering, University of Alberta.

The subject of continuous beams has received considerable attention in several of the latest text-books. The methods usually employed, however, are not, in all cases, conducive to their practical application. Only a limited number of cases for different loadings can be found already worked out and for this reason a rigid application of the theory is often avoided in practice. Rapidity, accuracy and ease with which results are obtained, are the requisites of any engineering practice, and it is hoped that the following method will promote all of these, as well as stimulate those who are interested to add more to what is here presented.

The general equation for the theorem of three moments for beams of constant modulus of elasticity and moment of inertia can be written as follows: (See article by Prof. Slocum in the Engineering News, Feb. 19, 1914.)

$$M_1l_1 + 2M_2(l_1 + l_2) + M_3l_2 = -\Sigma P_1 l_1^2(k_1 - k_1^3) - \Sigma P_2 l_2^2(2k_2 - 3k_2^2 + k_2^3) - 6EI\left(\frac{h_1 - h_2}{l_1} + \frac{h_3 - h_2}{l_2}\right);$$

where E is the modulus of elasticity and I the moment of inertia of the sectional area. The remaining notation may be obtained from Fig. 1.

If the supports are on the same level, and the load P_1 is unity and P_2 is zero, then the formula becomes:

$$M_1l_1 + 2M_2(l_1 + l_2) + M^3l_2 = l_1^2(k_1 - k_1^3).$$

If P_1 is zero and P_2 is unity, it is,

$$M_1l_1 + 2M_2(l_1 + l_2) + M_3l_2 = l_2^2(2k_2 - 3k_2^2 + k_2^3)$$

In applying these equations to any particular case an influence line may be plotted for the various values of k which lie between 0 and 1. Take the case of a continuous girder with two equal spans. Consider the load of unity in the first span only. Since $M_1 = 0$ and $M_3 = 0$

$$2M_2(l + l) = l_1^2(k_1 - k_1^3)$$

$$M_2 = \frac{l}{4}(k_1 - k_1^3).$$

$$\text{Then, } l\,R = \frac{l}{4}(k_1 - k_1^3) + l\,(1 - k_1).$$

$R_1 = 1 - 5/4k + \frac{1}{4}k^3$ upwards
$R_3 = \frac{1}{4}(k - k^3)$ downwards
$R_2 = \frac{1}{2}(3k - k^3)$ upwards.

The following table gives the values of R_1, R_2, and R_3 for values of k from 0 to 1 with the load of unity in the first span only:

k	R_1	R_2	R_3
.0	+1.0000	+ .0000	—.0000
.1	+ .8753	+ .1495	—.0247
.2	+ .7520	+ .2960	—.0480
.3	+ .6318	+ .4365	—.0683
.4	+ .5160	+ .5680	—.0840
.5	+ .4062	+ .6875	—.0937
.6	+ .3040	+ .7920	—.0960
.7	+ .2108	+ .8785	—.0893
.8	+ .1280	+ .9440	—.0720
.9	+ .0572	+ .9855	—.0427
1.0	+ .0000	+1.0000	—.0000

From this table the influence line shown in Fig. 2 may be plotted.

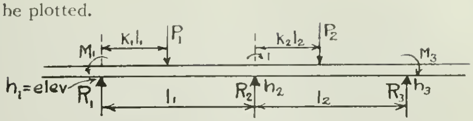

Fig. I.

In this case it is not necessary to work out a table for the unit load in the second span because the curves are symmetrical, as may be seen in the figure. Since the influence line for any particular number of supports and ratio of spans is always the same, after it is once plotted it may be used to solve problems for any loading.

Problem 1.—Consider a continuous girder with two equal spans, with a uniformly distributed load of w pounds per linear foot over both spans. Since the product of the ordinate to the influence line at any point and the load at that point will give the value of the reaction for which the influence line is drawn, it is only necessary, in this case, to find the area under the curve. The areas below the horizontal axis are considered to be negative areas.

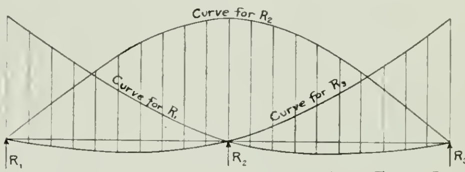

Fig. 2.—Influence Lines for Reactions. Two Equal Spans.

For those who are familiar with the calculus, it is sufficient to say that the area may be quickly obtained by integrating each curve from $k = 0$ to $k = 1$. This will be found to give the well-known values:

$R_1 = \frac{3}{8}wl$ upwards,
$R_2 = 5/4wl$ upwards,
$R_3 = \frac{3}{8}wl$ upwards.

The following graphical method is found to be more convenient as well as useful. It consists of drawing a curve such that the ordinate at any point will give the area under the influence line between the ordinate and the reaction R_1. This curve, which has been called the area curve for the lack of a better name, is also the same for any particular number of supports and ratio of spans and therefore when once obtained may be applied for any loading. The influence line is plotted first, as shown in Fig. 3, and each ordinate has been multiplied by w. The

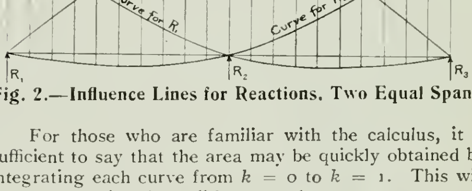

Fig. 3.—Area Curve for R_2.

middle ordinate is then drawn for each strip and horizontal lines are drawn to intersect the vertical ordinate at R_2. R_1 is chosen as a convenient pole and a new curve is constructed, as shown by drawing a string parallel to each ray in turn until it intersects the ordinate which bounds each strip on the left. The last ordinate on the new curve

is the total area under the influence line. In this case it is 1.25 w on the same scale as the ordinates to the influence line. From this R_2 = 1.25 wl, as given above. R_1 and R_3 may be obtained in a similar way from Fig. 4.

If the area curve has been drawn, as has been done in this case, for w = 1, then any distribution of uniform loading may be dealt with as follows: Lay off on the span the part which the uniform load covers and draw the ordinates at each end to the area curve. The difference in value of these ordinates multiplied by the loading per linear foot between the ordinates multiplied by the span in feet will give the reaction for that loading. The area curve for R_1 and R_3 is shown in Fig. 4, and has been constructed in the same way as that for R_2 in Fig. 3.

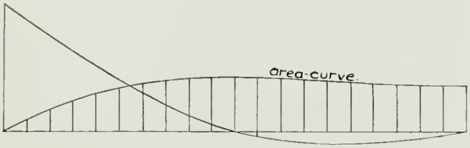

Fig. 4.—Area Curve for R_1.

In dealing with concentrated loads the ordinate to the influence line multiplied by the load at the ordinate will give the reaction. Each load is considered separately and the results added to obtain the total reaction.

Problem 2.—Consider a continuous girder of two equal spans of 12 feet and loaded as shown in Fig. 5.

To find the centre reaction R:

From the area curve (Fig. 3) the difference in ordinates at
k = 1/12th and k = 6/12ths the span from R_1 is + .180
k = 2/12ths and k = 11/12ths the span from R_2 is + .460

The ordinate to the influence line (Fig. 2) at
k = 9/12ths the span from R_1 is - - - + .918
k = 8/12ths the span from R_2 is - - - + .470

+ .180 × 200 lb./1 × 12′ = + 432
+ .460 × 100 lb./1 × 12′ = + 552
+ .918 × 500 = + 459
+ .470 × 200 = + 94

R_2 = Total = + 1537 pounds upward for the loading given.

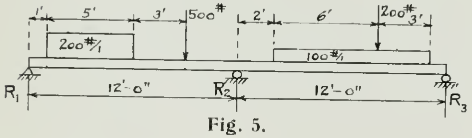

Fig. 5.

To find the end reaction R_1

From the area curve (Fig. 4) the difference in ordinates at
k = 1/12th and 6/12ths the span from R_1 is + .261
k = 2/12ths and 11/12ths the span from R_2 is —.061

The ordinate to the influence line (Fig. 2) at
k = 9/12ths the span from R_1 is - - - + .166
k = 8/12ths the span from R_2 is - - - —.078

+ .265 × 200 lb./1 × 12 = + 636
—.061 × 100 lb./1 × 12 = — 73
+ .166 × 500 = + 83
—.078 × 200 = — 16

R_1 = Total = + 730 pounds upward for the loading given.

To find the end reaction R_3

In this case the curves in Fig. 4 must be reversed or the loading and reactions may be reversed. Therefore, take R_3 to the left.

From the area curve (Fig. 4) the difference in ordinates at
k = 1/12th and 10/12ths the span from R_3 is - + .347
k = 3/12ths and 11/12ths the span from R_2 is - —.034

The ordinate to the influence line (Fig. 2) at
k = 8/12ths the span from R_2 is - - - + .595
k = 9/12ths the span from R_1 is - - - —.058

+ .347 × 100 lb./1 × 12 = + 417
—.034 × 200 lb./1 × 12 = — 82
+ .595 × 200 = + 119
—.058 × 500 = — 29

R_3 = Total = + 425 pounds upward for the loading given.

To check the work, the sum of the three reactions must be equal to the sum of the vertical loads.

Sum of vertical loads = 2,600 pounds downward.
Sum of reactions = 2,592 pounds upward.
Error - - = 8 pounds.

From this it will be seen that the error made by using this method, with no more than ordinary care, is well within the limit allowable for practical work. The diagrams used were drawn to a small scale. Greater accuracy may be obtained by using a larger scale, though a very large scale is not to be recommended because the accuracy of the graphical construction decreases rapidly when the scale becomes excessive.

PRODUCTION OF CASINGHEAD GASOLINE IN CALIFORNIA.

Estimates made recently in connection with the development of casinghead gasoline, as the fluid extracted from wet gas is called on the southern Pacific coast of the United States, show that the production will have increased by the fall of this year about 40 per cent. over what it is now, and, it is believed, nearly 100 per cent. in the next 6 months.

The present output of all the plants in California exceeds 20,000 gallons per day. Compressors are operated in all parts of the state, except in the Midway field. It is only recently that the first compressor plant was installed in Coalinga field, on the Turner Oil Company's property; and this has proven to be a very successful one, turning out about 2,000 gallons daily. Other plants throughout the state are yielding from 500 to 2,000 gallons per day.

At present the Union Oil Company in Santa Maria field is making additions to its plant, so as to give it a capacity of 8,000,000 cubic feet of gas per day. This compressor plant will cost nearly $500,000, and, it is said, will be the largest in the world. Further enlargements are being made also in the Santa Maria field on the plant owned by the Rice Ranch Oil Company and on that of the Purity Gasoline Company, so that, when completed, the former will be capable of producing 2,000 gallons a day and the latter 1,500 gallons.

All this is shown in contrast to the fact that two years ago, in the state of California, about 1,000 gallons per day represented the total output of casinghead gasoline.

The product is very high-grade and is mixed with one to one-and-a-half parts of distillate before it is used commercially. Consequently the production secured for commercial purposes may practically be estimated at 50,000 to 60,000 gallons a day, worth at present wholesale prices about $600,000. The value of the casinghead gasoline output, untreated, is lower, being about $300,000.

Mills Brothers, Toronto, now have their office at 215 Ryrie Bldg., not in the Lumsden Bldg., as stated in a recent issue.

Editorial

TRACKAGE REQUIREMENTS OF INDUSTRIAL ENTERPRISES.

One of the chief problems in connection with factory construction is trackage. We are disposed to term it a "chief" problem for the reason that in designing a layout for factory and industrial enterprises it often happens that neither the architect, engineer nor owner gives the matter of trackage much thought. He relies on the supposition that after the land has been acquired and the building erected the tracks can be run into it without trouble. This is a serious oversight, as an important factor in the success of an industry is the quick and economical handling of the raw material to the factory and of the finished product away from it.

As Mr. G. H. Herrold, C.E., of the Civil Engineers' Society of St. Paul, remarked when discussing Mr. King's paper, appearing, in part, in this issue: "A first-class factory poorly erected with reference to trackage, resulting in awkward switching facilities, is only half a factory."

In designing such trackage, it is necessary for the engineer to be familiar with the daily car requirements of the establishment and also with railway switching methods in general and the particular switching services to be obtained at this point. It is sometimes stated that designers of factories have little conception of permissible grades or curvature for practical switching. This often results in requiring additional land for right-of-way, and a track longer than necessary. Sometimes it also requires the building of trestle work or the making of excessive fills in order to bring the track to the factory at the proper level and give a length of track along the factory, which should be level to permit the hand-shifting of cars, if necessary, during the day.

That the tracking problem is not given some attention by our designing engineers of factories is, of course, generally untrue. Nevertheless, it forms a vital part of factory equipment and constitutes requirements to suit the individual case. The simplest track possible is one switch and a stub track running along the factory, which may serve the purpose for small outputs, although a double-end track is more desirable, as it facilitates better handling of the cars. If the nature of the industry is such as to require a different class of cars for the finished product than for the raw material, arrangements should be such that empties and loads can be placed at the factory doors in the morning in the order required and the loads and empties removed from the other end of the track in the afternoon without disturbing any cars not yet unloaded or being loaded. If the business of the factory is sufficient to require two or more tracks, one should run at each side of the factory, one for raw material loads only and the other for loading and outgoing loads only. This is in line with the general tendency of factory design to begin its processes at one side of the factory and deliver the finished product on the other side, eliminating cross-handling as much as possible.

Referring to the remarks of Mr. Herrold, the economical design of factory buildings involves the following problems in approximately the order given:

A study of the processes to be carried on in the factory.

The design or selection of the machinery.

The layout of the machinery and determination of floor space.

The layout of yard room.

The determination of the daily car requirements.

The investigation of switching service in the locality selected for location.

The design of the track layout desired.

The fitting of buildings and tracks to the ground owned or available by actual surveys.

The general revision of all plans to compromise with conditions.

LONG CONCRETE ARCHES.

In the progressive march of science and engineering there occurs, at intervals that possess a semblance of periodicity, epoch-making events whereby the veil of familiarity is lifted to display before the world some superlative achievement, surpassing all others existent in its class, but almost inevitably destined to experience, some day, the event of being itself similarly surpassed. The literature of the engineering profession makes frequent reference to some new enterprise which is, for a brief period of time, "the largest in existence." Bridges, tunnels, dams, ocean liners, sky-scrapers, canals, hydro-electric power developments, etc., have all at one time or another taken advantage of our susceptibility to regard them, unthinkingly, as the last word in their particular line of engineering enterprise. The frequency of such occurrences, however, has come to be a mark of engineering activity throughout the world.

The design and construction of reinforced concrete bridges serve as an illustrative example of this progress. Since the beginning of the 20th century there have been a dozen or more occasions to refer to some new and surpassing construction throughout the various countries.

In *The Canadian Engineer* for June 27th, 1912, an article was published describing the Ponte del Risorgimento, which, with its arch span of 328 ft. in a 33-ft. rise has for several years maintained its distinction as being the largest reinforced concrete arch in the world. It was built in 1911 over the Tiber in Rome, and its design was noteworthy in that at its crown the thickness of the arch is only 8 in., increasing to 20 in. at the springing lines. Stiffening ribs, 8 in. in thickness, extend throughout its entire length.

This bridge over the Tiber has resigned its distinctive greatness to an arch which is now being constructed at Langwiez, Switzerland, and which has a 330-ft. span. This bridge, however, unlike its predecessor in design, is of massive construction, with a rise of nearly one-half of its length.

The Ponte del Risorgimento, noted above, had taken the title from the Grafton bridge in Auckland, New Zealand. This was a reinforced concrete structure with a 320-ft. span and a rise of 86 ft. begun in 1907 and completed in 1910. The Munro Street bridge in Spokane, Wash., also of concrete, had a span of 285 ft. and a rise of 117 ft. For a list of long concrete arches giving dates of erection, principle dimensions, etc., the reader is referred to *The Canadian Engineer*, Vol. 22, No. 26, page 843.

ECONOMICAL DESIGN OF INDUSTRIAL WORKS.

THE economical design of factories involves the solution of a large number of simple engineering problems and requires a broader knowledge of engineering than most types of buildings. The designer should be an engineer. He should have a fair working knowledge of architecture as well as of civil, structural, mechanical and electrical engineering, and he should acquire a clear understanding of the particular machinery to be installed and the processes to be carried on in the construction he is setting about to design. It is the work of an industrial engineer rather than an architect, but the former should not minimize the importance of the architectural requirements of the work and devote all his attention to the considerations of economy of construction and efficiency of operation. Although the æsthetic considerations are not as important, they should be given due consideration.

In a paper presented to the Civil Engineers' Society of St. Paul by W. E. King, C.E., and published in the June issue of the Association of Engineering Societies, the work of the industrial engineer in the design of industrial structures is discussed and the problems relating thereto are outlined in order to give a general view of the economics of this form of construction. The following is extracted from Mr. King's paper:—

The first consideration is the proper locality for the industry. This is largely an economic problem, which the engineer may or may not be required to study.

The cost of any manufactured commodity to the retailer consists of the following items: Cost of raw materials, cost of the transportation of these raw materials to the factory, cost of labor on materials, cost of power, overhead charges, including interest on money invested, depreciation of plant, insurance, office time and advertising, cost of distribution, profit to the manufacturer.

Assuming the price to be received for any finished commodity to be fixed by competition, then that project which will pay the largest profits, is, of course, the one where the sum of the first six charges is a minimum. This does not necessarily mean that any one item should be reduced to a minimum, but that the sum of all the items taken together is the least possible. The usual difficulty is that some one man almost always plans each project with the idea of reducing some one item to a minimum. For instance, a man who has spent the larger part of his time in handling of workmen will insist that the plant be so located that there will be an abundance of cheap labor. If he had at one time been a purchasing agent he would plan his plant to save all freight possible on raw materials. The sales manager is interested in the location of the factory with respect to the market. The man who furnishes the money is sometimes unduly interested in cutting the first cost down to a minimum, without regard to whether the interest on his money might be larger if more money were invested.

It should be the duty of the engineer to study these questions and to so present them that they will occupy their proper rank of importance. This rank is, of course, different in different kinds of factories. In the fabrication of structural steel, for instance, perhaps the most important factor is freight. This includes freight from the rolling mill to the factory and freight on the finished product from the factory to the consumer. In some parts this freight amounts to more than half the cost of the finished product.

Where freight is one of the chief considerations, charts may be prepared showing the zone in which a product may be profitably marketed. The boundary of each zone will be determined by considering the sum of the freights on raw and finished materials for the proposed location as compared with other possible locations. The properly prepared chart will show the overlapping territories where competing factories sell on an equal basis. It will show the area where the factory in question has the advantage, and it will also indicate the areas which cannot profitably be reached.

The matter of available market probably reaches its greatest importance when the capacity of a profitable factory is about to be increased. It may be that the selling organization is now reaching all of the profitable market zone, and that to increase the sales the product must be marketed at a disadvantage.

Some industries use large amounts of fuel or power, which requirement is the determining factor in their location. In connection with this there is a tendency to group factories around water-power sites, which will probably not be as marked in the future, because our modern methods of electrical transmission allow power to be economically delivered at a considerable distance.

Having determined on the vicinity where the factory is to be built, the next consideration is the purchase of the exact site necessary for the project. The exact area of land which is necessary is usually a troublesome one. Most successful projects are hampered by lack of room to provide for their growing needs. On the other hand, it is a serious handicap to a young industry, to be burdened with heavy interest charges and taxes on land not at the time in use.

The size and shape of the area necessary for present needs is usually determined by making a preliminary plan of the whole project. If the engineer be unfamiliar with the need of the industry in question, this will usually involve quite an extended study of the methods of manufacture used by the particular organization and of similar organizations in other places. If, however, the designer has already prepared plans for other similar plants, the tentative preliminary plans involve only a study of the peculiar requirements of the special case. This preliminary plan should, of course, take in the reasonable growth of the industry, which usually may be approximately obtained by a comparison with similar industries in other communities. With the approximate area required clearly in mind, a search of the locality will usually show a number of available sites. For projects of some importance, plats are usually prepared showing how the proposed sites may be developed. These plats should show the approximate grades and elevations of all adjacent streets, the location of sewer, gas, water and power connections and the available connection to adjacent railroads or sidetracks. If grading of streets or of the lots will be necessary, this should be estimated and added to the comparative price of the lots. For the purposes of comparison the cost of the sidetrack, including necessary grading, the cost of sewer, water, gas and power connections should be obtained. Very often the owners will buy a lot first, without considering the cost of these things, which must be added to make the lot available, and in so doing they fail to get the most economical site. Plats showing the proposed sidetrack should be submitted to the railways interested and assurance should be had from their engineering and contracting departments that they are willing to put in the desired connection. If the sidetrack must cross the public road it is just as well to be sure of the permit before putting money into the lot.

Sidetracks.—At this time a study should be made to determine the number and length of sidetracks which will be required. In general, the track should be long

enough to hold as many forty-foot cars as the company will need to load and unload in any one day. In isolated places, where the cars are not set as often as that, the sidetrack must be long enough to allow for all the unloading and loading which must be done between each setting by the switch engine. Sidetracks for loading and unloading should in general be level. The rules of the railroad in question, of the state and interstate railway commissions and the state labor laws are the determining factors in the amount of room required for sidetracks.

Building Plans.—After the exact location of the site is determined, then the plans of the buildings may be prepared. It is a mistake to make the final plans of any building before its definite location is settled. The natural grades of the land itself, the streets, the points of the compass and the condition of the subsoil almost invariably change the plans to such an extent that they must be revised or redrawn. All of these conditions should be determined by an exact survey before work on the plans commences.

As before stated, the basis for the design of the factory building should be a complete understanding of the processes to be carried on in the building. Too many factories are built first and the machinery just put in, one piece at a time, after the building is completed. This usually results in the uneconomical use of the floor space, unused spaces occur in some parts and a congested condition results in other parts.

The first plans to be prepared should be complete machinery plans. A study should be made of the progress of the materials through the shop. In general, the manufacturing processes should be so arranged that there will be no lost motion. The various materials which go to make the finished product should all travel through the various parts of the factory in such a way that they will arrive at the assembling-room without having travelled any greater distance and without having been transferred more times than is absolutely necessary. Leaving the assembling-room, the materials should go by the shortest possible route to the storage and shipping-rooms. This part of the work is, of course, best planned with the prospective superintendent of the shop. It is sometimes difficult to get the benefit of this man's detailed knowledge and experience without letting his narrowness of viewpoint blind the designer to the broader phase of the question.

As a rule, a good factory superintendent has spent the larger part of his life in some one factory. He probably has made that factory a success. That leads him to think that he knows all there is to know about that business. At least he thinks he knows more than any engineer whom the owners can hire. That is generally true, but his difficulty is that he is so close to his job that his perspective is warped. For instance, if ten years ago he tried a belt-conveyor in his factory which he bought and installed improperly himself, and then afterward abandoned because it did not do the work required, he is convinced that he does not want a belt conveyor in his new factory. The fact that belt-conveyors have been improved since he tried them and that there are thousands of them working satisfactorily under similar conditions will impress him only if you can overcome his prejudices. If you can make him feel that he and the engineer are working together to get the best possible design and that you realize the value of his suggestions, then, generally, it is possible to get him to listen to yours.

The building should be built to suit the machinery. The columns and beams, the height of stories, the location of heating and plumbing pipes, the sprinkler system, the natural and artificial lighting should all be arranged to suit the machinery.

The economical arrangement of the structural parts of the building should also be taken into consideration in the arrangement of the machinery. If possible, the columns should not be spaced to suit special machines unless there is some very decided advantage in doing so. It must be remembered that the life of a building is several times the life of the machinery installed, and that the machinery of the future may be entirely different.

Types of Factory Buildings.—There are two types of factory buildings which are here considered separately. The first is the ordinary one-story building with a hip-roof, which may or may not be surmounted by a monitor. It usually has large, unobstructed floor space to provide for the movement of cranes and other large machinery. The second type is the warehouse type of one or more stories in height. Industries which require a clear floor space of more than twenty-five feet in either direction are usually housed in one-story buildings, because it is expensive to carry the weight of upper floors on long spans. Where the materials manufactured are of such size that columns spaced from sixteen feet to twenty-five feet on centres are not objectionable the building of several stories is usually more economical.

A one-story building costs the most per sq. ft. of floor area. This cost per sq. ft. of floor area decreases somewhat with the number of floors built, up to four stories. Above that height the cost per sq. ft. gradually increases. There is comparatively little difference in the cost per sq. ft. of the floor area between a three and an eight-story building.

If basement floor space is suitable it is the cheapest which can be obtained, except where the loads to be carried on the first floor are extremely heavy. A one-story shop building in fireproof construction will cost from from $1.25 to $2.00 per ft. of floor space area, depending upon the height of the story, depth of footings, length of spans and kind of exterior finish used. Fireproof buildings of more than one story may be built for as little as fifty cents per square foot of floor area. These approximate figures do not contemplate any sort of plaster or interior finish except whitewash. They do include a properly finished cement floor. The cost per sq. ft., of course, decreases as the size of the ground plan increases. It is more for a long, narrow building than for a square building. However, a factory building should not be made too wide on account of the difficulty in properly lighting the interior. For ordinary factory work from 40 to 50 ft. is the best width. A building of this width can be lighted with a story height of from 12 to 14 ft. If the width of the building be made from 75 to 100 ft., then the story height should be increased to from 14 to 16 ft., the windows being placed as high as possible.

One-story shop buildings are usually built of what may be termed semi-fireproof construction. They are usually built of materials which will not burn, but cannot be said to be entirely fireproof, because the steel trusses are usually left unprotected, so that they might be damaged in case of fire occurring in the contents of the building. As before stated, the one-story plan is usually adopted where large, unobstructed floor spaces are required. This results in long-span steel trusses supporting the roof.

The most common type of roof is the "A"-shaped roof. This roof has many advantages. It is easy to keep watertight, it clears itself of snow easily, and with monitors or ventilators at the peak provides good ventilation for the factory. If these monitors are made wide enough

and are provided with windows they admit considerable light, but if the building is high and wide, monitor windows usually do not admit a satisfactory light.

A better type of roof, where light is essential, is the sawtooth roof. This roof is made up of a series of pitched roofs, rising towards the north and stepping down with a vertical step, in which windows are installed. These windows, facing towards the north, admit a diffused light, which illuminates the floor below without casting shadows. If the windows in the sawtooth construction are arranged to swing, they provide as good ventilation as the old monitor type. The disadvantage with sawtooth construction is that it presents a number of valleys where snow may lodge. In some cases steam pipes have been installed to melt the snow. This serves the purpose, but is rather expensive. In buildings where there is considerable steam in the air condensation gutters are necessary under monitor and sawtooth windows.

Roof.—The most unsatisfactory problem in shop building is probably the roof. It first must be watertight; second, if the building is to be heated in winter, it must be of such material that condensation will not occur on the under side; third, it should be fireproof; fourth, it must compete with a large number of cheap roofs which are lacking in one or all of these qualifications. A standard roof construction consists of three-inch hollow book tile, laid on steel tees. This tile is covered with some good prepared roofing, which is cemented and tacked to the tile. This roof is very expensive, but it fulfills all the requirements stated above. It costs, including supports, about thirty cents per square foot.

Another good roof is 2-inch dressed and matched sheathing, laid on wood or steel purlins and covered with a good prepared roofing. It is just as good and much cheaper than a book tile roof, but, of course, is not fireproof. It will cost about 20 cents per sq. ft., including supports.

In some instances a thin concrete slab laid on steel or concrete purlins has been used. Considerable condensation occurs under such a roof in cold weather. Furthermore, it is very difficult to keep a tin roof slab from being damaged by frost while being laid in cold weather.

If the shop is not to be heated in winter time, corrugated iron laid on steel purlins makes a very inexpensive fireproof roof, costing about 12 cents per square foot in place, including supports. It is fairly watertight, but, of course, is very cold in winter.

There are, of course, many other kinds of roofs, but the price for any roof comes between the limits here given.

There is not so much choice in the materials of construction of the side walls of a building as the roof. They may be of brick, stone, concrete, corrugated iron or glass. In this vicinity brick is the most usual and satisfactory material. Buildings with high stories are usually made with steel frames, the walls being simply curtain walls bricked in between the columns. Hollow brick should be used for the inside layer of brick to prevent condensation of the side walls.

Concrete for side walls is more expensive and less satisfactory than brick. Concrete blocks are sometimes used, and are probably all right where enough cement is put in the blocks. Such walls are, however, weak, due to the lack of bonding between the blocks.

A 12-in. common brick wall in this part of the country will cost about 38 cents per sq. ft. in place. With a good facing brick and some architectural decoration the cost may be increased to from 40 to 60 cents per sq. ft.

In the modern factory building the question of material of the outside walls is not an important feature, because from 75 to 100 per cent. of the wall area is occupied with windows and doors. The old style shop building did not, as a rule, admit enough light. Our new buildings probably admit too much. It is a mistake to assume that a workman needs as much light to work by as there is out under the open sky. Too much light is almost as bad for the eyes as too little. Most of the inconvenience of working indoors comes from working with a strong light from one side which casts shadows. Windows should be so arranged that light will reach every point from at least two directions and be of as near the same intensity in both directions as possible.

Another question upon which there is usually some argument is the kind of windows to be used. The three types most in use are the standard wooden sash, the rolled steel sash and the fire underwriters' sash of sheet steel or copper. The underwriters' sash is very little used for shop buildings because of the expense. They will, however, greatly reduce the insurance rate upon such walls of the building as have a bad fire exposure.

The most satisfactory sash at the present time, for factory work, is the rolled steel sash. This is a comparatively new product, having been on the market for only a few years. Where large areas are to be glazed the small size of the steel muntins and mullions permits the maximum amount of light to enter the building. Several factories have been built with the side walls almost entirely of glass, the only obstructions in the walls being the columns and the brick work at the floor line. Steel sash have a few disadvantages which should be taken into consideration. The ventilation is usually secured by pivoting a part of the sash near the middle. In factories where screens are necessary it is not possible to have ventilation because the screen will not permit the ventilator to swing. In this northern climate storm sash are desirable because of the loss of heat through the glass by conduction. Steel sash are too heavy and too expensive to use for storm sash. If wooden sash be used the advantages obtained by the use of steel inside sash are lost.

The cheapest sash to use is undoubtedly the double hung wooden sash with which we are all familiar.

Four General Classes.—Factory buildings of more than one story naturally divide themselves into four general classes, according to the materials of which they are constructed. This classification is really made by the fire underwriters inasmuch as the different types take different insurance rates. In fact, the rate of insurance is the consideration which most often determines the type of construction.

These classes are, frame construction, slow burning timber construction, structural steel and reinforced concrete.

In the frame construction class should be included all buildings having either brick or timber walls, wherein the floors are of wood and the joists narrow and spaced close together. Such buildings are, of course, the cheapest which can be built. By far the larger number of the present factory buildings are of this type. When an industry is in an experimental stage and the process of manufacture and the machinery are likely to be changed with experience, it is more economical to build in this manner. If a building is anything more than a temporary structure the extreme fire hazard, the danger to employees upon the upper floors and the lack of rigidity for supporting machinery are disadvantages which should be taken into consideration.

In the slow-burning mill building construction, as described by the fire underwriters, the walls must be of

brick or stone. It differs from the frame construction in that the joists are spaced from 3 to 6 ft. apart and are timbers of considerable size. The floors are matched planking. All stair and elevator hatchways must be enclosed, with doors at each floor opening. This construction is, of course, somewhat more expensive than the frame construction. Its principal advantage is that it takes an insurance rate about 20% less than frame construction.

Any timber construction has several advantages over more permanent types such as concrete or steel. Alterations in the buildings, due to changes in processes of manufacture and the installation of new machinery, are much more cheaply and rapidly made. The expense of attaching shafting and machinery to the finished structure is considerably less. Wooden buildings are more rapidly constructed than either reinforced concrete or structural steel buildings.

The columns in buildings with wood beams should be spaced from 12 to 18 ft. on centres. If a greater column spacing than this is required it is usually more economical to make the beams spanning in the longer direction of steel. These beams may rest on cast iron or steel columns, the remainder of the construction being of wood.

A better construction consists of steel columns and beams throughout. The floors may then be made of reinforced concrete or tile. If the columns and beams are then covered with fireproof material such as tile or concrete the building may be regarded as the best type of building which modern civilization has produced. In such a building the steel columns do not occupy so large a percentage of the floor area as do concrete columns. Exact stresses in a steel frame building are more easily computed. The chance for variation in the strength of the material due to faulty workmanship or design is not nearly so great. Alterations of the building are more economically made in a steel than in a concrete building.

The most popular type of factory building in many localities is reinforced concrete. A properly designed concrete building is the very best building which can be put up for many industries. It is entirely fireproof and takes the same rate of insurance as a fireproof steel building. Such buildings are probably the most rigid type which can be constructed. The material will stand a large amount of abuse in the way of faulty workmanship and design. Other types of buildings deteriorate with age, but a concrete building increases in strength. So far as we are able to determine at this time, our concrete building will be as good in the structural parts fifty years from to-day as they were when built.

The floor spans of a concrete building may economically be made from 16 ft. to 24 ft. in length. The exact span for minimum cost, of course, depends upon the expense of the foundations. The more expensive the foundation piers the longer may be the economical span. We find that the flat plate type of column pier is considerably less expensive than the old-fashioned masonry piers of the pyramid type.

The statements made concerning the exterior walls of one-story buildings are, of course, true in regard to buildings with a greater number of stories. It is usually economical to build self-supporting exterior walls for buildings up to three stories in height. For buildings higher than three stories the walls are often made twelve inches thick and carried upon the steel or concrete frame of the building.

The details of the work which have been described in the foregoing paragraphs are interesting in illustrating the method by which we try to arrive at the final economical design. A factory is made up of such a large number of details that only a few can be touched upon at this time. The arrangement of electric lighting and the ventilating systems, so as to give each worker sufficient air and light, are other interesting problems.

Finally, it may be said that in the last analysis the most economical factory building is the one where each worker is given the best conditions for doing his work, for the least cost.

UNION STATION, TORONTO.

The contract for the construction of the new Union Station for the city of Toronto was awarded last week to the P. Lyall Construction Company, of Montreal and Toronto, the amount of the contract being approximately $4,000,000. The station is being built by the Toronto Terminals Railway Company, Mr. J. R. W. Ambrose, chief engineer. Messrs. J. M. R. Fairbairn, assistant chief engineer, C.P.R., and H. R. Safford, chief engineer, G.T.R., are consulting engineers to the organization formed for the purpose of handling the enterprise.

The new station will be constructed on a site east of the present building and will be bounded on the north, east and west by Front, Bay and York Streets respectively. The site forms a portion of the fire-swept region which has remained for the most part unoccupied and desolate since the conflagration of 1904.

Messrs. Ross, Macdonald and Jones are the architects with whom is associated Mr. J. M. Lyle, Toronto. The erection of the new Union Station will form a part of a $15,000,000 development project which includes a large amount of grade separation to be affected along the water front.

REINFORCED CONCRETE SEWER AT VICTORIA, B.C.

A reinforced concrete sewer is under construction in Victoria, B.C., that will drain a section of the city 425 acres in extent; also, 800 acres in Saanich and 1,000 acres in Esquimalt. It will be two miles in length when completed, and will empty into an outfall near Macaulay Point, where it will discharge through several hundred feet of steel pipe at a point below water level where the tides admit of unusually favorable disposal. The trunk sewer is 27 in. in diameter at its beginning, increasing to 36 in. at the outfall, and the sections of reinforced concrete pipe are cast in 5-ft. lengths.

The excavation for the sewer consisted of about 7,250 ft. of rock tunnelling and 3,100 ft. of open work. The tunnel work attains a depth of 65 ft. below the surface, and consists essentially of three separate tunnels, the first of which is now being driven and in connection with which two shafts have been sunk. The tunnel is being constructed 5 ft. in width and 7 ft. in height. The excavated material is for the most part solid rock, and admits of an average progress of 5 ft. per day. The work is in charge of Mr. A. E. Forman, assistant to City Engineer Rust.

Another notable reinforced concrete pipe line in Victoria is that in connection with its water supply. It is a 28-mile conduit, 42 in. in diameter, and is being constructed by the Pacific Lock-Joint Pipe Co., of Tacoma.

Coast to Coast

Prince Rupert, B.C.—The G.T.P. Railway officials expect to have the big dry dock at Prince Rupert completed before the end of the present year.

Edmonton, Alta.—Work on 137,000 square yards of paving and concrete sidewalks will commence almost immediately. The work will cost in the neighborhood of $400,000.

Windsor, Ont.—As a result of the decision handed down in the High Court in Toronto, all work on the city's new incinerator plant at Windsor has been abandoned temporarily.

Brantford, Ont.—It is reported that by August 1 negotiations will have been completed, and both the Brantford Street Railway and the Grand Valley Railway will belong to the city of Brantford.

Moose Jaw, Alta.—A recent report states that the C.P.R. line of 70 miles from Kerrobert to Monitor, Alta., will be completed shortly. This will establish through connection from Moose Jaw to Lacombe, Alta.

Halifax, N.S.—Telephonic communication with Prince Edward Island on a commercial basis was formally inaugurated on July 7. The new cable was laid by the Maritime Telegraph and Telephone Company.

East York Township, York County, Ont.—It was announced at the meeting of East York township ratepayers that the construction work on the hydro-electric power line extension up the Don road would be commenced immediately.

MacLeod, Alta.—It is expected that the Calgary MacLeod branch line of the C.N.R. will be completed this season. The new line will run directly north to Red Deer, continuing north several miles west of Lacombe and Edmonton to Athabasca Landing.

Brandon, Man.—No definite decision was arrived at by the Railway Commission at its recent sitting in Brandon in reference to the city's application for an order directing the Grand Trunk Pacific Railway Company and the Canadian Northern Railway Company to establish joint terminals in Brandon.

Saskatoon, Sask.—A great many gas and oil leases have been filed during the past few weeks at the Dominion lands office in Saskatoon. The district in which the lands leased are located is an area of over 60,000 acres, partly in the Hanley district and partly in the townships on the boundary or near the Hanley district.

Victoria, B.C.—Arrangements have been completed by the contractors, Messrs. Grant, Smith, and McDonnell, for the immediate shipment of rock to the piers under construction by that firm at Ogden Point from the new quarry which has opened up at Esquimalt. More rapid progress will now be made upon the work.

Hamilton, Ont.—The works committee of the Hamilton council has decided to recommend to the board of control that a by-law be submitted next January to ratepayers regarding the purchase of a stone quarry, as well as with reference to the offer of the Canada Crushed Stone Corporation to supply stone to the city at from 85 to 90 cents per ton.

Winnipeg, Man.—A communication from the Dominion public works department to the Winnipeg and St. Boniface harbor commission, stated that parliament has granted the sum of $200,000 for harbor improvements to be effected on the Red River at Winnipeg and St. Boniface. Work on the docks is to be commenced and carried on as rapidly as possible.

Victoria, B.C.—According to the assertion of H. E. Beasley, general superintendent of the E. and N. Railroad, the opening of the line for service will take place between July 25 and August 1. The construction of the Trent River bridge has been completed, and the laying of rails and ballasting is practically completed into Courtenay, the temporary northern terminal of the line.

Weyburn, Sask.—Within the coming year, the town of Weyburn expects to acquire connection with three railways. The C.N.R. has promised construction of a link to that centre. Through trains from Winnipeg to St. Paul to be operated over the C.P.R. cut-off to Vancouver are now definitely promised. And the G.T.P. is already completing plans for opening up the territory to the southeast of Weyburn, and the position of the town as a distributing centre is expected to be assured.

Montreal, Que.—The G.T.R. Company has completed the installation on the Victoria Jubilee Bridge across the St. Lawrence River, a new type of automatic train signals, which is the first of the kind to be used in Canada. The new apparatus, known as the alternating current, 3-position semaphore, consists of eleven signals, the total length of the first line covered being 3½ miles. It replaces the Hall banjo type, which was installed in 1902 and which was at that time the first automatic signal put in use in Canada.

Vancouver, B.C.—The plans for the Dominion Government drill hall, which is to be erected at Vancouver at a cost of $350,000, have been completed by Perry and Fowler of Vancouver, and are now on inspection. The building measures 278 by 174 feet. The drill hall proper, measuring 225 feet by 120, will extend up to the roof of the building with a sweeping arch above. It will be well lighted and ventilated. Surrounding the drill hall on the main floor will be company armories and officers' rooms. The basement will provide a swimming pool, gymnasium, miniature rifle range and bowling alleys as well as ordinance store rooms, armory repair shop and sheds of different descriptions.

Chatham, Ont.—Chatham is experiencing considerable difficulty in arriving at a solution to its power problem. The Chatham Gas and Electric Company has refused to accept the proposition recommended a short time ago by the Hydro-Electric Commission that the city purchase the plant of the gas company for the sum of $410,000. The last offer of the company to the city is to reduce the rates of electricity to a basis equal to the probable rate that Hydro power would be sold at in Chatham, run the plant for 10 years, and then take the accrued profits and turn the plant over to the city without the expenditure of a dollar. The city council is now considering the advisability of accepting this proposition.

Montreal, Que.—At the Maisonneuve plant of the Canadian Vickers Company will commence on August 1 the construction of what will be the second largest icebreaker in the world, and will cost $1,000,000. It is to be used by the Canadian Government for icebreaking in the river and gulf of St. Lawrence, and is to be launched next May. It will be of the heaviest type of construction, will carry a crew of 90 men and will have the following dimensions: length, 292 feet; width, 56 feet; draft, 19 feet. It will be equipped with 8,000 horse-power engines. To form the launching ways between 800,000 and 900,000 feet of southern pitch pine is being brought to Montreal from Georgia in a vessel which sailed for Montreal on July 4th.

St. Hyacinthe, Que.—Within 35 miles of Montreal, across the St. Lawrence River, and close to the town of St. Hyacinthe, drillers are boring for natural gas under the direction of the promoters, the Canadian Natural Gas Company. The company has secured the right to operate throughout the counties

of St. Hyacinthe and Richelieu, an area of 250 square miles. One well was sunk to a distance of 1,860 feet, and produced a flame when lighted of from 75 to 100 feet in height, giving a pressure from a 2½-inch pipe, of approximately 600 pounds to the square inch. Encouraged by this success, the company extended its operations and have now almost completed the sinking of another well. The power for operating the machinery for this second well comes from the gas flowing from the first. It is the company's intention to sink a third well this summer, so as to ascertain definitely the extent of the "find."

Squamish, B.C.—The P.G.E. Railway Company has appointed Mr. J. Cumming in full charge of all the harbor and railway development work to be carried out by the company at Squamish. The harbor work will involve changes in the channel at the mouth of the Squamish River at its entrance to the Sound. The plan is to alter the course of various channels in such manner as to bring the river up against the base of the mountain and thus reduce erosion. The entire plans for this big undertaking will not be finished for several months, but in the meantime it will be possible to proceed with filling and banking work, and the clearing of the Indian reserves recently acquired by the company at Squamish. The reserves contain altogether 1,100 acres, from which should be deducted 200 acres of steep mountain sides. Besides these 900 acres, however, the company is filling in 200 acres of tideflats on the southwest waterfront of the old townsite of Newport. Wharves and waterfronts are to be laid out by Mr. Cumming, as well as a wide boulevard on one side of the old townsite.

Winnipeg, Man.—It has been announced that the administration board of the Greater Winnipeg Water District will call very shortly for tenders in connection with the various works in connection with the 84.72 miles of aqueduct for the Shoal Lake water project, which will cost approximately in totum $8,729,000. Advertisements are to be placed in journals in Canada, the United States, England, France, and Germany. Last year a division of cost of the work was made by the consulting engineers of New York and Boston as follows:—1,880,000 cu. yds. earth excavation west of the Summit Cut, at 60c., $1,116,000; 1,100,000 cu. yds. earth excavation in Summit Cut, at 75c., $825,000; 94,000 cu. yds. of rock excavation, at $2.50, $235,000; 2,300,000 cu. yds. refilling and embankment at 40c., $920,000; 340,000 cu. yds. concrete at $13.00, $4,420,000; 29,000 cu. yds. reinforced concrete at $17.00, $493,000; 13,000 ft. timber platform at $40, $520,000; steel for reinforcing aqueduct, $70,000; special work at and near river crossings, including waste weirs, $80,000; gate and screen chamber and other works at intake, $50,000; total for concrete aqueduct and appurtenances, $8,729,000.

Victoria, B.C.—An announcement has been made by J. S. Maclachlan, Government resident engineer, to the effect that by the end of July, the first signs of the Ogden Point breakwater, being constructed by Sir John Jackson, Limited, will appear above water. Previously, difficulty has been experienced in the laying of the granite boulders which form the foundation, owing to the inclined surface of the sea bottom at the inner end of the breakwater. But the work has advanced, nevertheless, satisfactorily; and, according to the engineers' statistics, the weight of granite blocks laid since the operations were started amounts to 3,677 tons. Throughout the month of June the divers placed in position a total of 1,199 tons. June has also been a record month in the dumping of rubble on the breakwater site, 60,606 tons having been dumped. This exceeds that of the previous month by 10,000 tons. The total amount of rubble now dumped is placed at 373,608 tons, which now comes to within 20 feet of low water as far as the final stretch, or the last 700 feet of the breakwater. An idea of the work which has been done may be gleaned from a consideration of the base of the breakwater, which is 200 feet in width and tapers up to a height of 72 feet. The contract is so far advanced that actual operations will be started this month on the concrete work forming the superstructure of the great sea wall. At the present time 1,250 barrels of cement have been delivered on the site by the Associated Cement Company, of Bamberton, which has been awarded the contract to supply all the cement necessary for the breakwater. Before being used this cement is to be given a 28-day test. The leveling off of the wharf area is now practically complete, 1,717 cubic yards having been leveled off last month. And the fifth and last of the dolphins has been driven, marking the extreme end of the sea wall.

Vernon, B.C.—A publication from Vernon states that July will see the commencement of construction on the branch line of the C.N.R., running from Kamloops to the Okanagan Valley. The Hon. Price Ellison, provincial minister of finance, has signed the $5,110,000 guarantee passed by the British Columbia Legislature in February; and the Hon. Mr. White, Dominion minister of finance, has signed the guarantee of the Dominion Government to the C.N.R. amounting to $45,000.000. The $50,000,000 worth of bonds which have thus been made available are to be marketed at once in England. Operations will be begun simultaneously at three points, Vernon, Armstrong and Kamloops. From Vernon construction work will proceed in four directions; from Vernon toward Armstrong, toward Kelowna, toward Okanagan Landing, and up the White Valley toward Lumby and Shuswap Falls. The entire branch line will be about 148 miles in length. From Kamloops to Vernon the survey is 81 miles long, from Vernon to Kelowna 35 miles, from Vernon to Okanagan Landing about 4 miles, from Vernon to Lumby 17 miles and from Lumby to Shuswap Falls 10 miles. The last named 10-mile extension is not included under the recent guarantee, but will be built to reach the company's power site and townsite at the falls, where electric power is to be developed to operate the Lumby and Kelowna lines and probably the entire line through to Kamloops. Active development work on the power site will probably not be begun until next spring. But in every way possible, the work will be hastened; and grading, with the exception of the few heavy pieces of rock work on the Kamloops-Okanagan line, is expected to be practically completed by January 1, 1915. In connection with the section from Vernon to Okanagan Landing, the C.N.R. plans to build a lake fleet of passenger steamers and freight barges, which will increase the traffic from this district.

PROGRESS OF CONSTRUCTION ON THE P.G.E. RAILWAY.

A report upon the work done up to date upon the P.G.E. Railway, was made recently by A. H. Sperry, general manager of the railway company, to D'Arcy Tate, vice-president of the company, and to the Premier of British Columbia, Sir Richard McBride. Mr. P. F. Welch, of the firm of Foley, Welch and Stewart, the contractors for the railway construction, has chief charge of the work, and has in his employ 5,600 men. The work on the road is being rushed as fast as possible to an early completion. It is planned to have the grade work completed all the way to Fort George this year, before the frost enters the ground. It is stated that an excellent standard of efficiency is being maintained in every detail of the work along the entire 810 miles of length of the railway from Squamish to Peace River, via Fort George. Mr. Sperry reported that for a distance of 13 miles from Vancouver, grading and tracklaying have been completed and

that on July 1 next, a local service will be inaugurated in that section of the country.

There is a gap of some 20 miles between Horseshoe Bay and Squamish, where heavy rock work will be necessary. This section will be left by the construction gangs until all the other portions of the contract between Fort George and Vancouver are well on towards completion. It will then be undertaken and promptly finished.

Between Squamish and Clinton, where the heaviest work has been encountered, the grade is all but completed. Steel is laid as far as Cheakamus River; and as soon as the bridge is completed at this point, steel will be laid right through to the Pemberton Meadows country, and thence through to Lillooet.

It is intended that ballasting shall go on simultaneously with operations of construction, so that the road will thus be put into operation with the minimum of delay. There has been considerable delay in the section of Cheakamus, but this part of the line necessitates the construction of 12 bridges.

After passing the Pemberton Meadows, the track has been continued to cross the Fraser at Lillooet. Here a further delay of a few weeks will ensue to permit of the building of a large bridge. The piers for this structure are already in place; and once the bridge is finished, the laying of track will continue to Clinton and above that point.

In November next, Mr. Sperry expects that construction will have advanced to such a degree of completion as to permit of the inauguration of a mixed train service from Squamish to Lillooet, a distance of 120 miles, this run being made in five or six hours. Mr. Sperry has already placed orders for a large amount of rolling stock, which is to be utilized in equipping the road for regular traffic. This equipment is to be thoroughly modern and up-to-date, so that the railway service will not be excelled by that of any other transcontinental system in Western America.

PERSONAL.

GERALD PONTON, C.E., of Calgary, has been in England during the past month investigating the various methods of road building.

ARTHUR SURVEYER, of Surveyor and Frigon, Consulting Engineers, Montreal, is leaving for Europe on August 1st, to attend the "White Coal" Congress at Lyon.

CHAS. HARPER, B.A., of the research laboratory of Queen's University, Kingston, has been appointed professor in charge of the Department of Science at Moose Jaw College.

The Canadian Northern Railway Company announces, from its Winnipeg office, the following appointments taking effect July 5th:—

Mr. I. L. Boomer, Superintendent at Edmonton, (3rd district Western), becomes Superintendent at Calgary (4th district Western Division, newly created).

Mr. J. C. O'Donnell becomes Superintendent at Edmonton, (3rd district Western), in place of Mr. Boomer. Mr. O'Donnell has been promoted from Trainmaster, his headquarters formerly being at Rainy River, Ont., on the 1st district Central.

Mr. M. G. Hurd, formerly Chief Dispatcher at Saskatoon, (2nd district Western), becomes Chief Dispatcher and Trainmaster at Calgary (4th district Western).

Mr. R. Nelson, formerly Chief Dispatcher at Edmonton, becomes Chief Dispatcher and Trainmaster at Edmonton (3rd district Western).

OBITUARY.

The death is announced of Mr. Everett Ketcheson, an assistant engineer on the construction of the Trent Valley Canal. Mr. Ketcheson was drowned in Trent River on July 11th.

From Haileybury comes the report of the death of Mr. Murdock Lloyd, mining engineer of Toronto, from injuries sustained from a boiler explosion at the Tough Oaks Mines at Swastika.

A fatality occurred near Lytton, B.C., on July 6th, when Mr. John Middleton, a member of a Canadian Northern Railway survey party was killed by falling a distance of 70 feet from a ledge of rock.

While taking measurements in a sewer tunnel Mr. Robt. Strathern, a resident engineer, Department of Sewers, city of Toronto, was asphyxiated by illuminating gas which had escaped from a broken main and had flooded the sewer. Several other members of Mr. Strathern's party were overcome and narrowly escaped death. In connection with their removal from the tunnel, and with an attempt to save the life of the resident engineer, is associated the name of Mr. M. P. McDonald, assistant engineer, whose heroic efforts have occasioned great admiration.

COMING MEETINGS.

UNION OF CANADIAN MUNICIPALITIES.—Annual Convention to be held in Sherbrooke, Que., August 3rd, 4th and 5th, 1914. Hon. Secretary, W. D. Lighthall, Westmount. Que. Assistant-Secretary, G. S. Wilson, 402 Coristine Building, Montreal.

WESTERN CANADA IRRIGATION ASSOCIATION.—Eighth Annual Meeting to be held at Penticton, B.C., on August 17, 18 and 19. Secretary, Norman S. Rankin, P.O. Box 1317, Calgary, Alta.

AMERICAN PEAT SOCIETY.—Eight Annual Meeting will be held in Duluth, Minn., on August 20th, 21st and 22nd, 1914. Secretary-Treasurer, Julius Bordollo, 17 Battery Place, New York, N.Y.

CANADIAN FORESTRY ASSOCIATION.—Annual Convention to be held in Halifax, N.S., September 1st to 4th, 1914. Secretary, James Lawler, Journal Building, Ottawa.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown. Indianapolis, Ind., Secretary.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—11th Annual Convention; 5th American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau St., New York, N.Y.

In *The Canadian Engineer* for July 2nd, an error appeared in reporting the name of the writer of the article entitled "Laying Outside Hill Roads," appearing on page 108. The author's name is Capt. A. C. Garner and not "Gardner," as appeared.

A weekly paper for engineers and engineering-contractors

SOOKE LAKE WATER SUPPLY FOR VICTORIA, B.C.

A PROJECT TO CONVEY 16,000,000 GALLONS PER DAY THROUGH 27.3 MILES OF REINFORCED CONCRETE GRAVITY PIPE LINE AND 10 MILES OF STEEL PRESSURE PIPE, WITH A 136,000,000-GALLON INTERMEDIATE RESERVOIR.

THERE is some interesting history associated with the present undertaking by which the city of Victoria, B.C., will be supplied with 16,000,000 gallons of water daily through the Sooke Lake system. The question of water supply for the city extends back to 1868, when a system was adopted whereby a private company supplied the city through wooden pipes from a series of wells. Four years later the city began to investigate Elk Lake (see Fig. 4) as a possible source of supply. The official report concerning it estimated a supply of 25 gal. per capita per day for a population of 90,000. A scheme was entered into whereby for many years the city has received its supply from Elk Lake through open gravity sand filters and by a gravity system. Later, a pumping plant was installed, necessitated by fire protection requirements and by increased consumption. As the daily consumption further increased, the level of Elk Lake became lowered considerably and the quality of water impaired. Meantime the Esquimalt Waterworks Co. supplied Victoria West from the Goldstream Lakes. The cost to the city of the former is 2 cents per thousand Imp. gal. and of the latter 6 cents per thousand Imp. gal. Compared with this, the old well system in vogue before the Elk Lake scheme cost the city 0.75 cents per gal.

In July, 1911, the city decided to actively engage without delay upon plans for the extension of its water supply. Sooke Lake, which lies about 18 miles northwest of Victoria, was subjected to careful hydrographic investigation, including the study of rainfall, run-off, contour surveys, determination of area of watershed and possible supply. Owing to the expeditious circumstances, this work was pushed ahead with all speed, and before the end of the year tenders were called for. This procedure was authorized by a by-law which had received the assent of the electors on January 12th, 1911, for the borrowing of $1,500,000 for acquiring and constructing the Sooke Lake water system. In January, 1912, the contract for the construction of the entire work was let to the Westholme Lumber Company, of Victoria, for the sum of $1,169,170, the system to deliver 16,000,000 gal. of water daily, as stated. In April, 1913, after completing 38½ per cent. of the work when, according to contract, 65 per cent. of it should have been completed, the Westholme Lumber Company abandoned the contract and Water Commissioner C. H. Rust thereupon took over the work, to be done by the city, charging the expense to the contractor, as he was entitled to do by the provisions of the contract. The city has since been carrying out the work by day

Fig. 1.—Portion of Reinforced Concrete Flow Line Near Humpback Reservoir.

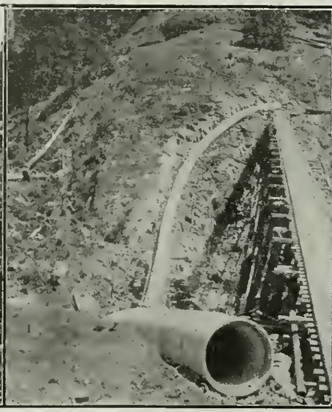

Fig. 2.—One of the Inverted Siphons. Construction railway is also shown.

Fig. 3.—Site of Humpback Reservoir.

labor, with the exception of sub-contracts for the construction of concrete flow line, pressure pipe line, and other small portions.

The scheme constituted the conversion of Sooke Lake into a reservoir with a 12-ft. lift of water level; the laying of a 40-in. reinforced concrete pipe line 27.3 miles in length from thence to Humpback reservoir, about 10 miles outside the city, and the connection of Humpback reservoir with the Smith's Hill service reservoir, in the city, by a 36-in. steel pressure main. This service reservoir has a capacity of 16,000,000 Imperial gal. daily and is located at an elevation of 213 ft. above sea level.

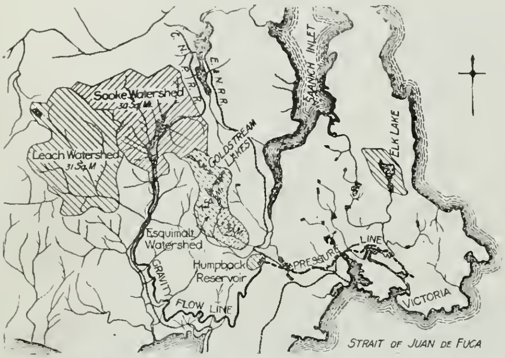

Fig. 4.—Watersheds Around Sooke Lake and General Layout of the Scheme.

Sooke Lake, as stated, is distant 18 miles from Victoria. It is long and narrow, being 4 miles in length and ½ mile in width at its widest point. It is in reality a series of three lakes, the farthest from the city being the largest and having a depth at several points of 150 ft. It has a remarkably pure and wholesome supply of water, outpointing in this respect the other two divisions of the lake. The three sections have an area of 964 acres and the watershed which they drain covers 31.35 sq. miles. At low-water the lake is 342 ft. above normal water level in the city service reservoir. Sooke Lake is fed by a large spring on the west and Ferguson Creek on the east side. The watershed is bounded on the west, south and east by the Leech River, Esquimalt, and Goldstream Lake watersheds, the first and third having areas of 30.33 and 10 sq. miles respectively.

The Sooke Lake water supply scheme includes also the use ultimately of the Leech River supply. It is proposed to build a diversion dam and to bring the water to Sooke Lake through a 5-mile conduit. The dam will have a height of 45 ft. above the present low-water level and will divert a supply equal to 100 ft. per second.

Early construction work entailed the devastation of the shores of Sooke Lake, which were cleared to 15 ft. above low-water level, thereby effecting the destruction of 300 acres of thick forest. It should be stated that the entire watershed is densely wooded with Douglas fir.

The plan and elevation of the Sooke Lake dam, showing the intake tower and channel, is given in Fig. 5. The channel is excavated to 4 ft. below low-water. In the intake tower the water will be controlled by seven sluice gates, four of which are 24 in. x 30 in. and three are 30 in. x 42 in. The gates will be protected by bar screen cages anchored in the concrete. Two 40-in. riveted steel pipes will convey the water from the intake tower to the concrete screen house. In the latter a set of twelve screens of 40 mesh will be installed. Past the measuring weir the water will be conveyed over cascades to the conduit pipe at a grade elevation of 12 ft. below the low-water level of the lake.

The cross-section of the dam is given in Fig. 7, together with a section of the earth-filled portion indicated in Fig. 5. This earth embankment has a concrete core wall bonded into the natural rock.

To the east of the screen house an ogee weir section 200 ft. in length is being constructed. This is also bonded into the natural rock with a cut-off trench at the upstream face. It will average 15 ft. above the foundation.

The reinforced concrete flow line has a reinforcement of wire mesh. It is being built by the Pacific Lock Joint Pipe Company, of Seattle, in 4-ft. lengths with a 3-in. thickness of wall. The contract was awarded to this company in November, 1913, for the sum of $329,760. The 40 in. in diameter is an internal measurement and is calculated to furnish a flow of 16,000,000 Imp. gal. per

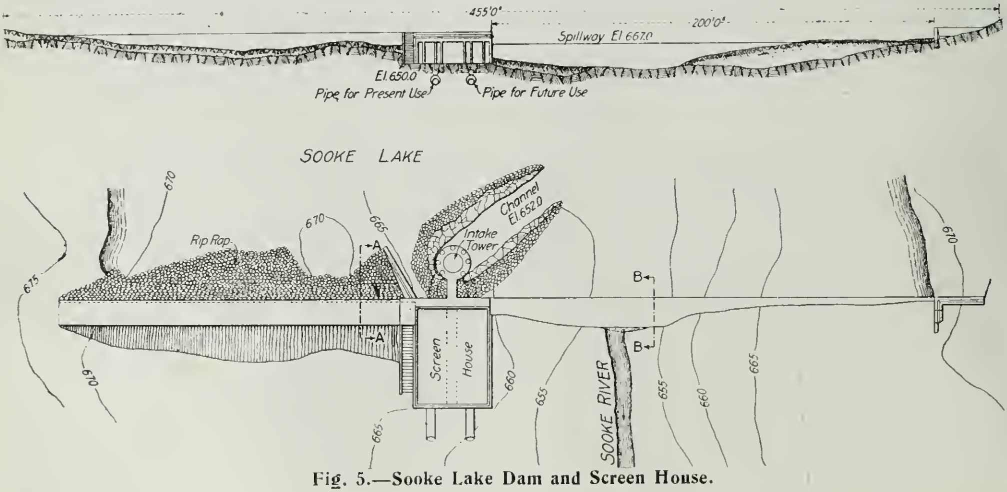

Fig. 5.—Sooke Lake Dam and Screen House.

day, the flow in the pipe being estimated for $C = 120$, in the Chezy formula, or $n = .012$, approximately, in Kutter's formula. The finished pipe is hauled from the site of manufacture at Cooper's Cove (see Fig. 8) by an incline railway to the grade and conveyed from there by the construction railway.

The pipe is laid on crushed stone ballast. The pipe line right-of-way is 100 ft. in width, from which all trees liable to fall upon it have been removed. At every 2,000 ft. on the line is constructed an open standpipe, while all inverted siphons will have steel reinforcement and will have waste outlets at the bottoms controlled by 6-in. gate valves. Fig. 2 shows one of these siphons under construction. There are six of them, the deepest being 600 ft. long with a maximum head of 90 ft.

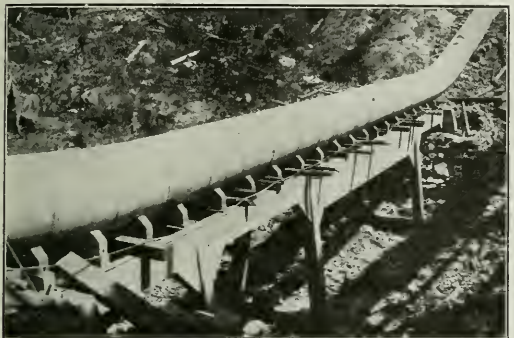

Fig. 6.—Concrete Trestle Carrying Pipe Across Gulley Susceptible to Floods.

In order to protect the flow line from water accumulating on either side, drainage openings of different types are being located where necessity demands along it. Usually the water will be carried along and passed under the pipe line through small holes which penetrate the ballast at points where the roadbed is in the rock. In cases where the volume of water may be considerable concrete side walls will support the pipe, if the span requires it, and also where it needs protection from scour of earthy material underneath. In cases where there is some embankment, drainage will be effected by vitrified pipe varying in diameter from 12 in. to 24 in. Where embankments are unusually large the pipe will be supported by open ravine culverts of about 15-ft. span. Steel bridge spans varying in length from 45 ft. to 80 ft. with concrete abutments will be used to cross transverse streams at low points of the siphons. The pipe line will not be covered except in deep cuts where protection from slides is necessary. Fig. 6 shows a section of pipe line supported by a concrete trestle.

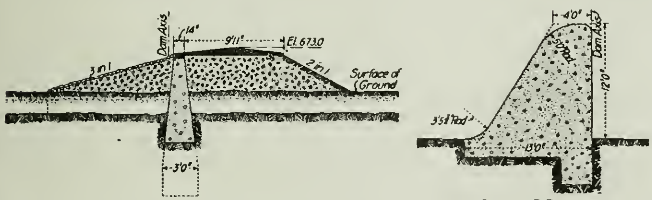

Fig. 7.—Sections of Sooke Lake Dam and Earthfill.

The Humpback reservoir, the site of which is shown in Fig. 3, was decided upon after a good deal of careful investigation. The location of a reservoir at a proper level near the city formed one of the difficulties to be contended with. The reservoir site has an area of about 40 acres and was densely wooded, requiring clearing. The soil is of a black peaty nature. This has been covered with an 8-in. layer of gravel and sand. The material for this covering was procured in the immediate vicinity. The reservoir will have a capacity of 136,000,000 gal., which may be held in reserve in case any accident occur in the flow line pipe. Ordinarily the water will be delivered directly from Sooke Lake to Smith's Hill reservoir through a by-pass pipe. The latter will act as a standpipe, the pressure from Sooke Lake being too great to permit delivery directly into the city distribution system.

Fig. 8.—Site of Manufacture of Pipe Sections at Cooper's Cove.

The dam at the Humpback reservoir has been constructed of concrete. Excavation to a depth of about 30 ft. provided a satisfactory rock foundation. The dam itself has a maximum height of 60 ft., a length of 600 ft., and contains over 8,000 cu. yds. of concrete.

From this reservoir to the city the water supply will be conveyed through a 36-in. riveted steel pipe. Cast iron outlet pipes, two in number and 34 in. in diameter have been installed at the dam for delivering the water to the pressure system. A gate house is provided with control valves, screens, etc. Waste water will be discharged from the dam through a 16-in. cast iron pipe.

The water is to be delivered from the pressure pipe line to Smith's Hill reservoir, which is situated at the southern limits of Victoria. There is a drop of 167 ft. between the two reservoirs. The riveted steel pipe line leading thereto consists of 20,500 ft. 5/16 in. in thickness and 36,500 ft. 3/8 in. in thickness. The pipe sections are about 22 ft. in length; i.e., four plate lengths. The specifications call for plate manufactured by the open-hearth process. The rivets are to be of extra soft steel, pneumatically driven, and the maximum angle of any joint must not exceed 3°. Specifications also call for a pipe coating of bitumastic, or some equally efficient preparation.

A short distance below Humpback dam a recording Venturi meter is being installed. Four concrete gate houses with 36-in. rising stem gate valves will be located along the line and 6-in. gate valves will be provided at

the base of all depressions for use in emptying the pipe. Nozzles providing for corresponding air valves will be inserted in top of the pipe at every summit point. As announced in *The Canadian Engineer* for April 16th, the contract for the construction of this riveted steel pipe line from Humpback to Smith's Hill reservoir was awarded by the city council to the Burrard Engineering Company, the price being $304,000.

The work, since its abandonment by the Westholme Lumber Company, has been carried out under the direction of the City Water Commissioner, Mr. Chas. H. Rust. In July, 1911, Mr. Wynne Meredith was retained as consulting engineer on the project. Mr. Boyd Ehle is resident engineer.

It is estimated that the cost of delivering 16,000,000 gal., which is the maximum capacity of the concrete gravity flow pipe line, including all charges, will be 2¾ cents per thousand gallons. The proposed raising of the dam at Sooke Lake to include the Leech River supply, as outlined in Mr. Meredith's 1911 report, will provide approximately 54,000,000 gal. per day, and will lower the cost to about 1⅓ cents per thousand gallons. It will provide the city of Vancouver with a reservoir storage of 17,358,000,000 gallons from the combined watersheds.

WATER SUPPLY AND SEWERAGE SYSTEMS FOR SMALL COMMUNITIES.

THE benefits to be derived from a public water supply and sewerage system have been brought out very prominently by Mr. W. H. Dittoe, chief engineer, Ohio State Board of Health, in the official organ of the board. The advantages resulting from community life have been recognized since the beginning of history and we are told that in the most remote times the people banded together forming tribes or communities to mutually assist in their own betterment. Out of this tendency grew the ancient town in which the inhabitants were more or less committed to mutual protection. The advantages of community life have progressed with the advance of civilization and learning and in comparison with advantages offered by the modern community those of ancient cities or villages appear insignificant. Community life has its disadvantages, however, and becomes a detriment to the welfare of the people unless necessary municipal improvements are provided. In the present day a community to be considered modern must provide every possible municipal improvement for the convenience of its citizens as well as for its own development and growth. The large cities can, and do, expend great sums of money in providing public water supplies, sewerage facilities, street paving, collection and disposal of waste material, street cleaning, municipal lighting and numerous other public service advantages. This extensive municipal improvement is not possible in the smaller communities, but in every case those improvements which affect the health of the community may reasonably be demanded. In this classification fall public water supplies and sewerage systems. Unless a community can offer the benefits to be derived from such installations the advantages from community life are minimized and overbalanced by the dangers to which the inhabitants are subjected. This neglect results not only in general unhealthful conditions but also in retarding the development and growth of the community.

The installation of a public water supply, which will furnish the maximum benefit to the community, should be the first step taken in the development of municipal improvements. Following the provision of a public water supply and simultaneously with it, if possible, a complete sewerage system should be installed. After these most important improvements have been provided other municipal enterprises may be undertaken as the financial condition of the community will permit.

Public water supplies are obtained from two general sources, namely, from surface streams, lakes or ponds and from underground water-bearing formations. In either case it is well to remember that the original source of the water is the same, namely, precipitation. In spite of the popular belief, not all water supplies obtained from underground sources are suitable for public supply purposes. Water obtained from surface sources is rarely, if ever, to be considered satisfactory in its raw state. In the selection of any source, due attention must be given to the quantity available, for in many cases a disregard of this important factor has led to considerable financial loss. The development of the supply is also of great importance, as upon this may depend the maintenance of the good quality of the water. Proper management and operation of the works after they are installed is a factor influencing the benefits derived from the supply. Also, the advantages of a water supply cannot be fully derived until the supply has come into general use by the citizens. It may be stated that the maximum benefits resulting from the installation of a public water supply can be realized only by meeting the following conditions:

1st. The supply must be of adequate quantity;

2nd. It must be of good quality from a physical, hygienic and chemical standpoint;

3rd. Its development must be adequate, safe and economical.

4th. It must be maintained properly following its installation.

5th. It must be universally used.

The questions relating to quantity, quality and development are dependent upon preliminary study and the preparation of proper plans. The maintenance and use of the supply are, however, conditions which are subject to the control of the authorities in charge.

The benefit resulting from water supply installations may be measured by the improvement in the health of the community or by financial considerations. The improvement of health conditions is dependent primarily upon the quality of the water supply developed. If the supply is of good quality from physical, hygienic and chemical standpoints, is properly developed and is generally used, we may expect the maximum reduction in diseases resulting from water-borne infection. In proportion to the extent to which any of these features are deficient the improvement in health conditions will be lessened. It is frequently the case that a water supply of excellent sanitary quality but of objectionable physical or chemical quality is installed and on account of its unfavorable appearance is not used for drinking purposes. As a result, private wells continue to furnish water for this purpose and no marked improvement in health conditions results. Prejudice against public water supplies frequently contributes to prevent the general use of a supply entirely satisfactory. In such cases the maximum benefits are not realized. The method of development of a water supply of good quality may frequently determine the advantages to be derived, for instance, a ground water supply of a high degree of purity may deteriorate by storage in an uncovered pump well or reservoir. Algal growths may cause tastes and

odors to appear at certain seasons of the year which will contribute to make the water supply generally unpopular.

One of the principal advantages to be derived from a water supply, and one which is generally recognized, is the introduction of modern plumbing facilities in the home. This permits the abandonment of private wells, which may be dangerously contaminated, and the use of indoor sanitary equipment, which makes possible the removal of the insanitary privy.

From a financial aspect the introduction of a public water supply is to be considered a good investment. There results an actual saving to the individual, a general increase in property values, the provision of fire protection and an attraction to industries in search of a suitable location. The financial measurement of the advantages of a public water supply is determined largely by the quality, quantity, development and use of the supply. The consideration of the financial value of a water supply from the standpoint of its quality has been dealt with completely by Whipple in his treatise on the "Value of Pure Water." Assuming absolute purity as a standard of greatest value, he has shown, for instance, that unsatisfactory physical quality may result in a loss of from five to twenty dollars per million gallons of water pumped; unsatisfactory hygienic quality, fifty to one hundred dollars per million gallons; and objectionable chemical quality, ten to twenty dollars per million gallons. The mere provision of a water supply may, therefore, not result in a great financial advantage; it is also required that the quality be such as to bring the maximum benefit to the community.

Considering next the advantages of a sewerage system, a few brief words of explanation of what a sewerage system is may be of benefit. Sewerage systems are divided into three classes, according to their use. The sanitary sewer system is employed for the removal of house sewage and all objectionable liquid wastes. Storm sewers are used for the removal of surface drainage, while combined sewers are utilized for the removal of all classes of wastes and surface drainage. For the small village, especially where treatment of the sewage may be required, the sanitary sewer system is by far more preferable than the combined sewer system for the removal of sewage. Any sewer system, to furnish good results, must be of proper capacity, laid with proper grades and in general designed according to good engineering practice. Its construction must also be carefully supervised. After its installation it must be maintained in its most efficient condition. Of course, the sewer system will not furnish maximum benefit until it has become universally used. We may, therefore, state that the full advantage of a sewer system will be realized only when the following conditions have been met:

1st. It must be properly designed and constructed.
2nd. It must be properly maintained.
3rd. It must be universally used.

The first two factors are dependent upon preliminary study and the plans under which the system is built, but the use of the sewers is a matter which can be regulated by the authorities in charge.

The benefits resulting from the installation of a sewerage system may be measured according to the same standards as a public water supply improvement, namely, by the effect on the public health and from financial conditions.

It seems unnecessary to refer to the improvement in health conditions resulting from the installation of proper sewers. First of all, a public water supply cannot be fully enjoyed in the absence of a sewer system. The provision of a system of sewers may, therefore, contribute some of the benefits resulting from the public water supply development. With provision of sewers the abandonment of cesspools and privies is facilitated and general cleanliness of the community is encouraged. Drainage and drying of the soil also results, which has an important bearing upon the general health. It may be expected that, following the installation and use of a system of sewers, the death rate from typhoid fever will be reduced about 50 per cent. Records of results obtained in a certain town in England indicate a reduction in deaths from pulmonary tuberculosis of over 50 per cent., following the introduction of sewers.

From a financial aspect the installation of a sewerage system is highly beneficial. It results in an actual saving to the individual as it provides an ever-ready means of disposal of house sewage at a cost considerably less than would be demanded in the installation and maintenance of cesspools. Increased property values also result from improved sewerage, and it may be expected that individuals and manufacturers will be attracted to a well-sewered community and thus enhance its value. The degree to which the sewer system becomes a benefit is, however, dependent upon the extent of its use. Frequently it has been found that the citizens of a community have failed to appreciate the value of a sewer system and have neglected to properly utilize it. The result has been a continuance of the privy and cesspool nuisances and general insanitary conditions of the community. It is well to remember that following the installation of a sewer system its general use should be required by the municipal officers in authority.

Having reviewed the advantages to be derived from public water supplies and sewerage systems, a brief explanation of the method of obtaining these advantages may be of value. A popular desire for the improvements is, of course, necessary before the village authorities can hope to make the actual installations. However, before the expression of the electors is obtained it is important for the village authorities to become thoroughly informed as to the general method of development of the works and the cost of the same. When the council of a village has determined to take steps to install a public water supply or sewer system a competent engineer, experienced in this field of work, should be retained to make preliminary surveys, general plans and an estimate of cost for the improvements. In case of a water supply the preliminary survey should include a study of available sources and in this connection the considerations of quantity and quality enter. No source of supply should be determined upon until a complete test as to its quantity and quality has been made. In the case of a sewerage system the preliminary survey should include the general layout of a sewer system and location for outlet or treatment plant. After the preliminary survey has been completed general plans and an estimate of cost should be made and these submitted to the village council for adoption. Following their adoption by the council they should be submitted to the Board of Health for approval and after this approval is secured the village authorities should immediately take up the question of educating the people in the advantages to be derived from installing the improvements contemplated. In some cases this campaign of education may require the utmost effort on the part of the village authorities. After a favorable expression of the electors on a bond issue is secured the village should again call upon their engineer to prepare detail plans and specifications for the work. These should be submitted to the Board of

Health for approval and following such approval the contract for the work should be advertised and awarded according to law. The duty of the village authorities does not cease at this point and during the construction of the work a competent engineer should be retained to protect the interests of the village and see that plans are strictly adhered to. When the works have finally been installed according to the plans and specifications the village authorities must assume the duty of properly maintaining them. Too much emphasis cannot be placed upon the necessity for proper maintenance of water supply and sewerage improvements. In small villages the authorities are likely to become lax in this duty, especially if political considerations govern the selection of men employed in public service. The beneficial effects of public water supplies and sewerage systems are largely dependent upon the care with which they are managed and operated. Aside from the financial considerations the beneficial effect upon the public health may be impaired if works of this character are carelessly maintained and operated.

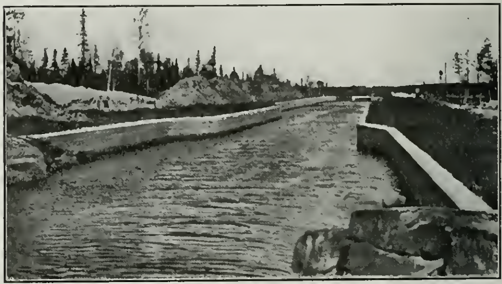
PIER CONSTRUCTION AT VICTORIA.

In connection with the construction, by the Department of Public Works of British Columbia, of several piers at Victoria, B.C., eighteen concrete cribs are being constructed. All of them, with the exception of two, are being built with the aid of a large, floating dry dock, recently leased by the contractors, Grant, Smith and Co. and McDonnell, from the Seattle Dry Dock and Construction Co. The dock, although not a new one, has a capacity of 8,000 tons. It is 325 ft. in length, with a 102-ft. beam, and towers 32 ft. 6 in. above the deck of the pontoon or scow. Its sides are 40 ft. in height.

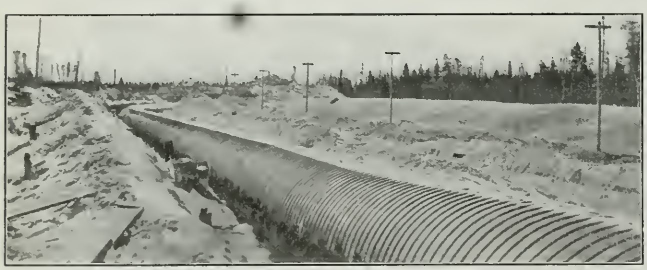
The dry dock was delivered to the contractors on May 28th, and will shortly proceed to Esquimalt, where the concrete cribs will be constructed and floated, one by one, to the dock site upon completion. These cribs will be 100 ft. in length, 39 ft. in width, and have a height of 39 ft. Each will weigh 3,500 tons, and two of them will be built simultaneously on the dry dock. The first two cribs are being constructed by the method first adopted, that of building them on marine ways and launching them with rollers. This method is being abandoned, however, for the remaining 16 cribs, it having been found uneconomical.

THE WAWAITEN FALLS AND SANDY FALLS HYDRO-ELECTRIC POWER PLANTS.

THE Northern Canada Power Company, Limited, operates two hydro-electric plants on the Mattagami River, namely, Wawaiten Falls, twelve miles southwest, and Sandy Falls, six miles northwest from the town of Timmins, Ontario. It is from these two plants that the gold mines of Porcupine derive their power. The following data concerning them are from the recent report of the Timiskaming and Northern Ontario Railway Commission, prepared by Mr. A. A. Cole, its mining engineer.



Headgate and Canal Leading to 12-ft. Iron Pipe Line, Wawaiten Falls.



Wood Stave Pipe, 1,550 ft. Long, 9 ft. Diameter, at Wawaiten Falls.

Wawaiten Falls plant is located in the township of Thornloe at the foot of Lake Kenogamisee. A concrete dam 1,000 feet long at this point, diverts the water into a 1,200-foot canal. From the intake at the foot of the canal, water is carried by 1,500 feet of 12-foot iron pipe to a 40-foot diameter surge tank on top of the hill overlooking the power house. Two 8-foot iron pipes, 1,300 feet long, lead from this surge tank down the side of hill direct to the wheels in the power house.

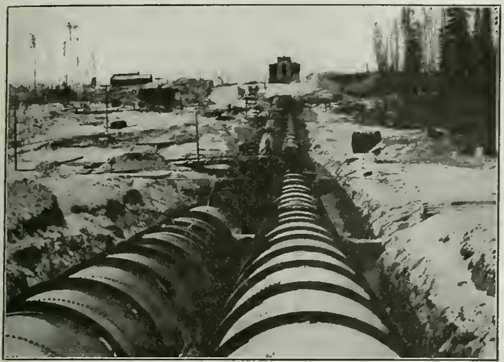
The power house is of reinforced concrete and contains two 3,300 horse-power Morgan-Smith water-wheels operating under a head of 125 feet, direct connected to two 2,500 k.v.a., 3-phase, 12,000-volt Canadian Westinghouse alternators; two 70 kilowatt exciter sets driven by independent water-wheels and Westinghouse switching and switchboard apparatus. During the summer and autumn of 1913, the power company installed 1,500 feet of 9-foot wood stave pipe line from the intake of canal to surge tank, duplicating the

View of Wawaiten Falls Dam from Lake Kenogamisee.

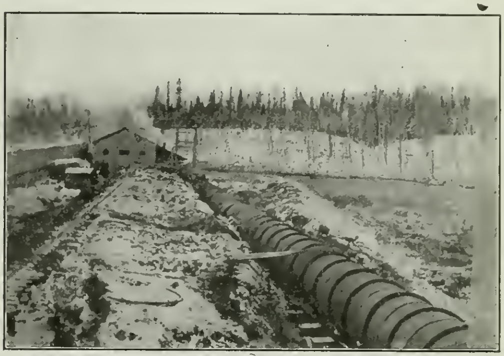
present 12-foot iron pipe. Material for this line is 2-inch Oregon fir, and was installed under the supervision of the Pacific Coast Pipe Company's engineer.

Sandy Falls plant is located in the township of Mountjoy. A timber dam of approximately 1,500 feet in length diverts the water into a wooden flume 14 feet by 16 feet by 700 feet long. Water from the flume is taken direct to the wheels in the power house by means of short lengths of 10-foot pipe. The power house is of timber construction covered with asbestos and corrugated iron, and contains two 1,200 horse-power Morgan-Smith wheels operating under a head of 33 feet, direct connected to two 950 k.v.a., 3-phase, 12,000-volt, Canadian Westinghouse alternators with exciters on the same shaft. Switching and switchboard apparatus is of Westinghouse manufacture. During the summer of 1913, the power company commenced extensive improvements at this plant. The timber dam is being replaced with a concrete dam and wooden flume with steel pipes. It is expected this work will be completed during the summer of 1914. The transmission lines consist of two complete circuits on a single pole line from each plant, and are so built and connected that plants are operated in parallel. Power is supplied to consumers at approximately 12,000 volts, 3-phase, 25-cycle.

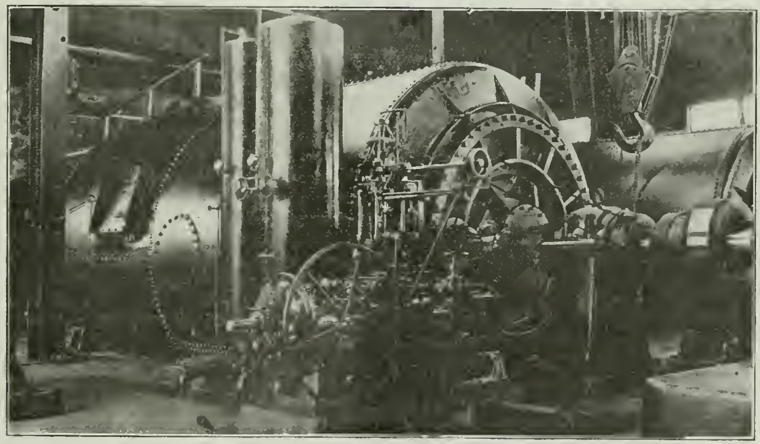
The power company has 35 miles of main and branch transmission lines now operating in the district.



Two 8-ft. Iron Pipes, 1,300 ft. Long, from Surge Tank (in distance) to Power House at Wawaiten Falls.



Sandy Falls Power Development—New Steel Pipe Leading to Power House.



Two Morgan-Smith 3,300 h.p. Water-wheels with Lombard Governors, Wawaiten Falls, Ont.

On Thursday, July 9th, the Westinghouse strike at East Pittsburgh was called off by the workmen, a large number of them reporting for work on the following day, and the works since the beginning of last week have been running full time.

On July 4, a section of the Port Arthur C.N.R. steel dock about 70 feet square and containing about 3,120 tons of steel rails, collapsed. The dock is practically new, having been built only three years ago.

As a result of the decision of the railway commissioners, made in Calgary on June 22, it is expected that the coal mines near Lethbridge, Alta., will go into operation on July 1. The understanding reached with the railways is that coal sent forward for storage and not used until after September 1 will get the new freight rate. The old rate will be paid up to September 1, and all the coal in bins on that date will be given a rebate to reduce the rate to that figure.

APPLIED GEOLOGY IN MUNICIPAL ENGINEERING.*

By Herbert Lapworth, D.Sc., M.Inst.C.E.

FEW municipal engineers of to-day can fail, after much experience, to realize the importance of practical geology in the construction of their works. The success of underground water supplies, whether attained by knowledge, trial and error, or by a stroke of luck, is admittedly dependent in each case upon the local geology. In works of sewerage, again, the cost may be largely influenced by the nature of the geological materials met with in the trenches and tunnels, producing as they may do difficulties and expense in excavation, timbering, dealing with ground-water, and modification in the design and construction of the permanent work. The same general principles apply to all deep excavations or foundations that may be carried out by the municipal engineer, whether in the construction of new roads with deep cuttings; sea, river, and retaining walls; bridges, reservoirs, sewage tanks, or large buildings. The geology of building stones, road-metals, and similar materials, though in a lesser degree, is of importance in all those branches of municipal work in which they are constantly employed.

One of the most striking factors that has forced applied geology upon the attention of the engineer has been the number of disputes which have arisen between contractors and municipal authorities concerned almost solely with the "nature of the ground" encountered during construction of public works. A few of these cases have been taken to the courts, some to arbitration, while others have been privately settled. In most instances the cause of the dispute has been due to some misunderstanding as to the "nature of the ground," or, in other words, the geology of the excavations; and almost invariably the ultimate result has been costly.

Frequently this kind of trouble has been the result of providing intending contractors with inadequate or misleading descriptions of the strata, obtained from trial holes or borings. Another cause has been the enforcing under the contract of a type of construction unsuited to the kind of ground unexpectedly encountered in the trenches or foundations.

Quite outside the question of legal disputes, however, serious difficulties have arisen, and heavy expense has been incurred by locating works in bad ground, either through lack of previous geological investigations or by wrong deductions from haphazard exploration, when such troubles might have been avoided in the original location or largely anticipated by investigation with practical geological knowledge.

It is a remarkable fact that this branch of engineering, common as it is to all classes of the profession, and on which so much frequently depends, is so strangely ignored in our own engineering literature, and until recently so little considered in the scientific training of civil engineers. Thus we find in our engineering text-books the most minute mathematical investigations of structures, more or less without relation to the varying geological materials on or in which they may be placed.

As a minor example, retaining walls, the dimensions of which, other things being equal, depend entirely upon the geology, water-bearing nature, and dip of the materials to be supported, are subjected to detailed mathematical analysis which may, in the drawing office, be slavishly applied to practice by arithmetical and graphical calculations, without any knowledge of the ground in which the walls are to be built.

To a limited extent the design of tunnel and sewer sections, for example, in "good" and "bad" ground, are considered in text-books; but no account is given of the many types of material met with underground, under varying conditions; nor of the principles of the occurrence of underground water, the great variation in cost, and the difficulties of construction under different geological conditions. Under "earthwork" we find the usual tables of slopes, prismoidal formulæ, and the like, but practically nothing on the highly important subject of "slips," or treatment of soft, unstable, or "bad" ground.

It may be argued, and rightly, that these are matters of actual practice and experience; but this does not excuse the failure of these treatises to impress the student with the great variation in cost and difficulties of engineering construction in different deposits, and the fact that efficiency and economy in construction might be as much the result of geological knowledge and investigation as of skill and experience in calculation and design. In some degree this void in the engineering text-books is due to the extreme complexity and variation in the physical properties of the geological deposits, which render them incapable of mathematical analysis.

Another inconsistency is sometimes to be seen in the letting of large contracts, where we may have items in the schedule of quantities amounting to only a few shillings, yet the contractor may be wholly ignorant of the character of the ground in which the works are to be constructed, and may in consequence under-estimate by several thousand pounds the cost of excavation.

The causes which have contributed to the scant consideration of practical geology among engineers are not easy to determine. Probably the chief of these is the fact that, whatever geological difficulties do arise during construction, it is always possible to complete engineering works, whether economically or not, without geological knowledge, and the engineer is not likely to be blamed by his employers for what turns up unexpectedly below ground.

Secondly, there is a pessimism among certain engineers, some of whom, though they may be experienced in excavation work, have little time for geology, and see only a comparatively heterogeneous mass of deposits underground in no cort of order, and to be classified broadly into two types—"rock" and "muck." There is also the optimist, who expects the geologist by surface indications alone to prophesy precisely what will be met with in almost every yard of his proposed trench, and in consequence loses faith in the accuracy and practical application of the science.

Thirdly, we have scant consideration of the subject in the engineering and geological text-books. The former have already been discussed. The latter, while containing all the necessary elements for the study of the subject, rarely present the applied or practical side of the science, except on the very broadest lines, and include matter that is unnecessary to learn, and which has rarely any direct bearing upon engineering questions.

In the writer's opinion, every civil engineer should be familiar first with the elements of geology, i.e., the principles of stratification, and formation of rocks and deposits, and the various structures occurring in them as the result of formation, change, weathering, or earth movements. He should be able to recognize and describe correctly all the common solid rocks and unconsolidated

*From a paper read at the 41st Annual Conference of the Institution of Municipal and County Engineers, Cheltenham, June 24th-27th, 1914.

deposits. He ought also to understand a geological map as he does a working drawing, and be able to plot approximate geological sections from it, as well as accurate geological records from borings, trial-holes, trenches, and tunnels. A training in petrology is desirable for the road engineer; but expert knowledge in this branch of geology usually requires more time than the professional engineer can afford. A thoroughly practical geological training, however, cannot be acquired without considerable experience in the field.

Of equal importance is the subject of hydro-geology. This includes the principles of the occurrence of underground water in different geological deposits, the laws of flow through porous and permeable materials, underground water-levels and their fluctuations. The mathematical side of this subject has been considered in great detail by foreign scientists and engineers; but so far the quantitative results have been of little direct application to practice, owing to the extreme complexity of underground conditions. Nevertheless, the principles arrived at are of great value in clearing one's ideas, assisting one to anticipate or prophesy, and to deal more rationally with underground-water problems where a certain amount of local information has already been secured. The value of this science is not only found in questions of water-supply, but in the excavation of trenches, cuttings, deep foundations, tunnels, drainage, and the like.

It would be impossible in a paper of this kind to cover the whole of that region in municipal engineering on which practical geology has a direct bearing. The following are merely a few selected instances commonly occurring in practice.

Preliminary Geological Investigations on Important Works.—In the majority of important public works it is desirable to ascertain by means of trial holes or borings the nature of the ground in which the works are to be constructed. The object of these investigations may be to determine first, the necessary dimensions of the permanent work and its approximate cost; secondly, the ground-water levels; thirdly, whether any saving may be affected by a change in location, if practicable; and lastly, to enable contractors to make a fair tender for the cost of construction. As regards the latter, it has given rise to discussion among engineers, whether data obtained from trial holes and borings should be shown to tendering contractors, because of the possibility of future claims or litigation. Information of this kind, however, allows a contractor to put in a fairer price, and avoids the necessity of his protecting himself, as he often does, by increased prices for unknown ground. Without such knowledge, a contractor's tender must usually be either unfair to the municipal body or the contractor himself; but there are pitfalls, of course, although the more practical geological knowledge there is brought to bear on the investigation, the less will be the risk.

As regards the selection of sites for boring, etc., it is essential that the number of holes should be sufficient to give reliable information, and the strata must be correctly described. Each hole should be sunk to the full contemplated depth of the excavation, and located on the centre-line, or within the limits of, and not outside, the work itself.

An interesting example of the result of sinking trial holes clear of the work occurred recently in this country in connection with a tunnel sewer. The trial holes, in order to save expense, were sunk in a railway cutting parallel to the sewer. These proved the ground to consist entirely of sandstone and conglomerate, whereas at least half the length of the tunnel was found to be in marl, the discrepancy being due to the cross dip of the strata. In the sandstone and conglomerate the tunnel was driven without timber, while in the marls close-timbering was required throughout, owing to falls from the sides and roof. An action was brought by the contractor against the public authority on the basis that misleading information had been supplied to him.

In the solid rocks the selection of the sites for trial holes, etc., can often be much assisted by a knowledge of the surface geology. This is especially applicable to tunnel work and the like; but the majority of municipal works are founded close to the surface, and the nature of the ground is dependent more on the character and depth of the soils, sub-soils, and surface deposits of the districts. As the detailed structure and arrangement of these surface deposits cannot be foretold with any accuracy from surface indications, trial holes or borings are essential.

Water Supply.—It is perhaps in questions of water supply, and especially in schemes from underground sources, that a sound knowledge of geology and hydro-geology is essential. The selection of a site for a well or boring, which will yield a satisfactory amount of pure water requires intimate acquaintance with the local geology, the order, arrangement and structure and water-bearing characters of its various strata, both as regards its solid rocks and superficial deposits. Familiarity with hydro-geological principles will also assist the investigator in analyzing more rationally from data in local wells and springs the existing underground water resources of the district, and in considering questions of possible pollution from farms, fields, cess pits, cemeteries, and polluted streams. Similar principles apply largely to water supplies from springs.

Geological considerations are also highly important in the selection of sites for impounding and service reservoirs, dams, and embankments, and in the location and construction of lines of aqueduct, pipes, and tunnels; but these are matters, perhaps, more usually in the domain of the consultant, dealing with large schemes, than in the routine work of municipal engineers.

Lines of Sewers and Pipes.—In the construction of lines and sewers we find many questions arising, where applied geology may be of use in location, design, and construction. The most serious difficulties are generally encountered in the unconsolidated deposits of alluvial, glacial, and other recent origin. The beds of clay, silt, mud, running sand and peat, which so frequently occur in these formations, are usually capable of supporting only relatively low pressures, and require great skill and experience in the treatment of cuttings or excavations, being especially liable to slips, and to act as a semi-liquid when their existing stability is disturbed by any excavation within their mass. Occurring as they do in the low-lying areas in valley bottoms, estuaries, and mud flats, they are liable to be saturated with ground-water, which further reduces their stability, and adds greatly to the difficulties of engineering construction.

In addition to the obviously water-logged ground formed of these deposits in low-lying areas, many lines of pipes and sewers may be constructed in water-bearing rocks, and deposits below the saturation level. The opening out of a deep trench in porous or permeable material below the saturation level has the effect of draining the measures on both sides of the trench, and producing a lowering of the water-levels in the vicinity. This may often give rise to claims for damage to local wells and springs. Any trench excavated below river-level, in a valley bottom and in permeable strata, will tend to collect a large volume of water; and similarly where the satura-

tion level rises from the valley bottom more or less parallel to the ground surface, a deep trench, although distant from the river, may require heavy pumping during construction. In all permeable surface deposits and permeable strata, such as chalk, sandstone, sands, and heavily fissured rocks, in which trenches are to be excavated, it may be often worth while to determine the underground water-levels in local wells, in order to see whether it is possible to fix the levels of the permanent work above them. Local wells have not infrequently been drained dry during the construction of a deep sewer, and sometimes permanently, so that it has been necessary to deepen them in order to restore their water supplies.

In considerations of this kind, hydro-geology has shown that the saturation level is subject to seasonal fluctuations; hence it may happen that a trench excavated in dry ground above the saturation level during one part of the year may be flooded during the winter and early spring seasons when the ground-water is high.

Heavy pumping, and consequent lowering of the saturation level in certain sands, peat-bogs, and marshes, may also seriously affect the foundations of adjacent buildings, producing cracks and settlement. Cases are on record where the saturation level has been lowered several feet by pumping, and accompanied at a distance of 200 feet by a settlement in the building of several inches.

In hilly districts, sewers and lines of pipes may require to be constructed in steep sidelong ground and scree slopes. Here there is a strong tendency for the surface material to slip into the trench, and great pressures may be brought to bear upon the timbering, and even upon the permanent work, which may be forced downhill and fracture. Such catastrophes have occurred both on lines of cast iron pipes and brick culverts in this country.

In certain types of ground again, such as those formed of steeply dipping shales or clay masses, or surface materials upon a highly inclined rock surface, slips are liable to occur, and even the permanent work may require to be strengthened.

Another curious phenomenon is occasionally found in deep trenches wholly in clay deposits, which may appear to be perfectly consolidated and firm during excavation. The weight of the material on both sides of the trench may be sufficient to cause the plastic material to flow, with the result that the timbering must be crushed in and collapse, accompanied by an uplift of the bottom of the trench, and of the permanent work. The writer has known of a length of over 100 yards of culvert invert, and side walls destroyed in this way. In some of the glacial clay deposits of Lancashire the trench bottoms have been observed to rise between the operations of trimming the trench bottom and bedding the pipes.

In ground of soft clays, mud, silt, running sand or peat, the difficulties of construction are, of course, at their worst. Special precautions must then be taken from the outset in timbering, strengthening the section of the permanent work, draining, and so dealing with the foundations below formation level, as to enable the ground to support the weight of the overlying structure.

The subject is too vast, however, to discuss here; but it may be taken for granted that in questions of this kind, the engineer armed with a sound knowledge of the local underground geology and its relation to the subsiding surface is likely to be more efficient, not only in dealing with lines of pipes and sewers, but with reservoirs, filters, bacteria beds, and other works.

Roads and Road Metals.—In the construction of new roads in the colonies or other foreign countries, practical geology may be a very important factor in location, where the choice of a route may be guided by the geology of the district to be traversed. Thus areas liable to slips, or former of very soft or very hard material, or requiring heavy retaining walls, may sometimes be avoided by deviation. In this country, however, the routes of the few new roads that are now being, or likely to be, constructed, are more or less fixed within rigid limits. Still, even here, practical geology and hydro-geology, when combined with engineering experience, are valuable aids in the excavation and drainage both of the cuttings and the road-bed itself.

As regards the materials for road metals, a sound knowledge of the occurrence and petrology of road stones is decidedly useful. The early experimental and scientific work of Lovegrove, Howe, Flett and others was a promising beginning in the scientific study of road metals. The introduction of tar and bituminous compounds, the tests of different materials in actual use on the road marked further stages. But road engineers are still finding difficulty in arriving at standards of value in road materials, and much practical and scientific work seems still to be necessary, both from the engineering and geological aspects. The modern road must necessarily be a complicated study, containing as it does problems in physics, chemistry, and geology. Perhaps with the establishment of courses in highway engineering at the universities, we may stimulate scientific research in this direction, and in conjunction with the practical results and experiments of road engineers, evolve a new technology, for which there seems to be a considerable need.

SUDBURY AND COPPER CLIFF SUBURBAN ELECTRIC RAILWAY.

Announcements have appeared from time to time in these columns respecting the organization and construction of the Sudbury and Copper Cliffe Suburban Electric Railway. Latest advices contain the following information relative to it:—

The provisional directors of the road are Messrs. L. Laforest, Bell, Cochrane, Morin, Mackey, McCrea and Norton. Mr. C. D. Norton is engineer for the company.

The only route upon which any survey work has been done up to the present is the Copper Cliff route, 5.1 mi. in length, with a grade of 4 per cent. The curvature is as follows: one 50-ft. radius, one 200-ft. radius, one 20°, two 15°, five 10° and a couple of curves of about 1½° or 2°.

There will be one 3-span trestle bridge, two single-span trestles and two small deck culverts. Corrugated iron pipe will be used for culvert work.

On the Copper Cliff route two miles have already been graded. The company is employing day labor and propose laying track by the same method. Some station work has, however, been let by contract. An 80-lb. rail is being used. On the 0.43 mi. of track in the town of Sudbury a permanent pavement is about to be laid. The ties will be laid on a 6-in. concrete base and filled in with concrete between. The Warren Bituminous Paving Co. is doing this work.

With respect to rolling stock, it is proposed to acquire two interurban cars and one city passenger car, although the entire question of rolling stock has not as yet been definitely decided upon. There will, however, be a combination freight and express car and a combination work and tank car and snowplow.

Mr. Norton states that it is proposed to use D.C. current at 200 volts on the Copper Cliff route outside the town of Sudbury and 600 volts D.C. within the town limits.

WOOD PRESERVATION.

A PAPER recently appeared in the Journal of the Royal Society of Arts, written by Mr. A. J. Wallis-Taylor and descriptive of modern processes for the preservation of wood. It is stated that wood should be seasoned for at least 6 to 12 months before treatment. (1) Kyanizing consists in steeping timber in a 1 per cent. solution of mercury chloride for 7 to 11 days. (2) Burnettizing comprises preliminary steaming, followed by impregnation in a 2½ to 2 per cent. solution of zinc chloride under a pressure of 7 to 8 atmospheres. In the zinc-tannin or Wellhouse process, treatment in a partial vacuum follows the preliminary steaming, a small percentage of glue is added to the zinc chloride, and after impregnation for 2½ to 6 hours at 100 to 125 pounds pressure per square inch, the timber receives a final treatment with a 0.5 per cent. solution of tannin under the same pressure for two hours. (3) Creosoting usually involves steaming of the dried timber, heating under reduced pressure, and treatment with creosote oil under a pressure of 100 to 180 pounds per square inch. The amount of creosote absorbed by the timber varies from 7 to 20 pounds per cubic foot, and the temperature of the treatment should be between 100° and 130° C. In the Curtis-Isaacs process, the timber and creosote are heated to above the boiling-point of the sap at ordinary pressure in a retort having vents open to the air; the vents are then closed and the creosote is forced into the wood under pressure. The Rueping process consists in forcing, first, compressed air at a pressure of 80 to 100 pounds per square inch into the pores of the wood, and then at a higher pressure creosote oil, without relieving the air pressure. In the Lowry process treatment with creosote oil at 77° to 82° C. under a pressure of 180 pounds per square inch is followed by draining and a rapid vacuum treatment. In the zinc-creosote or Rutger process an emulsion of ½ pound of "dry zinc" and 1.5 to 4 pounds of creosote oil per cubic foot of timber is used; the emulsion being continuously agitated (e.g., by a centrifugal pump). The Hasselmann process uses a solution containing copper, aluminum, and potassium sulphates, heated 118° to 126° C. under a pressure of 35 pounds per square inch. In the creo-resinate process (especially suitable for wood paving blocks) air at 121° C., under a pressure of about 100 pounds per square inch, is substituted for steam; the antiseptic agent consists of 50 parts of creosote oil, 48 of resin, and 2 of formaldehyde, and impregnation is followed by a treatment with lime water at 100° C. under 150 pounds pressure. The Guissani process uses a mixture of anthracene and pitch heated to 140° C., in which wood is submerged until it is free from moisture and sap, after which it is successively treated with cold, heavy tar oil, and cold zinc chloride solution. In the saccharine solution or Powellizing process, suitable for the treatment of green wood, a solution consisting mainly of sugar, with a small percentage of arsenic, is used. The vulcanizing or Haskinizing process consists in roasting wood, which has been previously dried by steaming, to a temperature high enough to coagulate its dried albumins (71° to 94° C.), and to resolve some of the fibre and sap with the production of wood creosote. In addition to the use of definite antiseptics and of a large number of metallic salts for wood preservation, mineral oils, preferably mixed with asphaltum can be used to fill up the open wood cells, thus protecting the timber from the action of heat moisture, and air. By the zinc chloride process the life of wood is more than doubled; creosoted wood lasts 25 to 50 per cent. longer than wood treated with zinc chloride, but costs three or four times as much. The amount of preservative injected into one cubic foot of various classes of timber ranges from about 3 pounds of mercury chloride in the case of hard woods to about 6 pounds for moderately hard woods and 10 pounds for soft woods, the corresponding amounts of creosote oil being 3, 10, and 20 pounds respectively. The average costs of preserving timber with zinc chloride, creosote oil, and mercury chloride are approximately 2.5 cents, 10 cents, and 16 cents per cubic foot respectively.

CIVIC WORK IN HAMILTON, 1913.

In the annual report for 1913 of Mr. A. F. Macallum, City Engineer of Hamilton, the population of the city is given as 100,808; and its acreage, 6,450. During 1913 a new 4-ft. intake into Lake Ontario, 2,120 ft. in length, was laid., the new pumping station at Burlington Beach was completed, and a new high-level pumping station of 4,000,000 gal. capacity also erected. A standpipe, 100 ft. in height, with a capacity of 80,000 gal., was erected on the mountain and connected by a 12-in main to the high-level pumping station.

The large trunk sewer on Ottawa Street and many small sewers were finished during the year. Construction

Asphalt Plant at Gage Avenue, Hamilton; 1,500 Yards Capacity.

work in connection with the West End sewage disposal works (for illustrated description, see *The Canadian Engineer*, Jan. 22nd, 1914), progressed very favorably. The grit chambers and sludge tanks were finished and the excavation and piling done for the six Imhoff tanks, three of which were partially completed before the close of the season.

In connection with pavement work, a new asphalt plant with a capacity of 1,500 yds. per day was built in the east end of the city. When it had been completed, the city operated both asphalt plants, with the result that more asphalt pavements were laid in Hamilton in 1913 than in any previous year. In addition to sheet asphalt, a considerable amount of creosoted wood block and asphaltic concrete pavements were laid. The total yardage of various kinds of pavement laid during the year was computed in our issue of April 16th to be 279,-497 square yards.

The Province of Ontario has produced 200,000,000 ounces of silver since the Cobalt deposits were discovered in 1903.

THE TRAINING OF THE HIGHWAY ENGINEER OF THE FUTURE.*

By H. Percy Boulnois, M.Inst.C.E.

THERE can be no doubt that the introduction of self-propelled traffic by means of the internal combustion engine has entirely changed the problem as to the weights and speeds of the traffic which the road of the future may be called upon to bear. With horse-drawn traffic these weights and speeds were limited within almost rigid limits, but with modern traffic these limits are removed and no one can tell as to what weights, and at what speed, the traffic of the future may develop. It is true that legislation may, from time to time, impose restrictions on the traffic, as it has frequently done in the past, but the clamor of commercial needs and the popular outcry for increased means of transport will very soon break down any such artificial barriers to progress, and the highway engineer of the future will have to provide for these inevitable changes which are certain to take place.

The past evolution of our railways is one instance of the change that arose immediately mechanical methods of transport were introduced. The lightly constructed railway of the past has had to give way to a strongly built permanent way that will carry the enormously increased weights of the locomotives and carriages which are now imposed upon it, and the permanent-way engineer has had, from time to time, to strengthen and improve his roadway in order to meet the ever-increasing demands made on him by the locomotive and rolling stock departments. It is by no means inconceivable that the highway engineer of the future will shortly be called upon to make similar improvements in his roads, and he will suffer from the great disadvantage of not having that control over the user of his roads which the railway engineer enjoys.

But apart from this, we are already face to face with the fact that road construction is inevitably altering in its character. Where formerly there was but one form of construction for the ordinary road, viz., that which was known as "waterbound macadam," there are now already a large number of different methods of construction, for all of which special advantages are claimed. It is evident that the "road question" has entered a scientific field never before contemplated, and that something more will be required of the highway engineer of the future than the mere rule-of-thumb experience of the past. The question consequently arises as to whether there is a necessity for specializing in this direction, or whether the ordinary training of a civil engineer is sufficient for the purpose. The question is, therefore, is there a demand for the special profession of the highway engineer, and, if so, in what manner should he be trained?

That there is already a demand for the special profession of highway engineering is very evident, but the manner in which the highway engineer of the future should be trained is not so easily answered.

It is difficult to say exactly what this special training should be. In the United States an endeavor has been made to meet this question by giving a special course of training in highway engineering at the Columbia University in the City of New York, which might form the basis on which some such special training could be instituted in other technical universities and colleges.

It may, of course, be argued that technical instruction and laboratory experiments will not make roads, but I do not think it can be denied that the young man who is equipped with a thorough scientific and theoretical knowledge of his subject should be better able to cope with the present-day traffic problems than one who is not so equipped. The great Chinese philosopher Confucius, about 2,000 years ago, wrote:—

"The craftsman who desires to execute his work to perfection must first see that his tools are sharp."

This technical training must, however, be followed by practical experience, and there appears to be no better way of acquiring this experience than that of an articled pupilage under an engineer or surveyor who is responsible for the roads in his district.

If the road of the future will demand more science for its well-being, it is only right that science should demand better pay for its work. The specialist should always be able to secure better remuneration than the ordinary practitioner, and this should hold good for the highway engineer of the future.

I have endeavored to show in this short paper that:

(1) A new profession, viz., that of the highway engineer, is on the eve of commencing.

(2) He should receive a special training for the purpose of this new profession; and

(3) That his services require adequate remuneration.

*Abstract from paper read before the Institution of Municipal and County Engineers, of Great Britain, June 24-27, 1914.

UNIFORMITY IN BOILER INSPECTION.

A notable improvement that was arranged recently at a conference of boiler inspectors of the different provinces of Canada is the adoption of a uniform set of regulations for the entire Dominion. Doubtless the boiler manufacturers interested in Canadian business will appreciate the efforts that are being extended in an endeavor to bring the provinces into uniformity in this respect, as it will enable inspection in one province to be accepted in any other.

At the present time Manitoba, New Brunswick and Nova Scotia have no regulations, although legislation requiring them has been passed.

Mr. D. M. Metcalfe, chief boiler inspector for Ontario, is chairman of the conference.

RAILWAY ACCIDENTS IN CANADA.

During 1913, there were, according to the report of the Board of Railway Commissioners for Canada, 2,547 accidents on Canadian railways, involving the death of 643 persons, of whom 21 were passengers, 303 employees and 319 others. Of the 2,231 injured 410 were passengers, 1,603 employees and 21 others. With respect to accidents the report states:—

"Inquiries into derailments have brought out the fact that track conditions are largely responsible for such accidents. This is mostly accounted for by the fact that railway companies have not, on the whole, increased the efficiency of their roadbeds proportionately with the increases in the weight of their rolling stock." As to collisions it is said: "At first thought it would seem almost imperative that railway companies should be required to adopt, without undue delay, some form of positive block system on all lines. But we must not lose sight of the very important fact that the great majority of such accidents result from the non-observance of operating rules."

On June 26, the new municipal dock at Hull, Eng., was formally opened by their majesties, King George and Queen Mary. The dock has a frontage of one mile along the Humber, and embraces a water area of over 52 acres. Large new warehouses and 40 miles of railroad sidings have also been provided, together with special facilities for the shipment of coal. The total cost of construction exceeds $12,500,000.

HYDRO-ELECTRIC PLANT AT PANAMA

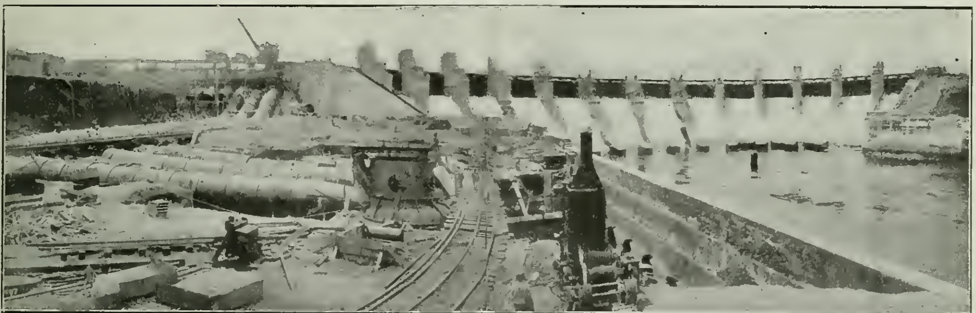
PROPOSED SUPPLY OF 12,000 KW. UNDER AVERAGE HEAD OF 75 FEET, TO BE DEVELOPED AT GATUN SPILLWAY FOR THE PERMANENT OPERATION OF THE CANAL.

Of particular interest in connection with the construction of the Panama Canal is the part which hydro-electric power is to play in its permanent operation. The supply of electrical energy for both lighting and power purposes on the canal is to be derived from a hydro-electric plant which is being installed at the Gatun spillway dam. It will utilize the surplus water of Gatun Lake, which is sufficient to supply 12,000 kw., of which 6,000 kw. will be developed by the plant at present under construction. The power will be used for lighting the canal, operating the gates and locking machinery, towing locomotives, and the general operation of machine shops, dry docks, waterworks and coal-handling plants at both ends of the canal. In conjunction with it there is a 4,500-kw. electrical supply, steam generated, at Miraflores, erected a few years ago to supply power for construction work. This will be used as an auxiliary to insure continuous service in case of accidents. The full utilization of the power available at the Gatun spillway, i.e., the entire 12,000 kw., will be brought into play with the proposed electrification of the Panama Railroad.

The head works of the development consist of reinforced concrete passages 12 ft. in width, fitted with wrought iron racks 29 ft. 7 in. high, to intercept floating debris from the surface of the lake. Through these passages water is admitted into the pipe lines by three head gates 10½ ft. in diameter. These cuts are of cast iron and watertightness is insured by bronze-capped seats. The available head from Gatun Lake to mean tide level of the Pacific varies between 79 ft. and 91 ft. representing extremely dry and flood seasons respectively. The plant is designed to develop full capacity under an effective head of 75 ft.

Intake Gates.—Each gate is equipped with two steel stems fitted with bronze nuts working in roller thrust bearings, and the nuts are fitted with steel bevel gears arranged to be operated by a 15-h.p., 220-volt, alternating current motor with a speed of 750 r.p.m. The motor is placed between the stems and has shaft-extensions on each side carrying two bevel pinions arranged to engage the gears on the stem nuts. The stands which carry these nuts are equipped with hand operating mechanisms, arranged to be disconnected when the gate is operated electrically.

The gates are equipped with automatic control devices, consisting of a limit switch geared to one of the gate stems and a float switch actuated by the water in the pipe. The gate-motor switch is closed at the power house, the gate being closed and the pipe line empty. When the gate has opened a distance which would fill the pipe line in about five minutes, the limit switch opens the circuit and stops the motor. When the pipe line is filled and the water rises in the 36-in. vent just below the gate, it actuates a float switch and again closes the motor circuit, thereby causing the gate to be opened fully, when the limit switch again operates to prevent over-travel. The gate is closed by reversing the main switch at the power house, causing the motor to operate, the limit switch stopping the motor when the gate has reached its closed position. An auxiliary hand-operated (2 men) mechanism is also installed for operating the gates.



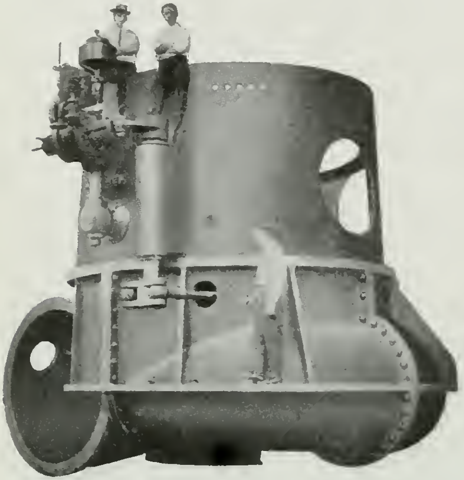
View of Gatun Hydro-electric Installation, Showing Pipe Lines, Turbines and Ogee Spillway Dam.

Pipe lines 10.5 ft. in diameter and 420 ft. long lead from the gates to the turbines to which they are attached by 90-deg. bends of 70-ft. radius. Each of the pipe lines is arranged for attaching a Pitot tube, while its unit is in service. The pipes are of ⅜-in. plate, courses 8 ft. long and three sheets around the circumference. Each course has a centre ring ⅜ x 3-in. Z-bar. The pipes are covered with reinforced concrete as rust protection. Each pipe has two 6-in. saddle-nozzle connections located 45° on each side of the vertical centre line of pipe. From these connections there are two Pitot-tube guide supports placed across the pipe at right angles to each other. These are bolted in the pipes and, while intended to be permanent, can be removed readily if desired.

Each 6-in. outlet on the pipe is closed by a gate valve with tongued and grooved flanges which match the base on the Pitot tube apparatus. Each Pitot tube is arranged to measure both the static and velocity heads at practically

the same point in the pipe, and readings are obtained by means of "U" tubes containing a colored liquid having a specific gravity of about 1.25. Carbon tetrachloride, thinned with gasoline to the proper specific gravity and colored red, is usually used for this purpose.

One end of each "U" tube is connected to the static and the other to the velocity side of the Pitot tube; the difference in height of the colored liquid columns is read, from which the velocity of flow in the pipe is calculated.



Pelton-Francis Turbine, 3,600 h.p.

The principal buildings connected with the actual operation of the canal are the hydro-electric station at Gatun spillway; the gate control house at the spillway; the four substations of the transmission system at Gatun, Miraflores, Cristobal and Balboa; and the three lock control houses. All these structures are designed along simple lines in harmony with the unbroken surfaces of concrete of the adjacent engineering works.

Generating Station.—The hydro-electric station measures 61 ft. by 137 ft. and has an extreme height of 74 ft. The building is designed on the unit principle, to admit of future extension, and consists of a single room open to the roof, exposing the trusses upon which are laid reinforced concrete roof slabs, which, in turn, receive red Spanish tiles. The walls are of poured concrete, 30 in. thick to the level of the crane rails, near the cornice. The exterior overhang of the main roof is 13 ft. 2 in. and that of the monitor roof 4 ft. 8 in., the exceedingly large projections having been generally adopted for all the permanent buildings in the Zone as a shelter from tropical rains, as well as from the heat of the sun.

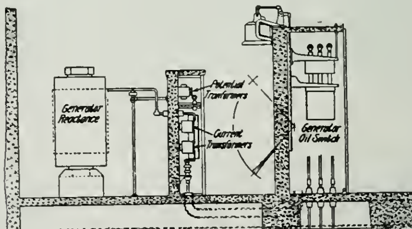
Beyond the general use of tiles for flooring, and an interior white-enamelled brick wainscot 14 ft. high, to relieve the coarseness of the walls, there is no difference in the finish of the concrete surfaces within and without. The dead surfaces of the concrete or stuccoed walls, which will probably be improved when weathered, are further relieved on the exterior by the red tile roofs. The principal ornamentation is on the under-side of the broad projecting cornice, which is broken up into panelled coffers. A number of these contain light outlets that cast light down on the walls and throw the structure into strong relief at night.

The interior has four principal elevations, namely, a pit for the three 2,500-kw. hydro-electric turbines, a main floor, and two galleries. The turbine pit, with an area of over 2,100 sq. ft., is located 6 ft. below the level of the main floor, and is reached by iron stairways descending alongside the turbines. From the pit other stairs lead down to the store room on the north side, and to the air-compressor and oil-pump compartments at the ends. The pit is lined with white-enamelled brick, and the 14-ft. wainscot extends from the main floor up to the first gallery elevation on the south wall of the pit.

The main floor is divided into two parts, one being devoted to the use of the electrical equipment, and the other forming an uninterrupted passage on the longitudinal axis of the building, terminating with two large entrance doors at either end. Easy access to railway wagons is afforded by means of a track which enters this floor through the northwest door, thus giving every facility for handling heavy machinery by the 30-ton electric crane running the length of the building overhead.

Concrete stairways at either end of the building give access to the mezzanine and second galleries, which are devoted to the switchboards, oil-switch compartments, reactance coils and other electrical equipment. Two such galleries extend the entire length of the station on the northeast side, and in the south corner are superimposed two smaller ones used as a machine shop and an office respectively. The sashes in the large side wall windows are operated in sections by a hand gear system, and the continuous bottom-hinged sashes in the roof monitor are operated by motors.

Water Turbines.—There are three 2,000-kw. main generating units in the hydro-electric station, each driven by a special, 50-in., vertical, single-runner, Francis turbine. Each has a maximum capacity of 3,600 h.p. when operating under an effective head of 75 ft. and at a normal

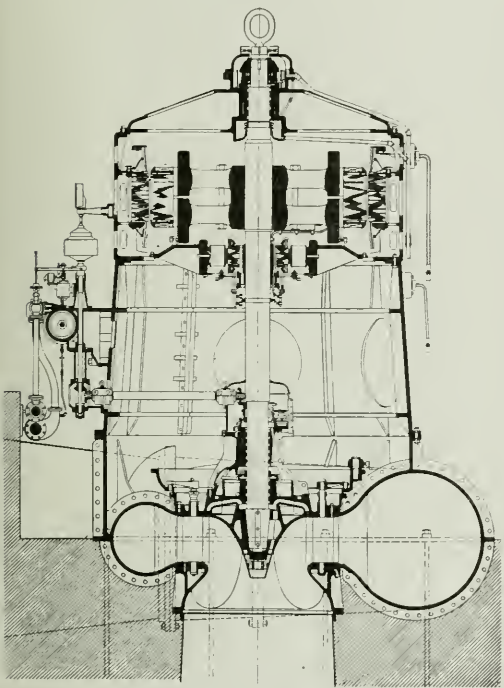


Arrangement of Switching Apparatus.

speed of 250 r.p.m. The centre of the runners is 20 ft. above tail water, and the discharge is through steel-lined concrete draft tubes 71 in. in diameter at the turbine and increasing to an elliptical section of 9 x 17 ft. at the outlets. The linings are of ¼-in. steel. A roller thrust

bearing mounted on top of the generator carries the weight of the revolving parts of both the turbine and generator. The turbine is so designed, however, that, when running at full capacity, the runner exerts an upward thrust of 10 tons, thereby relieving the thrust bearing of that amount of load.

Oil for the thrust bearing is supplied by a small pump geared to the turbine shaft, and a tank is provided below



Cross-section of Turbine, Generator and Exciter.

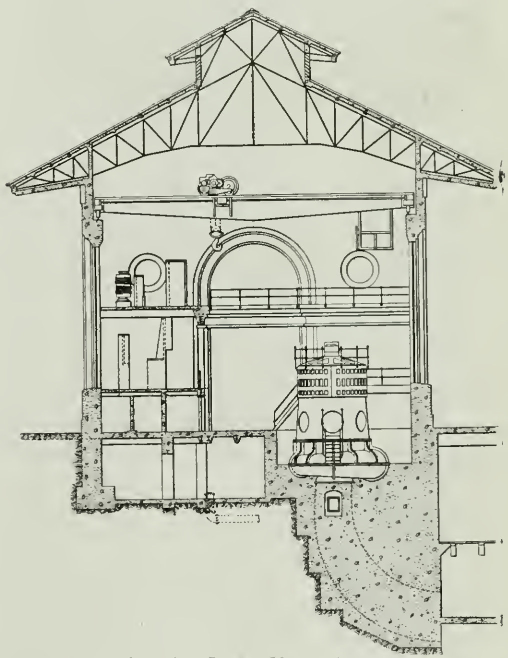
the pump to receive the overflow from the bearing. In this way a constant circulation of oil is maintained. As this oil returns to the suction tank, it passes through the lower guide bearing on the main shaft, lubricating it.

The runners are made of special bronze and weigh approximately 7,000 lb. each. They are taper bored and held in place on the lower end of the shaft by bronze nuts. The surfaces of the runner vanes are all hand finished to reduce hydraulic losses.

The speed of the turbines is controlled by Pelton oil pressure governors, mounted on the distance rings and driven by bevel gearing from the main shaft. Tachometers are mounted above the governors and are directly connected to the governor heads. The governors are fitted with small electric motors for varying the speed of the main units for synchronizing purposes, and a device is provided on each governor for varying the permanent drop in speed from no-load to full-load. This can be adjusted for any variation from 5 per cent. drop to absolutely constant speed from friction load to maximum load. The governors are also fitted with hand control mechanism for adjusting the gates independent of the oil pressure.

The wicket gates for controlling the supply of water to the runner of the turbine are steel castings with hand-finished surfaces. Each gate has its pivot stem extended upward through a packing gland and is fitted with an operating lever. All the gate levers are connected to the gate ring by means of bronze links, and the gate ring is connected to the governor rock-shaft. All the regulating mechanism is, therefore, outside the turbine case, except the gates themselves. The water passages on each side of the gates are provided with renewable rolled-steel wearing plates. Pressure oil for actuating the governors is supplied by two Pelton rotary pumping units, driven by 10-h.p. alternating-current motors at a speed of 375 r.p.m., each pump being capable of supplying the governors on all three units. The governors work on an open system, there being no vacuum chambers used. The discharge oil from the governors is led into oil-sump tanks, from which it passes into the suction of the pumps. Each oil pump is connected to a steel pressure-oil receiver with an air space above the oil. The oil-sump tanks and pipe connections are installed in duplicate, and valves are provided to enable one set to be cleaned while the other is in service.

Generators.—The three main generators are of a three-phase, 25-cycle, revolving-field type, developing 2,000 kw. at 0.8 power factor, 2,200 volts and 250 r.p.m. They have 25% two-hour overload rating, and are of General Electric Co. make. The exciter is mounted below the main generator but is readily accessible through large



Section Showing Power House Arrangement.

holes in the distance ring, a platform being provided inside the ring from which the exciter commutator and generator-collector rings may be reached. All windings were made moistureproof on account of extreme climatic conditions. Provision is made for securing the magnet frame of the exciter to the revolving element of the generator, so that the complete rotating element, together with the exciter frame, is raised at once in disassembling.

In addition, there are two motor-driven exciters. These consist of a 100-kw., 125-volt, 500-r.p.m. generator, direct-connected to a 150-h.p., 2,200-volt, 25-cycle squirrel-cage type induction motor. They are mounted on a common base plate and provided with three bearings. These exciters can also be used for charging the control battery.

Distribution System.—On account of the distance, current is transmitted at a voltage of 44,000 from the power station to both ends of the canal. The step-up transformers are, however, not located in the power plants, but in substations in their vicinities; therefore, the power plants generate and distribute only 2,200-volt current.

The system of connection throughout employs the double-switch scheme, with provision for disconnecting any oil switch for cleaning or repairs without interrupting the circuit. This system was naturally selected for this station because it was considered the most flexible for the requirement of uninterrupted service.

The double 44,000-volt transmission line runs across the Isthmus, connecting Cristobal and Balboa with the two power plants. There are four 44,000/2,200-volt substations stepping down at Cristobal and Balboa, and up or down at Gatun and Miraflores, depending on which of the two plants is supplying power. Thirty-six 2,200/240-volt transmission stations for power, traction and light at Gatun, Pedro Miguel and Miraflores locks have been provided. Three 2,200/220-110-volt transformer stations are installed for the control boards at the locks; and stations at Cristobal and Balboa for the coal handling plants, machine shops and drydocks.

The complete hydraulic equipment for this installation, including the racks, head-gates, pipe lines, Pitot tube testing apparatus, turbines, governors and oil pumping units, was designed and built by the Pelton Water Wheel Company; and all the electrical apparatus, including the generators, switchboards, transformers, head-gate motors, limit switches, float switches, etc., were furnished by the General Electric Company. All details of design and construction were subject to the approval of the Isthmian Canal Commission and its engineers.

Pittsburg business men, who are understood to be working in the interests of the Pickards Mather Company, of Cleveland, O., are investigating the iron deposits in the neighborhood of Savanne, a point on the C.P.R., about 75 miles west of Fort William, Ont.

Mr. P. C. Burpee, C.E., president of Concrete Builders, Limited, Fredericton, N.B., has made a business inspection trip throughout the principal brick-making cities of Quebec and Ontario, and has purchased a 10-inch tamper and brick machine, capable of making 10,000 bricks per day. It is the intention of the company to manufacture only fancy brick.

In connection with the extensive additions to be made by the Ford Motor Company, Detroit, Mich., which will double the capacity of its plant, and are to be completed this year, there will be erected a power house at a cost of about $5,000,000. It will be 240 feet long, 150 feet wide, and 85 feet high; and it is stated that it will contain the largest gasoline engine in the world, one which will drive motors that will produce 80,000 horse-power. Several buildings will also be constructed, each 900 feet long, 60 feet wide, and 6 stories high.

A new means of transportation is planned in the survey of the Saskatchewan River, which is to be completed this fall by engineers of the Dominion Public Works department. They have been engaged in the work for three years, and the idea is to have a 5-foot waterway from the Rockies to Winnipeg. This would be sufficient for barge traffic. The cost is roughly estimated at $15,000,000, the principal item of expense being a series of locks along the river. The total cost would be reduced by valuable water power to be developed along the route.

THE CARE OF WIRE ROPE.

EXPERIENCE has taught that there are four leading causes for the destruction of wire rope, namely, abrasion, overstrain, undue bending and corrosion. These, together with suitable methods to provide longer utility, are outlined in a recent issue of "Power," from which the following has been abstracted:

The cause of failure can usually be determined from the appearance of the rope. If, for example, the wires wear thin in a short time, the rope has been subject to abrasion; if the wires are but little worn and broken off squarely, usually sticking out all over the rope, it has suffered either severe bending stress or overstrain; and if the wires are rusty and pitted, corrosion is to blame.

Abrasion in a wire rope is frequently the result of: (1) Faulty grooves in wheels that are roughly worn or too tight for the rope. (2) Dragging of the rope upon the ground or over some fixed obstruction. (3) Using a rope under conditions for which none but the toughest steel (plough or improved plough) is adapted.

Badly broken wires, showing excessive bending, indicate that the wheels are too small or too numerous. Rope badly corroded shows the lack of proper lubrication.

In addition to the destructive causes mentioned above, ropes sometimes suddenly tear apart. Such cases are invariably the result of accidents to machinery or appliances, which bring upon the rope a load far beyond its capacity, or they are due to a serious weakening of the rope at the point of rupture, caused by some local abuses. One of the most common of these injuries is the damage arising from "kinking." If for any reason the rope is allowed to form a loop, and this loop is drawn taut, a kink will result. Though the kink may be straightened out, it leaves a permanently damaged and weakened spot and so should always be avoided. When a running rope has a socket attached to the end, constant vibration tends to weaken the wires, and this weakness is increased if water collects directly over the end of the socket. It is, therefore, advisable every three to six months to cut off a piece from the end of the rope and reattach the socket.

Besides the causes mentioned, the effects of which are usually revealed by inspection, temporary overloads producing excessive stresses are sometimes applied, and by straining the wires beyond their elastic limit tend to shorten the life of wire rope. Such excessive stresses are more apt to occur where a rope is slack, or is attached to a short length of slack chain, and the power to lift or haul a load is suddenly applied, with the result that, instead of the rope gradually adapting itself to the required pull, it is subjected to the jerk arising from the full inertia of the load. Lifting tests made on wire ropes, attached to chains having 2½ in. to 12 in. of slack attached, show that when loads are applied suddenly, the stresses are from one to four times as great as those sustained when the same loads are gradually applied.

When a complaint is made that a wire rope has not given satisfactory service, the first questions asked by the manufacturer are: "How was the rope lubricated?" "What is the condition of the inside wires?" These questions arise because the experienced wire-rope maker fully appreciates that a wire rope is a complex piece of machinery and knows that the importance of proper lubrication is too often overlooked.

A lubricant or preservative should not only penetrate to the hemp centre, in order to saturate it and prevent absorption of water, but it should also coat thoroughly the inside wires of each strand.

TRANSVERSE STRENGTH OF CUT SCREWS IN WOODEN JOINTS.

In *The Canadian Engineer* for March 14, 1912, an article was published giving the results of a nail test made in connection with the design of a hydro-electric plant at Sandy Falls, Ont. The purpose of the test was to ascertain the transverse holding power in pine lumber of 9-inch spikes (4½ to the pound), so that a well-proportioned joint could be designed. The results included several notable features of nailed joints, as follows:

(1) The permissible deflection value of 1/16 inch, i.e., the deflection which can be caused without weakening the joint is altogether too small. Joints tested to deflections of one inch or more seemed to be in no way weakened. This is a strong point in favor of the nailed joint.

(2) The percentage relation of elastic limit to ultimate load would depend on the assumed definition of the former. No satisfactory results were obtained, but they were sufficient to indicate that it is at least 50%.

(3) The relation between the strength of a joint and the number of nails is such that the former is proportional to the latter and quite independent of the arrangement provided failure did not occur by cracking of the timbers.

It is interesting to recall these tests in conjunction with similar ones, performed in Cornell University last year, to determine the transverse strength of ordinary cut screws in single shear in a wooden joint. The results were given in the Cornell Civil Engineer and from it the following has been extracted:

Three kinds of wood were used in the tests, cypress, yellow pine and oak. The cypress was fine grained and of uniform quality; its specific gravity was 0.442, and its rate of growth was 20 rings per in. The wood was thoroughly seasoned, and had a compressive strength of 4,980 lbs. per sq. in. The yellow pine was of a rather coarse but straight grain; its specific gravity was quite variable, the average being 0.648. The rate of growth varied from 8 to 15 rings per in., and this gave corresponding variations in results. The average compressive strength was 7,580 lbs. per sq. in. The oak was a good quality of red oak, well seasoned, of a firm straight grain and of uniform texture. Its specific gravity was of 0.701, its compressive strength was 8,440 lbs. per sq. in., and it had 20 rings per inch.

The test joint consisted of three pieces, each 12 ins. long and 6 ins. wide, the two side pieces B and B^1 (Fig. 1, a) having an 8-in. lap on the middle piece. The thickness of these pieces varied with the length of screw used, but the middle piece was always of sufficient length to cause the screws to be in single shear. The screws were arranged in the form of an equilateral triangle, the apex of the triangle being placed upward on one side piece and downward on the other (see Fig. 1, b). The test piece was subjected to compression, the forces acting as shown by the arrows in Fig. 1 (a).

It was found by experiment that screws could not be driven closer than 2½ ins. to an edge perpendicular to the grain without danger of splitting the wood. This distance was therefore used for all of the tests. It was found impossible to drive screws without previously boring holes, these holes having a diameter equal to that at the root of the screw threads. In oak, and where large screws were driven in yellow pine, separate holes had to be bored for the shank and for the threaded portion of the screw. A hole was also bored to receive the head of the screw, which brought the entire screw into action. In hard wood the driving of the screws was facilitated by lubricating them with thick, wet soap.

Method of Testing.—The procedure in testing was to measure the force at each 1/32-in. slip, up to a maximum of 6/32 in. This is more than would be allowed in any structure in practice, so it was not thought necessary to carry the test up to destruction. The deflection was measured by means of a steel pointer, attached to the middle piece, sliding over a celluloid scale, attached to the two outside pieces. The force was applied by turning the crank of the Olsen machine very slowly and at a uniform rate of speed. The result of rapid testing will be shown later. In making the tests it was found that the uniformity of results was materially affected by the bearing of the joint in the testing machine. To secure good results, it was necessary that the joint be so made as to have a full bearing on the table of the machine, and furthermore, that the axis of the joint be truly vertical.

Fig. 2 shows in a general way the forces acting on a screw in a joint. The screws were but slightly deformed in cypress, the wood being so soft as to crush readily without bending them. In yellow pine and oak, however, the screws were bent as shown. An attempt was made to derive a formula for the strength of a screw at a certain

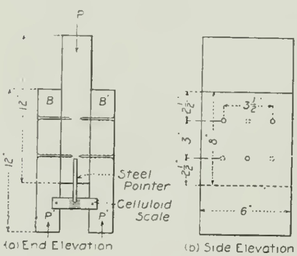

Fig. 1.—Arrangement of Screws in Test Specimen.

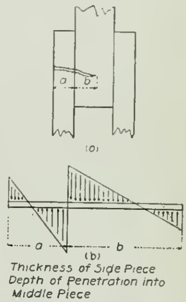

Fig. 2.—Distribution of Forces on a Cut Screw in Single Shear.

slip, but so many different factors, such as gripping of threads, amount of bearing, curvature of screw, etc., entered into the computations that it was found impossible to obtain anything of reasonable certainty.

Preliminary tests were made to determine the following items:

(1) Effect of driving, with and without boring holes.

(2) Effect of rapid testing.

(3) Effect of friction between adjoining pieces of the joint.

(4) Effect of varying the number of screws in the joint.

Effect of Boring Holes.—It was found, in the case of cypress, that there was a very small increase in the strength of the joint when the screws were driven without previously boring holes. In the case of yellow pine, there was a slight decrease in strength when no holes were bored.

The holding power of a screw driven in wood depends materially on the wood fibers securely gripping the screw threads; hence, if the screw is driven in such a manner as to break the fibers around the threads, the holding power will be decreased. The transverse strength, however, is not nearly so dependent upon the gripping of the threads by the wood as upon the bearing of the screw in the wood. In the case of cypress the fibers, not being broken in driving and being very soft, close tightly around

the screw threads and tend to increase the area of contact between the screw and wood, resulting in a slightly greater strength when driven without previously boring holes. In the case of yellow pine it is necessary to drive the screws with the hammer before using the screw driver. The fibers are therefore broken to a certain degree, resulting in a considerable decrease in the area of contact between the wood and the screw. This is probably the cause of the lower transverse strength in the case of the screw which has been driven without previously boring holes.

Effect of Rapid Testing.—When the load was applied too rapidly the values were not uniform, showing a great range as compared with those with slow testing. The values obtained by rapid testing averaged about 20 per cent. lower than the others. The difference was especially marked in the first few increments of slip, after which the values seemed to approach each other. This shows the importance of applying the loads slowly in tests of this nature.

Lubrication Tests.—The purpose of these tests was to determine what part of the strength of a joint is due to friction between the surfaces. It was found that in any case a lubricated test piece was but slightly weaker. It can therefore be assumed that the friction plays only a small part in the strength of the joint. The maximum difference between the lubricated and non-lubricated joints was shown in the first few increments of slip, the succeeding values showing little difference.

Effect of Variation in Number of Screws.—As the number of screws per joint is decreased, the strength per screw is slightly increased. This would naturally be expected, as the friction force remains constant in all the joints. An examination of the joints after testing showed that, as the number of screws per joint is decreased, there is a more uniform distribution of the total stress among the screws, thus giving a higher value for the joint.

Ratio of Strength to Penetration.—Curves, in which the load per screw, in pounds, was plotted against the slip, in inches, showed the following results:

In cypress, while a joint having a thin side piece may be stronger than one having a thick side piece during the first few increments of slip, it no longer continues to be so during the last few increments of slip. In yellow pine and oak, however, the thinner side piece remained the stronger throughout the entire slip. This is probably due to the fact that cypress, being softer, crushes after the first few increments of slip, and hence the difference in depths of penetration due to different side pieces affects the strength very little. In yellow pine and oak, the fibers remain intact a longer period, and therefore additional penetration gives additional strength. A number of typical load-slip curves for cypress are shown in Fig. 3, each curve representing an average of three tests.

An investigation of the relative thickness of side piece to the length of screw shows that, in general, the thinner side piece gives the stronger joint. A ¾-in. side piece and a 2½-in. screw gives a proportion of 0.3 between side piece and screw; and a 1-in. side piece and 2½-in. screw gives a proportion of 0.4. For a 2-in. screw the ¾-in. side piece gives the stronger joint, especially with the smaller gauges, the proportion being 0.385. For a 1½-in. screw the best joint was obtained with a side piece of ⅝-in., the proportion being 0.4. Thus it seems that a side piece about 0.4 of the length of the screw gives the strongest joint. Decreasing the thickness of the side piece increases the strength of the joint up to a certain limit, this limit being reached when so little bearing area is provided in the side piece that the wood is rapidly crushed.

The strength of a screw, for a particular gauge, is independent of the length, but depends on the penetration into the middle piece. Thus a 3-in. screw with a 1½-in. side piece (1½-in. penetration) shows practically the same strength as a 2½-in. screw with a 1-in. side piece (1½-in. penetration), the gauge remaining constant.

In yellow pine or oak the ratio of strength to penetration is very closely proportional to the square root of the penetration into the middle piece. For cypress the strength was found to be directly proportional to the cube root of the penetration into the middle piece. These laws, however, will not hold if the side piece is made much less than 0.4 of the length of the screw; decreasing the side piece beyond this point, while giving a greater penetration into middle piece, will give a weaker joint, due to insufficient area.

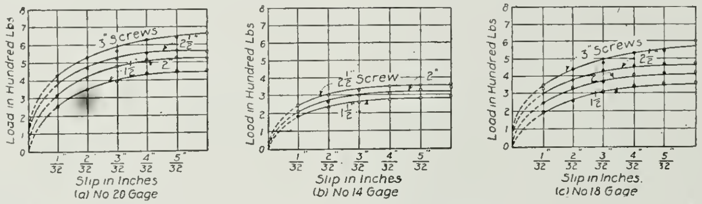

Fig. 3.—Relation Between Lengths of Screws, Load per Screw and the Slip of Nos. 20, 14 and 18 Gauge.

Transverse Strength Per Pound of Screws.—The following laws were deduced showing the transverse strength per pound of screws in the different woods:

(1) For a particular length of screw, the smaller the gauge the greater the strength per pound of screws.

(2) As the length of screw is increased, the gauge remaining constant, the transverse strength per pound is increased.

(3) As the gauges become larger, the difference in transverse strength per pound between screws of different lengths tends to become more nearly equal.

The curves in Fig. 4 show clearly that as the number of screws per pound is increased the strength per pound is increased, irrespective of the length or gauge. However, in actual practice, the additional labor cost of driving many small screws rather than a few large ones would offset the advantage of greater strength.

Relative Strength of Screws in Different Woods.—By taking the average strength of all tests made it was found that yellow pine was about 80 per cent. as strong as oak, and that cypress was about 40 per cent. as strong as oak. A comparison of the compressive strengths of these woods shows yellow pine to be about 92 per cent. as strong as oak, and cypress to be about 59 per cent. as strong as oak.

An attempt was made to establish a relation between the transverse strength per screw and the gauge or diameter, but no relation could be found.

The report contained tables giving the strength per screw, in each kind of wood, for increments of slip of 1/32 in. In yellow pine the strength varied with the specific gravity of the pine. After reducing all values to a common standard a difference of 0.1 lb. in the weight

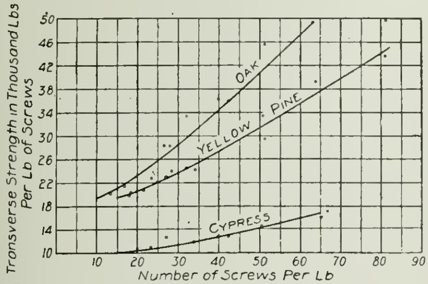

Fig. 4.—Relation Between Number of Screws per lb. and Strength per lb. of Screws.

of a joint was found to make a corresponding difference in strength of 10 lbs. at 1/32-in. slip and 30 lbs. at 3/16-in. slip. The following conclusions were drawn from the tests:

(1) In cypress the effect of boring holes for the screws is to slightly weaken the joint.

(2) In yellow pine the effect of boring holes for the screws is to slightly strengthen the joint.

(3) The effect of rapid testing is to give weaker joints and non-uniformity of results.

(4) Friction between adjoining pieces plays only a small part in the strength of the joint.

(5) Decreasing the number of screws per joint increases slightly the strength per screw.

(6) To secure the best results in a wooden joint, the outer piece should be about 0.4 the length of screw.

(7) For a particular gauge, equal penetration into the middle piece will give equal transverse strength, regardless of the thickness of the side piece, provided it supplies sufficient bearing area.

(8) The transverse strength per screw in yellow pine or oak varies directly as the square root of the penetration into the middle piece.

(9) The transverse strength per screw in cypress varies directly as the cube root of the penetration into the middle piece.

(10) For a particular length of screw the smaller the gauge the greater the strength per pound of screws.

(11) As the length of screw is increased the strength per pound is decreased, the gauge remaining constant.

(12) As the number of screws per pound is increased, the strength per pound is increased, irrespective of length or gauge.

(13) The strength of a yellow pine joint is about 80 per cent. of that of an oak joint.

(14) The strength of a cypress joint is about 40 per cent. of that of an oak joint.

(15) There is no apparent simple relation between gauge or diameter and transverse strength.

(16) The smaller the gauge the more economical the screw, the length remaining constant.

(17) The gauge remaining constant, the shortest screws will be most economical.

(18) The most economical screws of those investigated were: 2-in., No. 12 gauge; 1½-in., No. 8 gauge; and 1½-in., No. 12 gauge.

THE FUNDAMENTALS OF MINING EFFICIENCY.

THE following suggestions for increasing efficiency in mining operations, while not new, are such that, if conscientiously followed, an increase in production or a decrease in costs should be the result. While pertaining chiefly to mining, they apply with almost equal force to engineering construction and industrial work. They were presented in the Engineering and Mining Journal recently by Wilbur Meyers, of Negaunee, Michigan:

Efficiency in mining is as old as the industry itself. It is attained by the systematic analysis of existing conditions with continual study of how to improve these conditions so as to make operations safer and more productive for the same expenditure—this, combined with a common-sense attitude toward the ever-occurring emergencies that are a part of the business.

There are certain fundamental principles of efficiency that will apply whether mining is being carried on for coal, iron, gold or any other substance. The nature of mining makes efficiency particularly important. The policy of letting well enough alone because a routine management is paying small profits, is unreasonable when it is remembered that the wealth of the property is being exhausted and that there is no future chance to recover the money lost from year to year in producing at a higher cost per ton than was absolutely necessary. The main avenues of cost in any mine are labor and supplies; there are other expenses that must be met, such as taxes, insurance, royalties, personal injuries, legal expense in connection with damage suits, etc., but the cost of labor and the cost of supplies are the two great factors in mining costs, labor being the greatest of these two. One of the first necessary operations in introducing an efficiency scheme is to secure the good will of the workmen, since a contented workman in full sympathy with progressive ideas is much better material to work on than one suspicious and dissatisfied, antagonistic to innovations, which he fears are part of some new scheme to get the best of him. It is peculiarly necessary to get the good will of mine employees, since they work in isolated places, incapable of constant supervision. While it may be true that their work can be gauged by results obtained, yet these results will often be the maximum of the second- or third-class workman, the best workmen being afraid to let themselves out to their full capacity for various reasons. The management could do something to win and hold the good will of its workmen by getting their viewpoint, based on personal knowledge of working and living conditions.

Better light in the mine would be of benefit to the miner, eliminating some of the hazards surrounding his work and increasing productiveness, since he could detect and secure dangerous places more quickly, facilitating his work in different ways; it would help not only the miner but also the operator. Better ventilation, good drinking water, sanitation; all these have a direct bearing on a miner's comfort and safety, and incidentally on his productiveness, for as soon as the workman sees that the management is improving things for his benefit, he will begin to co-operate and his good will is won.

Harmony between different departments is another fundamental requisite of efficiency. Friction wastes power with men as well as in machinery. Sometimes there exist petty jealousies between the practical miner who has obtained his knowledge by years of experience and the engineer who has graduated from college after a four- or five-year mining course. Both types of men

are necessary and working in harmony each helps the other, while the company gets the best results from both. Sometimes the men at the shaft-top fail to work together with the men below, signals are misinterpreted, hoisting is delayed, etc. A smoker or concert occasionally, even a picnic, will get the men together in a happy frame of mind and eliminate a lot of petty jealousies.

One great aid to efficiency is the bonus or premium system, or profit-sharing with the employees; this identifies the interests of the workmen with the interests of the company. Such a system properly administered will enable the miners to earn more money per day and the company to produce at a lower cost per ton.

Education of the workmen is of the greatest importance. Either the boss or a skilled fellow employee as a companion, can show the green workman how to obtain a maximum result with the minimum expenditure of labor and also how to detect and secure dangerous places. Racial characteristics can be taken advantage of in this way, thus an old experienced Italian could have a younger man of his own nationality put with him to good advantage. If increased pay is given for increased production, this plan will stimulate both men to their best.

A suggestion box to enable the more intelligent workmen to submit to the management plans for improvements in methods often yields practical and economical ideas. If these are paid for and proper credit given to the workmen submitting them, it is an incentive to draw out the best working ideas.

If the foremen of different departments where the work is similar, are made to hand in to the office daily reports made out on standard blanks, a comparison of production and of accidents under each foreman can be made and friendly competition stimulated among the foremen, especially if the reports are known to be the basis for promotion.

Standardizing equipment and supplies will tend to reduce the quantity of supplies carried in stock and the amount of money tied up at any one time, and will facilitate repairs, inasmuch as the workmen will become acquainted with the kind of supplies needed and used and transfers of both equipment and supplies can be made from one part of the mine to another. If tracks of different gauge are used for tramming, there must of necessity be various sizes of equipment such as cars, motors, etc., and this equipment would not be interchangeable, whereas if all tracks are standardized, changes can be effected readily. Again, trolley wire may be either grooved, figure-8 or round; if two or three of these sections are used, there will usually be necessary two sets of supplies to accompany the wire; while if one kind is used throughout the mine, both on the surface and underground, there can be no misunderstandings when trolley wire is ordered.

Recovering timbers, rails, switchpoints, frogs, rail spikes, pipe, trolley wire, hangers, etc., from places that are to be abandoned, or caved, instead of allowing them to be buried, will materially decrease the total expenditure for supplies. If supplies are standardized, this recovered material can be used at once, being already underground, and a saving of time secured, because new supplies would have to be taken out of the mine warehouse and sent below.

Workmen can be educated to economy in the use of supplies. The common waste of oil by motormen is unnecessary. Miners often break or lose their tools when they do not like them, or when they want new ones, but if they have to return the old tools to get new, or else be charged for the new, the management will be pretty sure of getting maximum length of service from all tools issued.

Prompt return of dull tools to the blacksmith shop for resharpening is another practice that makes for efficiency. Where two shifts are worked, it is a common thing for one shift to leave its dull tools for the next shift, rather than to take them out.

Discretion in the choice of supplies is important; many joints are made with high-priced sheet packing when cheaper packing would serve the same purpose, or even asbestos roll-board or mill-board costing about one-quarter as much. Or take the common spike used for a 30-lb. rail, the size is either $3\frac{1}{2}$ x $\frac{1}{2}$ in., or 4 x $\frac{1}{2}$ in.; the cost, including freight from the wholesale house to the mine, will be approximately one cent per spike. The $3\frac{1}{2}$-in. spike runs about 140 more to the 200-lb. keg than does the 4-in. There are places where a $3\frac{1}{2}$-in. rail spike can be used instead of a 4-in. resulting in a possible saving of $1.40 per keg. Rail spikes are an excellent illustration, because so many are wasted in almost every mine, and in most mines are not recovered for use a second time, yet every 4 x $\frac{1}{2}$-in. spike saved represents a saving of approximately one cent.

A NEW GOVERNOR FOR WATER TURBINES.

Fig. 1 illustrates an improved governor for water turbines, designed by Percy Pitman, London, Eng. The characteristic feature of the device lies in the fact that floating levers have been entirely dispensed with. The inventor claims it to have a close speed regulation without hunting, to have all parts adjustable while in operation, and to be automatic, hand or distant controlled.

Referring to the figure, the governor sleeve is mounted on an aluminum crosshead *C*, which rises and falls with the sleeve *S*, it is adjustable to take up wear, and is prevented from revolving by stops. One end of the crosshead is directly connected to the piston valve *J* and the other end to the plunger of the oil brake *W*; this gives a direct force couple.

The compensating mechanism consists of a bronze sleeve *E*, which is a sliding fit in the valve body *A*, and inside of which the plunger *J* works. The sleeve is connected to the piston of the servomotor, as shown, or to some part of the gate-regulating mechanism; therefore, every movement of the piston valve is immediately duplicated by the sleeve.

An oil brake *W* is provided with a wide range of adjustment by means of the check valve *Y*. This controls the too rapid action of the governor, and prevents the valve sleeves or compensator from interfering with the action of the pendulum.

The body of the oil brake is coupled to the valve sleeves by the rocking beam *Z*, so that when the speed is changed and the valve sleeve moves upward, the compensating action causes the oil-brake body to move downward, and *vice versa*. The check valve *Y* on the oil brake can be so adjusted that, however sudden the change of load, the action of the governor pendulum is not interfered with by the back action of the sleeve. The rocking beam *Z*, the sleeve *E*, and the oil-brake body *W* are held rigid between every movement of the pendulum.

In the case of an impulse wheel with needle regulation or with a deflector, if it should be noticed that the governor carries a needle or deflector beyond the proper position and then oscillates several times after a change of load, it indicates that the oil brake is not slow enough

in its action. The remedy is to close down the valve *Y* still further. If the governor does not open or close the nozzle properly, the valve on the oil brake is unscrewed a little more.

Another feature of the governor is that of throttling the exhaust instead of the supply to the valve *A*. This arrangement takes some of the strain off the piston valve, resists the wear, puts it in more perfect balance, and makes the relay piston easier to move.

The crosshead is fitted with double-ball thrust bearings to take the end thrust in either direction. The bottom of the main spindle also has a double ball-thrust bearing *H*, and the bearings at the top and bottom are ball-journal bearings, as at *N*.

The horizontal driving spindle is provided with two radial ball bearings *P* and a double thrust bearing *Q*, to prevent any tendency to end movement and take the thrust of the driving gear.

The inventor claims that the great advantage of using oil for the relay is that the parts require no lubrication and the wear is negligible. The best oil to use is a pure hydrocarbon, which must be without mineral or free fatty acids. It should have a low settling point, and must remain liquid at low temperatures. It is important to

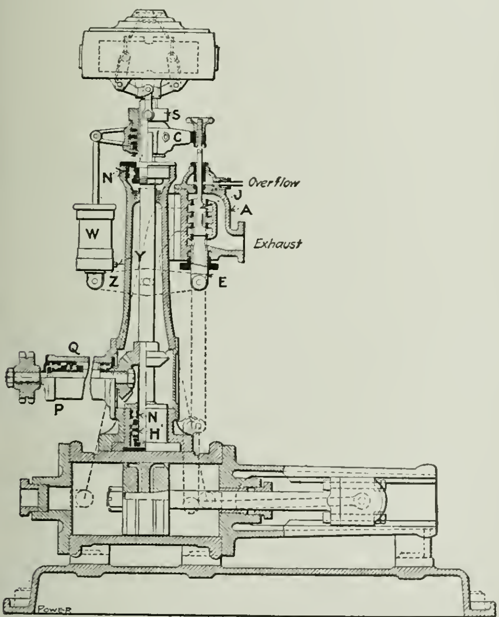

Fig. 1.—Sectional View of Hydraulic Governor.

select an oil suitable for the climate and the conditions under which it will be used. The viscosity of oil diminishes as the temperature rises, oils of high initial viscosity giving way more rapidly than oils of lower viscosity. An oil should be chosen which does not break down into vaseline after long use. Sometimes a really first-class oil, although it does not affect leather to any appreciable extent, is liable to affect packing-rings of the composition class, such as vulcanite or fibre, and its action on these is greater in hot climates. In cold climates a mixture of alcohol and glycerine can be used in place of oil to prevent risks of freezing.

THERMAL MEASUREMENT OF STRESS.

At one of his Cantor lectures before the London Society of Arts, Prof. E. G. Coker took up the subject of thermal methods of measuring stresses. He first dwelt briefly upon the history of the study since the discovery, by Magnus, that changes of stress were accompanied by slight changes of temperature. Then he gave a practical demonstration of a specimen, subjected to tensile stress, exhibiting a lowering of temperature, which was measured by a thermopile attached to a reflecting galvanometer. Of course, the experiment necessitated a careful protection of the specimen under examination from air currents, and flow of heat from surrounding objects. Such difficulties admit of easy control in a properly-equipped laboratory, and under proper working conditions. The illustrations are remarkably in evidence.

In discussing the phenomenon, Prof. Coker stated that the change in question was not to be confounded with the large and sudden rise of temperature observed when a specimen was stretched beyond its elastic limit, since within the elastic limit the stretching of a bar was accompanied by a fall, and not by a rise, of temperature. The theory of the matter had, he claimed, been worked out by Lord Kelvin, who deduced the following connection between the change of temperature and the change of stress:—

$$\Delta T = -\frac{T\alpha}{Js\rho}\,.\,\Delta p.$$

In this formula ΔT denotes the change of temperature corresponding to the change of stress Δp. T is the absolute temperature of the specimen, α its coefficient of expansion by heat, J Joule's equivalent, s the specific heat of the material under constant pressure, and ρ its density.

In the case of steel this density may be taken as 7.5 and the specific heat as 0.11 at 20 deg. Cent., while α was 1.2×10^{-5}, so that we get:—

$$\Delta T = -0.000012\,p.$$

The order of the effect is better shown by the following table:—

Stress. Lb. per Sq. In.	Temperature Cent. Tension.	Compression.
0	20.0	20.0
5,000	19.94	20.06
10,000	19.88	20.12
15,000	19.82	20.18
20,000	19.76	20.24

Thus a change of stress from 0 to 20,000 lb. per sq. in. produces a change of temperature equal to only about ¼ deg. C.

It is assumed in the above formula that the specific heat of the material and its coefficient of expansion are independent of the stress. The former assumption has not been actually tested, but it is very unlikely that the specific heat is sensibly different in strained and unstrained material. That the coefficient of expansion is independent of the stress has, however, been proved in Prof. Coker's laboratory in the case both of mild steel and brass.

Joule was, according to Prof. Coker, the first to test the accuracy of Kelvin's law, which he proved to be true for a considerable number of materials, using thermoelectric couples inserted in holes drilled in the specimen. In the speaker's own experiments he had simply pressed a thermopile against the surface of the test-piece, insulating it by a layer of thin paper or a coat of insulating varnish. It was essential that the load should be applied

to the specimen at a uniform rate, because the actual galvanometer readings had to be corrected for an inflow of heat by conduction and convection; and since these corrections were effected by means of "cooling" curves, it was necessary that the scale of time should be proportional to the scale of loads. A set of readings taken on a tension specimen were, the speaker continued, shown by the rising portion of the lower curve in Fig. 1. After the maximum stress was attained, the specimen was allowed to warm up, which gave the descending portion of the curve shown, and from this the rate of heat gain at any temperature could be deduced. It was assumed, for such small changes of temperature as were involved in experiments of this kind, that the rate of heat-flow was proportional to the temperature difference, and on this assumption it could be shown that the observed galvanometer readings should be multiplied by the factor $\frac{1}{2}\, c\, t\, D_t$, where D_t was the observed reading at the time t and c a constant deduced from the "cooling" curve. In this way the corrected curve shown by the upper curve in Fig. 1 was obtained, which corresponded, it would be seen, to a straight line law, the temperature rise being, therefore, proportional to the intensity of the stress.

It had at one time been thought that, by these thermal methods, an elastic limit could be detected below that observed in the ordinary methods of testing. The speaker had, however, found that this was not the case, the yield-point, as determined by mechanical means, coinciding with that indicated by the sudden heating of the bar. This was well illustrated in Fig. 2, where the two curves to the left were obtained thermally, and that to the right by an ordinary extensometer. When the yield-point of a bar was raised by stretching it beyond the elastic limit, the "thermal" yield-point was also raised to exactly the same extent.

Since a compression caused a rise of temperature, and a tension a fall of equal amount, thermal methods gave, he said, no indication of the existence of shearing stresses, since every shear could be replaced by a tension and a compression acting at right angles to each other. On the other hand, if a specimen were simultaneously subjected to two tensions at right angles to each other, the temperature change would be the sum of that due to each. Hence, if a channel, such as shown in Fig. 3, were subjected to bending, and an attempt were made to determine the stresses at different points by the thermal method, the results did not indicate the same linear distribution of stress as could be proved to exist by the extensometer. The curves yielded by the thermal method were, in fact, of the type represented in Fig. 4, and showed a marked departure from the straight-line law. This arose because a channel was not a symmetrical section, and when subjected to bending, the web also bent in a transverse plane. The thermal method added the stresses due to this warping of the web to those directly due to the bending moment, giving thus the results indicated in the figure. In an I-beam the web remained straight, and the thermal method gave results in exact accordance with ordinary extensometer observations.

Thermal methods of detecting changes of stress were, the speaker added, applicable to other materials as well as to metals. Excellent results had, for example, been obtained with a beam of slate. With cement and concrete, however, the results were discordant, unless the concrete was of an age measured by years rather than by months.

Since stressed and unstressed materials had different thermo-electric properties, it had been suggested that these might form a basis of stress measurements. Ewing's researches had, however, shown the phenomena to be of too complicated a character for this suggestion to prove fertile, and this conclusion was confirmed by the work of later investigators.

DEMONSTRATIONS OF STEEL FORMS.

M. S. Hotchkiss, president of the Hotchkiss Lock Metal Form Company, of Binghamton, N.Y., and three of his sales representatives, are making a tour of a number of Ontario towns and cities, demonstrating steel forms for sidewalks; curbs; combined curbs and gutters; combined walk, curb and gutters; street crossings; driveways; etc.

A number of orders have been received for these forms. Mr. Hotchkiss states that sales have previously been made in every province in Canada, and he is confident that steel forms will soon entirely supplant the old style wasteful wood forms.

The Hotchkiss Company have just issued a new catalog, entitled "Sidewalk Science," illustrated with views of their work, a number of which views were obtained in Canada.

Mr. Hotchkiss states that the amount spent by the average sidewalk contractor for lumber in a year would more than equip him with an outfit of steel forms which would last him a lifetime. These forms are very simple, the sidewalk forms, for instance, being composed of only two parts—the side rails and the templets, or dividing plates, which lock into the side rails. The side rails give perfect alignment and true surface, while the dividing plates provide an absolute cut and complete expansion. When put into position, they make a perfect form without the use of stakes or braces, and it is claimed that better work can be done with the steel forms than with the wooden forms, even when the construction with the steel forms is rushed at a much faster pace than is possible with wooden forms.

At the last meeting of the Lachine town council it was decided to see what could be done toward establishing better connections between Lachine and Dominion Park by writing to the Railway Commission with a view to building a tunnel on Sixth Avenue.

WATER SOFTENING BY MEANS OF PERMUTIT.

THE use of an artificial zeolite, known as permutit, for the purpose of softening water has recently undergone a two years' test in the boiler house of the government laboratories at Moscow. The advantage of the new process is that it requires only one filtering operation.

When hard water is slowly filtered through a layer of permutit, the lime and magnesia replace the soda in the substance; the soda passes into solution, so that an alkaline water flows off, while the lime and magnesia are retained by the permutit. When the permutit has become exhausted, it is regenerated by letting a solution of common salt enter through the layer from below; this time the chlorides of calcium and magnesium pass into solution, and the soda is retained by the permutit. The questions are: Can this exchange go on indefinitely and can the filtration be entrusted to a laborer, or does it require constant control by a chemist?

In the Moscow experiments, as described in "Engineering," two tubular boilers had in 1908 and 1909 been fed with water from an artesian well, the water not being treated in any way. A litre of water left 465 milligrammes of residue (88 mg. being CaO, 58 MgO, 131 CO_3, 7.4 Cl, and 0.4 mg. Fe); the total hardness was 16.9, and the temporary hardness 5. So much scale was deposited in the boilers that two permutit filters of cast iron, each charged with 230 kg. of permutit, were installed in January, 1910; they were used on alternate days, for filtration one day and for regeneration the next day. The permutit supplied was of coarse grain, the lumps being from 2 mm. to 5 mm. in diameter, and of the high water percentage of 55. The exchangeability percentage of the Moscow permutit was low, 1.35, as compared with the 2 per cent. now attained; this figure indicates the weight of CoO, expressed in per cent. of the total weight of the permutit, which is taken up from calcium-sulphate solution of 100 degrees of hardness. The rate of filtering was slow, 1.5 m. per hour. After filtering 8.6 cu. m. of water the filter was regenerated with a solution of salt containing 2.5 kg. of salt per cu. m. of soft water.

It had been noticed in the preliminary experiments that the filtered water had certain peculiarities, and when the filtering was prolonged beyond the exhaustion of the permutit, the filtered water contained increasing amounts of magnesia, and remained free from lime. Only when 62 mg. of MgO were found, did lime begin to appear in the filtered water. The investigation of this point showed that equivalent amounts of bases did not replace the same amount of soda in the permutit, but that the amount replaced increased. The permutit hence became sooner exhausted with regard to magnesia than with respect to lime, and as the water in question was comparatively rich in magnesia, considerable quantities of magnesia appeared in the filtrate before any calcium oxide passed through the filter. In calculating the amount of permutit required for softening water of a certain hardness, the lime hardness should hence be distinguished from the magnesia hardness.

When the filter was used for too long a period the filtered water contained magnesia, which would render it hard. This magnesia, however, proved harmless so far as scale formation was concerned. It made the water turbid; but the alkaline water cleared by settling, and the mud deposited was soft and could easily be removed from the boiler by a jet of water after six weeks' working; and no hard incrustation was found when the experiments were finally interrupted after two years of working. Thus it would appear that magnesium oxide (or rather hydroxide) did not create boiler scale, and that the control of the process is much more simple than might have been thought.

The records of the boiler performance demonstrated that the evaporation figure had been improved by 4 per cent. by the permutit treatment, although a poorer coal was being burnt in 1911 than before, evidently because the boiler-plates were now free of scale. The saving thereby effected was sufficient to justify the estimate that the softening plant would pay for itself in five years, provided that the permutit continued to do its duty. Careful observations showed that after two years the permutit operated as well as on starting and on weighing and analyzing the material a loss of only 3 per cent. was found. Thus permutit may be used for purifying water containing iron. The brass fittings on the boiler did not suffer from the permutit water, provided the boilers were blown off every day to prevent concentration of the soda in the water. This, however, does not prove that really high pressures and high superheating might not lead to corrosion in boilers fed with permutit-filtered water.

The investigations show that permutit softening cannot always be recommended. Sometimes the soda-lime treatment would be preferable. Water which runs turbid through a sand filter and is slimy is better treated with lime; as are also waters of very great hardness, or merely of high temporary hardness (rich in bicarbonates), for which the old softening would be cheaper. Where the price of salt is very high, the generation of the permutit may become too expensive. Little is to be gained by the sometimes advocated combination of the two processes, which would require an expensive plant and call for constant supervision by a competent chemist.

In connection with the Moscow tests, Mr. F. W. Hodson, M.Inst.C.E., of London, writes:

It is the common experience of all engineers who have been responsible for the adoption of softening plants with lime or lime-and-soda treatment, either for town or industrial purposes, that with most waters the performance of the softening plant, whatever its type, is not as perfect in practice as in theory, and that an after deposit occurs in the pipes and tanks through which the water passes after treatment. The effect of this may vary in importance from a considerable reduction in the diameter of a town's water-mains to a negligible accumulation of soft sludge in a boiler; but even in an industrial works it frequently leads to trouble and expense in connection with the stoppages of feed-pipes, valves, and economizers, and in numbers of cases has led to the abandonment of the softening plant installed.

Permutit apparently seems to offer a solution of this difficulty, for I have now had for several months comparative samples from a lime-soda softener plant before and after the water was passed through a sodium permutit filter. The former have varying amounts of deposit, the latter are perfectly clear. There are now three methods of using permutit:

1. By softening the water to zero with sodium permutit, and regenerating with common salt as described in the Moscow experiments.

2. By first softening the water with lime and finishing with sodium permutit in a smaller filter, and regenerating with a correspondingly reduced quantity of salt, owing to the prior removal of a portion of hardness.

3. By softening with lime and filtering through calcium permutit, and regenerating by washing back with raw water, thus saving all cost of salt. Calcium permutit has the remarkable property of being able to absorb free

caustic alkali, and of giving it up to water containing bicarbonates, and thus acts, within limits, as an automatic chemical regulator on the lime-softening operations, but without materially modifying the hardness of the water with which it is supplied. By acting also as a mechanical filter, it takes out the carbonate of lime remaining in suspension from the softening tank.

The practical questions which arise are in what cases, and with what class, of waters, are the lime and soda process, or the permutit process with its modifications, most suitable for use, and what are the relative costs of working in pence per 1,000 gallons treated.

For industrial purposes, in some cases considerations of space occupied by the plant would have a considerable influence in modifying the choice, and for the same quantity of the same water the sodium-permutit zero plant would apparently occupy much less area than the tanks and apparatus of a lime-soda plant. The choice may be further modified by the final composition of the water in respect of the purposes to which it is to be put, as a considerable difference can be made by adopting the sodium-permutit zero plant, in which all the calcium and magnesium salts are replaced by soda, or by adopting the lime process first, in which case only the permanent hardness is replaced by soda, and practical experience in the difference in composition of the resulting treated water would be of great value if any comparative results from combined lime-soda and permutit plants are available in this country.

The conclusion arrived at by Bahrdt, that little is to be gained by the combination of the two processes seems to require modification from this point of view, and it is also difficult to see why the combination should require the constant supervision of a chemist to any greater extent than lime-soda plant always does, as the permutit filter would tend to take care of the errors made in the lime-soda plant.

It also appears from Bahrdt's experiments that, as in the lime-soda process, magnesia is more difficult to remove than lime. In the older process the time element appears to have great influence in the result, and it may be that in the zeolite process the depth of the permutit, as influencing the length of time the permutit is in contact with the magnesia, may have a bearing on the results found.

PUNCHED HOLES IN STRUCTURAL STEEL.

IN "Le Genie Civil," C. Birault, chief of the department of testing materials of l'Ecole Centrale, Paris, discusses the effect on the elastic limit and tensile strength of drilled and punched holes in mild steel, such as is usually employed in building construction. He claims to have established that the resistence to rupture of solid bars, and perforated bars of the same metal, is not proportional to the section of the bars, making proper allowance for the perforations. Section for section, the advantage is in favor of the perforated bars if the holes have been drilled. The holes weaken the steel much less than would be expected, provided care is taken in drilling the holes, and in reaming them after they have been punched; and the elastic limit and the resistance to breaking are higher than before drilling.

Three bars were cut from one piece of steel. One bar was pulled in its original condition; the second bar was perforated with two drilled holes located on the small axis of the bar, and the third bar was perforated similarly, except that the holes were punched. The holes in each case were of 15 mm. diameter, and spaced three diameters from centre to centre. Several series of tests were made. The writer refers to a set of 3 bars from the same steel, the fractured ends placed in contact. The plain bar elongated more than the other two, since the molecular fatigue was less than in the perforated bars. The bar with the drilled holes (the middle one) elongated further than the one with the punched holes, and the holes were decidedly oval, which was not true of the punched holes. Comparison of the two perforated bars showed how the drilling or punching modified the properties of resistance. The fracture of the punched bar was not along the diameter of the holes, probably due to fissures in the metal caused by the action of the punch. The bar with drilled holes parted on their centre line. The numerical results also supported the evidence in favor of drilled holes. The results of three sets of tests were as follows:—

	Elastic. Limit, Kg.	Tensile. Strength, Kg.
Set from first bar—		
Plain bar	24.4	39.2
Bar with drilled holes.....	31.4	43.5
Bar with punched holes....	33.4	37.6
Set from second bar—		
Plain bar	23.4	37.9
Bar with drilled holes.....	29.3	43.3
Bar with punched holes....	31.3	36.5
Set from third bar—		
Plain bar	25.7	46.1
Bar with drilled holes.....	29.4	49.4
Bar with punched holes....	34.4	34.8

It will be noted that the elastic limit is higher for the bars having perforations than for the plain bars, with an increase for the punched holes over the drilled; while in tensile strength there is an increase for the bar with drilled holes, over the plain bars, the bars with punched holes losing decidedly in strength as compared with the plain. Averaging the results in terms of percentage, the bars with drilled holes have 12.3 per cent. greater average elastic limit, and 9.2 per cent. greater average tensile strength than plain bars of the same steel; while the punched bars show an average increase of 13.5 per cent. in elastic limit and an average decrease of 8 per cent. in tensile strength, as compared with plain bars of the same steel.

The author finds upon bringing into contact the fractured ends of the plain bar, that the two parts are not complementary; that there is a hollow space near the centre where the metal has evidently drawn away first, the break then proceeding gradually to the two sides. If, however, the metal is perforated with smooth drilled holes, not having fissures as in punched ones, this tendency of the metal to separate and weaken is removed, and the mean resistance to rupture is more uniform.

These tests show that insistence cannot be too strong on the practical importance of reaming punched holes in mild steel, a practice too often neglected for economical reasons.

A report of activities at Moncton, N.B., for the month of June states work is progressing on the diverting branch from Nelson to Derby Junction on the Intercolonial Railway. On the Canada Eastern branch of the Intercolonial Railway twenty-three miles of 80-lb. rails are to be laid; and about 40 miles of track reballasted. The new brick station at Bathurst was completed, and the brick and stone station at Sussex nearly finished. Also the block signal system is being installed on the double track between Moncton and Parrisee, and from St. John to Hampton.

AN INVESTIGATION OF COARSE AGGREGATES FOR CONCRETE.

IN an endeavor to develop some useful form of test for the coarse aggregates in concrete a method worthy of careful investigation and further development was described recently by Mr. Cloyd M. Chapman before the American Society for Testing Materials at its convention, June 30th to July 3rd, 1914, in Atlantic City, N.J. The method was used in the laboratories of Westinghouse, Church, Kerr & Company, New York, and consists essentially in determining the compressive strength of a specimen made up of a skeleton structure of the material under investigation. The interstices of the structure are filled with a standardized neat cement or a cement-sand grout in a sufficiently fluid state to flow into and fill all the voids. Before the grout is poured in the pieces of stone are in close contact with one another, the grout acting as a binder, holds the cement in place and prevents slipping of one upon another during the test. Mr. Chapman, who devised the method, submits that the compressive strength is a function of many variables in any case, but observes that it is probably of a less number in a specimen made up in this manner than in one in which the stone and grout are mixed together to make the concrete before being placed in the mold.

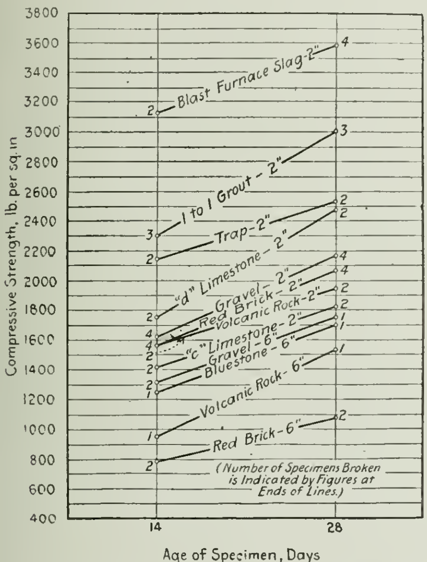

Fig. 1.—Compressive Strength of 1:2:5 Concrete in the Form of 2-in. Cubes and 6-in. Cylinders.

The details of manipulation are described by Mr. Chapman as follows: The molds used are 6-in. cylinders, 6 in. high, and 2-in. cubes. The size of stone used is ¾ to 1¼ in. (averaging about 1 in.) for the 6-in. specimens, and ¼ to ½ in. for the 2-in. specimens. Sufficient stone to fill the mold is soaked in water for 24 hours to saturate it so that water will not be absorbed from the grout.

Sufficient grout is made up of a mixture of equal parts by weight of Portland cement and a good grade of sand, screened through a 20-mesh sieve, with about 35 per cent. of water added, for the 6-in. cylinder specimens, and of neat cement with about 45 per cent. of water added for the 2-in. cubes.

The wet stones are mixed in with the grout until they are thoroughly coated. The mixed stone and grout are poured on a ¼-in. sieve and the surplus grout allowed to drain off. The stones, coated with grout, are placed in the mold and are packed down well, shaken while being put in place, so that they are in close contact with one another.

The remainder of the grout is well stirred up and poured into the mold near one side, jarring the mold continually so that all the voids between stones will be filled. The top of the specimen is finished smooth by adding grout and by slight troweling after the cement has begun to harden a little.

The 6-in. specimens are stored in a damp closet until broken at the ages of 14 and 28 days, while the 2-in. cubes are stored in water. The specimens are faced with a thin layer of plaster of Paris a few hours before crushing.

Fig. 1 shows graphically the results of the tests. It will be noted that several stones tested ranged over wide limits. The points plotted represent averages of from one to four specimens.

Other tests of a similar nature are under way at the present time, the primary object being to acquire a most suitable method, to be used as a standard for testing these materials.

CONSIDERATIONS AFFECTING THE DESIGN OF REINFORCED CONCRETE COLUMNS.

SEVERAL considerations affecting the design of reinforced concrete columns were presented by Mr. Ernest McCullough at a meeting of the Western Society of Civil Engineers in February last. His chief object in so doing lay in the hope of creating a discussion that would bring out some new data on the subject. The existing literature pertaining to the design of reinforced concrete columns was summed up by the author, whereupon he presented the following questions and opinions:

(1) What is the cross-sectional area of a reinforced concrete column? Commercial designers, almost to a man, use the cross-sectional area of the column complete. Others omit a skin ½ in. thick over the entire surface, but place the steel at least three times that distance from the surface, for fire protection. Others count none of the concrete as effective that is not enclosed within the upright reinforcement. Some building ordinances are so worded that any one of these assumptions may be used.

(2) What is the maximum compressive stress advisable on a column? Experiments have shown that no evidence of flexure appears in columns having a diameter less than one-twentieth the length, but neglect to say whether the diameter is gross or net. Few ordinances permit a reinforced concrete column to be erected with a length exceeding twelve times the diameter, again omitting to state whether the gross or net diameter is meant. Granting that no bending occurs, what should be the maximum stress? Commercial designers almost to a man use 750 lbs. per square inch on the gross section.

(3) Should the vertically reinforced column be used? American experiments seemed to indicate in one or two instances that horizontal ties around vertical rods were of no greater value to prevent buckling than the tensional strength of the concrete. American practice in the design of such columns proceeds upon the theory that such ties are for the sole purpose of assisting in prevent-

ing buckling of the reinforcement. If the Joint Committee Report is correctly read such ties are not required for any other purpose than to hold the steel in place during construction.

European experience and experiments indicate that while such ties have a value to prevent buckling of the steel, a distinct gain is made in strength by their use which is contrary to the general belief in America. The French Commission found that the spacing of these ties and the size of the wire affected the ultimate resistance of the concrete so materially that a formula was prepared into which a letter representing the volume of steel in ties was introduced. The Royal Institution of British Architects adopted rules based on those of the French Commission. A development of the formula gradually leads to the Considère formula for hooped columns, wherein the strength of the column is based on the fact that steel placed spirally as a hooping is 2.4 times as effective as the same volume of steel placed vertically.

The concrete column with vertical reinforcement, with ties only, is at present under suspicion and a free discussion of its value is invited. If it should disappear, then the sooner we know this the better. There are thousands in use over the country designed with a stress of 750 lbs. per square inch over the gross horizontal section, and with small ties intended to serve no other purpose than to act as stiffeners to prevent the vertical steel from buckling.

(4) Hooped columns should have the amount of steel limited and where should the limit be set? To Considère is given the credit for developing this column and he advised the use of mild steel for hooping. Professor Withey, of the University of Wisconsin, found that the elastic limit of the steel hooping was reached about the time the concrete was stressed to its ultimate strength, so he advised the use of steel having a high yield point. This seems logical, since the only reason for hooping is that it adds to the ultimate strength of the concrete.

(5) Are hooped columns dangerous from the standpoint of fire risk, when their strength depends upon the hooping?

(6) Are the present methods of fixing the pitch of the hooping adequate? The writer proposes a pitch of one-sixth the core diameter for columns having cores less than 18 ins. in diameter; one-eighth the core diameter for columns having cores from 18 to 24 ins. in diameter; one-tenth the core diameter for columns having cores more than 24 ins. in diameter; provided that the pitch shall in no case exceed 3 ins.

(7) The writer has seldom seen a design of a reinforced concrete building in which the effect of wind on the structure seemed to have been considered. Is this typical of reinforced concrete buildings and why?

(8) Some building ordinances state that unbalanced moments carried to columns must be provided for. How often is this done? The writer has not known of its being done, but there may be a few high-minded designers who do look out for this point. The writer proposes the following clause for all city ordinances: "For unbalanced moments carried into columns there shall be added to the load, for which the column is to be designed due to dead and live loads, the following percentages: To the columns supporting the roof, 30 per cent.; to the next lower tier, 25 per cent.; with a progressive reduction of 5 per cent. on each floor to 10 per cent. of the total load, which 10 per cent. shall be added on each floor thereafter to the first. This load shall not be counted in designing footings and shall be in addition to wind load. In addition to this increment wall columns to be designed for full live loads."

On this point of unbalanced moments, American text books are singularly silent.

(9) How should columns be carried up through buildings? It is convenient to have the steel rods one story in length and to place stubs at the floor levels for the purpose of delivering stress to the next section. Of what value are these stubs and how far should they extend above and below the floor level? Some engineers consider these stubs as nothing more than vertical pins, assisting to a slight degree perhaps in case of heavy winds. Other engineers proportion them on the assumption that the stress travels through the concrete to them from the steel on the floor above to that in the floor below. Has this assumption any basis in fact?

(10) Is it right to place the vertical steel in the concrete without providing plates at the lower end and caps over the upper end to distribute the load over a larger area of concrete than is provided by the end of the steel? The steel is assumed to be carrying throughout its length fifteen times the stress carried by an adjacent equal area of concrete, the bond stress throughout the length being constant. When the steel suddenly ends, with the concrete carrying its full load, what is the effect on the surrounding concrete when no attempt is made to transmit the stress directly through from end to end of steel, but on the contrary one bar may be some inches away from the parallel bar in the floor above, or below? Should there be plates at each floor and should there be plates in the footings? The writer recently examined plans prepared in the offices of engineers in high standing in which the lower ends of the column rods were hooked under the mat of steel in the footing. What is the general opinion of such practice?

MOTOR-DRIVEN STREET SPRINKLERS

That the trend of the times in the haulage field is toward the adoption of motor trucks in place of horse-drawn vehicles is a well recognized fact. For some reason private individuals and manufacturers have been quicker to see the advantages of trucks than have municipalities. This may come from the fact that business competition forces the adoption of every possible economy.

Municipalities are, however, susceptible to the economies involved and are taking up motor trucks in various departments, such as the collection of garbage and fire department.

The Tiffin Wagon Company, Tiffin, Ohio, have opened up a new field in the use of trucks by cities. They have brought out a new motor street sprinkler, and this will probably be followed by other motor-driven street cleaning equipment.

For this new vehicle they state that it distributes the water more evenly upon a street, that it covers practically twice the territory for each filling, and that it will cover three times the territory of the horse sprinkler in each working day.

It would seem within the province of all municipalities to encourage the use of motor vehicles in every possible way—both in their own service and at large. This is urgent. Sanitation demands that the horse be eventually dispensed with on public thoroughfares. Because of the capabilities of motor vehicles to negotiate better in crowded traffic, congestion, which is coming to be a serious problem in large cities, is to an extent relieved.

Editorial

ENGINEERS AND THEIR EMPLOYERS.

Canadian engineers, with the exception of a few, have much to learn in the art of arousing public interest in their work. Generally speaking, they do not appear to realize the value to themselves of a closer union with the public. This is so unfortunately true as to be detrimental to the value of their work when it is compared with activity in other walks of life, and it hinders an otherwise healthy development, in no small sense.

In some of the great undertakings of the country, the irrigation of vast tracts of land, the generation of electrical energy from natural water powers, the penetration of mountain ranges by our transcontinental lines, and even the bridges, buildings and canals under construction at the present time—their greatness is known to everyone, but not generally as the product of engineering. The part which the engineer plays in such undertakings is popularized in ways that are most elementary.

A study of industrial economics vindicates the prevalent impression that publicity is an important part of business, in that it provides the shortest route to the establishment of closer association between the producer and consumer, with the manufactured product as the medium.

In the case of the engineer there are a thousand and one problems confronting the public to which his services might well and satisfactorily be applied. There is no prejudice in the one against the other, but there is not that union which the exigencies of the case at hand frequently demand.

How much truth there is in the statement made a short time ago by a prominent engineer that the Canadian engineer's most powerful asset at the present time is a good business training! Undoubtedly the work of the engineer can scarcely be considered successful unless it is remunerative in some way. It is to render possible the transportation of a greater volume of traffic in a shorter time and under safer conditions, or, as in the case of water supply and sewerage schemes, it is to confer health and years of life upon many who otherwise would have their efficiency reduced by ill health or their lives prematurely terminated. In any case, the schemes with which the engineer has to do are schemes the main object of which is to facilitate business. In order that there may not be a misunderstanding that will produce unlooked-for and unfortunate results the engineer must be a man who can see things through the eyes of his employers so that the views of both may not divert one from another. This makes most desirable a closer intercourse between engineers and commercial men. The benefit to the engineer lies in his being better able to appreciate the scale of values that prevail in commerce and finance and at the same time to adapt his arguments in favor of a high efficiency to the point of view of the capitalist who does not always appreciate that the most expensive method may be the cheapest in the end. One sometimes encounters an opinion in the financial world that engineers are all right, providing the purse strings are held by someone else, that they are not to be trusted to do what they like, but must be kept under control by commercial men. In this respect the president of the Institution of Civil Engineers of Great Britain is quoted in "Engineering" of some months ago as having told a tale in one of his addresses of a great man in the financial world who said that of all the ways of wasting money the worst was giving it to engineers to spend.

Such an unfavorable feeling as this is not the result of a belief that the engineer has less ability than the financier, but that his education has not been sufficiently directed to the economic side of the questions which are presented to him.

COST OF STEEL MAKING IN THE ELECTRIC FURNACE.

According to Bulletin No. 67 of the United States Bureau of Mines, the cost of power for making steel in the electric furnace does not enter so largely into the final cost as it does in some other electrometal processes, especially the refining of molten steel. Plants are operating successfully under a power cost of 1 cent per kw.-hour in localities where material can be obtained at the price common to other processes. Plants such as the one at Ugine, France, have been established in remote localities, where the cost of power is but 0.2 cent per kw.-hour, but the cost of material is high.

For many years all high-grade steels were manufactured by the crucible process, but since the advent of the electric furnace there has been a gradual adoption of that furnace for refining steel. For the complete refining of the highest grades of steel the use of the electric furnace is now thoroughly established in Europe. Any product that can be made by the crucible process can be made by the electric furnace, and in most cases with cheaper raw materials and at a lower cost. In the electric furnace complex alloy steels can be made with precision. The high temperatures attainable facilitate the reactions and alloys need not be used so largely for the purpose of removing gas. Very low carbon steels can be kept fluid at the high temperatures. Steels free from impurities and of great value for electrical apparatus can be made. With the electric furnace large castings can be made from one furnace, whereas in the crucible process steel from several crucibles must be used. For small castings, which require a very high grade metal free from slags and oxides, electrically refined steel is especially adapted. The electric furnace gives a metal of low or high carbon content as desired, hot enough to pour into thin molds and still free from slags and gases.

There is now a tendency among consumers of rail and structural steel to require a higher-grade steel at an increased price rather than steel at a lower price. With the high cost of power that now prevails throughout the steel centres of the United States, the electric furnace can not compete profitably with either the acid Bessemer or the basic open-hearth process in manufacturing steel of like grade from pig iron. It is in combination with either of these processes that the electric furnace seems destined to be prominent in steel manufacture. The cost of super-refining in the electric furnace the molten steel from either of these processes, exclusive of the cost of the molten steel, varies from $1.50 to $2.25 per ton, depending on the cost of power and the impurities to be removed.

EXAMINATION OF CONCRETE FAILURES FOR THEIR DETERMINING CAUSES.*

By R. S. Greenman.

CONCRETE is said to be its own best inspector, and it is a well-known fact that defects in concrete will sooner or later make their presence known. For every fault there must be a reason. The reasons for poor concrete have been proportioned as being 90 per cent. due to poor workmanship, 8 per cent. due to poor aggregates, and 2 per cent. to poor cement. These percentages are not the result of tabulations, but are those prevailing in the minds of many who have had considerable opportunity for inspection of concrete, both good and bad. But whether or not these percentages are correct, the statement raises the question, "What are the reasons for poor concrete and how do we determine these reasons?" It is a certainty that neither a laboratory test nor a field inspection alone will give them, unless, of course, it be a simple failure. Yet there are people who will examine a piece of concrete in the laboratory and offer a solution of the problem simply by tests made there. And again, an inspector will look over a piece of concrete construction and with no knowledge whatever of the characteristics of the materials used, nor of the method of making, will attempt to tell how such and such a condition developed. Concrete failures can only be explained after thorough investigation by men who know good or bad concrete from long and close acquaintance, and whose minds are of an analytical and judicial temperament.

The more one sees of concrete the more one becomes convinced that it is the most abused structural material being used. The science of making concrete has been looked upon too generally as being very easily learned, with the natural result that a great deal of poor concrete has been made. Now, however, builders, contractors and engineers apparently desire to make concrete that will meet the standard in quality required of other materials, and yet, with all the precautions now being taken, there is still a large amount of concrete that is not satisfactory. The larger the work the greater the care taken; and, vice versâ, the smaller the work the greater the carelessness and the greater is the ratio of the failures, and it is the sum total of these failures that makes the loss caused by poor concrete so great.

In trying to solve a problem of poor concrete the elements to be investigated are the three already mentioned —cement, aggregates and workmanship—and water. The common tendency is to first place the blame upon the cement, but if we find that in accordance with good and generally common practice, the cement has been tested and has met the standard requirements, the cement then becomes a negligible factor; but if it has not been tested, it must be considered as a possible cause, and it may become a large item in the study. We must admit that since so much stress has been laid upon the value of having cement tested before use, and since it must indeed be a small work where it has not been so tested, the percentage of failures due to poor cement has been reduced to a very small amount.

If the next element has been given equally as thoughtful consideration previous to its use, there could not be so much poor concrete due to poor aggregates. The strong and weak points in both the coarse and fine aggregates have been too often neglected The coarse aggregates can usually be judged by easy inspections, but sand or other fine aggregates need very careful examination. Its characteristics—such as the grain, the grading, the cleanness, and its freedom from organic impurities and excess of loam—are items of knowledge which are obtainable mainly in the laboratory, but which are very essential for the correct diagnosis of a concrete failure.

The effect of workmanship is by far the largest factor, and in it all others are included, for a poor workman can destroy the value of the best materials. Under the head of workmanship must be considered such items as design, proportions, placing, and actions resulting from heat, frost, electrolysis, etc., which should have been taken care of during the process of making, hardening and preservation.

As another element of importance, it must always be kept in mind that the water used in making the concrete, or which may come in contact with it, may prove to be a very influential factor for harmful results.

Then, if one is given a concrete failure to diagnose one must look for a reason under cement, aggregate, workmanship and water. As stated, the easiest explanation is to look for some fault in the cement, but is, as has been suggested, the cement had passed the usual tests, then other reasons must be found. To find them requires that the investigator shall first know conditions and causes of failures, but these will not be further discussed except to point out the way to the reason; then the investigator must attack the problem with an open mind—that is, he must not jump at a conclusion and expect to be able to work out an explanation around that conclusion. Then it is even more essential that the investigator shall have had an opportunity to learn of results of tests, or to make tests that will enable him to judge the probable actions from the characteristics of the aggregates. Also, a very careful examination of the concrete in place is generally an absolute necessity.

To attempt to outline a plan for procedure in this examination would be folly, since each individual case has conditions that are decidedly its own, and the law of probabilities makes possible many combinations of causes which can only be worked out as one would solve any involved research problem. Clues must be sought, and a sharp eye, a quick ear, and a questioning tongue must be alert to grasp a clue and pursue it to a definite ending. If any one should be skeptical of the efficiency of this method, it is possible that a few illustrative cases, selected from a large number of diagnoses, may convince that one that the method has proven and can prove successful, far more than is generally expected.

Failure Due to Water.—A highway was being built and the plans called for several new concrete culverts. All but one of these culverts "set up," or hardened nicely. This one did not, and yet the same cement, sand and stone had been used as in all the other culverts. A reason for the failure of the one culvert was desired.

It was found that the brook which flowed through this particular culvert passed in its course the plant of a company engaged in the manufacture of medicine from herbs. The refuse from the plant so loaded the water with organic matter that it prevented a proper hardening of the concrete. No one connected with the construction of the culvert knew that water so contaminated would have that effect, and the complaint came in that the cement was not acting properly. The brook was temporarily diverted, other water was used and the concrete acted normally. A condition had existed there which would not have existed in city water, but which is found fre-

*Abstract of paper read before the American Society for Testing Materials, June 30-July 3, 1914.

quently in the country, especially in wooded sections. To detect the cause one had to know that certain elements, such as tannic acid, alkali salts, etc., foreign to most waters, do affect concrete.

Failure Due to Sand.—For an illustration of the effect of a poor quality of sand, consider the following case:

A cry of alarm came in from an engineer that the concrete in an important bridge abutment had been in place for over two weeks, and that in attempting to remove the forms it was found that the concrete was still so soft that it could be cut out with a knife. A brand of cement new to the work had been used, and the blame was, of course, placed on it. An examination showed that a footing for the abutment had been made of the brand of cement first used on the work and that, although ten days older, the concrete could easily be cut with a knife. The evidence eliminated the cement.

Examination of the sand showed it to be a well-graded, sharp sand, but a clue was furnished by some yellow-coated grains. The investigator had already had considerable experience with similar sand grains. A trip to the sand bank showed just what he expected to find. The bank had not been stripped of a top layer of yellow-coated sand, which gives a sand with which it is mixed a tendency to very materially delay the hardening of the concrete in which it is used. In time, usually several months, the concrete will harden and there is ultimately no harmful effect apparent. Lack of knowledge of this peculiar quality has caused an investigator of another piece of work to tear it out and rebuild.

Failure Due to Stone.—A very unusual condition existed in another case, but it emphasizes strongly the need of following clues. A concrete wall was apparently disintegrating due, as the engineers believed, to free lime in the cement. In various places on the face of this wall there appeared what can best be described as "blisters." By prying off these blisters there were produced small cones about 6 in. in diameter and 3 in. in height and in the apex of each could be seen a small, yellowish-white spot about the size of a small marble. The trouble was clearly not a case of free lime in the cement. One unusually large blister enabled the author to dig out from the apex a soft stone about 1½ in. in size. This stone did indicate the presence of free lime, and after a few weeks on the author's desk slaked into a powder. Examination of the stone composing the coarse aggregate soon brought out the following:

The crushed stone all came from the same quarry, but some came by a steam railroad and some by an electric railway. No concrete made by the former showed blisters. Concrete made from stone delivered by trolley did, but why? It seems that in the course of transportation by the trolley route, the stone was conveyed in waste dump-cars, across the grounds of the company owning the quarry and conducting a plant in which limestone is an essential raw material. These dump-cars had not been cleaned carefully, and to the good stone were added some small quantities of stone that had been through a chemical process and were on the verge of disintegration. In the concrete their expansive force blistered the face. By forbidding further deliveries by trolley the trouble was stopped.

These may be considered extraordinary cases, but it is the out-of-the-ordinary that makes trouble; if they were not the extraordinary they would probably have been guarded against. They are, at least, typical of points for which one must look if one would explain failures in concrete.

Failure Due to Workmanship.—Failures due to poor workmanship are seen so often that instead of citing particular cases it will be sufficient to briefly note some causes or results.

Failures from faulty design are shown in the mode of failure. The lack of proper proportioning may be clearly seen in a fractured surface; the grading of the aggregates is also similarly noted; and poor mixing and improperly placed concrete readily show themselves. All these are evident to an eye trained to know good or bad concrete. The failure to take care of laitance is made apparent by the seams that are bound to result from such a failure.

A concrete may be dense but not sound and hard, and "sounding" with a hammer will show up this characteristic. Too wet a mixture with fine sand or silt, or a crusher dust used as fine aggregate, may be a cause. It may be sound and hard and yet may be poor for certain uses because it is too porous. By scratching the face of unbroken concrete with a dull instrument, one may sometimes judge of proportions used and, in its early stage, can also judge somewhat as to the rate of hardening. A pocket glass in the field and a microscope in the laboratory help materially in determining the density, and in approximately the ratio of cement and fine aggregate to the coarse aggregates. The naked eye is all that is needed to observe concrete spoiled by sweepings of sawdust, shavings or blocks, or by waste carelessly dropped into a form. Lack of protection to fresh concrete from the sun or unusual heat may be noted by a "dried-out" and rapidly dusting surface, and from frost by a flaked and scaly surface.

Influence of External Forces.—Where concrete has apparently been good for a considerable period and has then begun to disintegrate, the reason for the failure must be sought in the character of the disintegration, whether it may be due to changes in the elements making up the concrete or to some external elements or forces that have entered into it. If due to an internal influence alone the fact will be noticed by the granular breaking up on the concrete. If due to an external force, such forces as sea water, alkali salts or electrolysis will be under suspicion as being responsible if the concrete has been under the influence of any of them. For many years all the failures of concrete were considered as being due to the formation of certain chemical relations; but as it is commonly acknowledged at present that an impermeable concrete will stand in sea water as well as elsewhere, although subjected frequently to more severe actions than other concrete, its failures are due frequently to the same causes as those of other concrete and therefore the same examinations should give the same results. Similarly, since electrolysis is considered as a cause for the breaking down of concrete, the liability of concrete being affected by its influence will depend upon whether the concrete comes under the influence of an electric current. If it does, then its influence needs to be examined. If it does not, then the examination should also follow the usual method.

The value of laboratory tests and analyses should not be overlooked. While perhaps not giving as definite information as a field inspection, they should be used to the fullest extent to help establish the strength or weakness of a reasonable theory for the cause of failure. Where time will permit, laboratory tests of concrete made of the aggregates under as nearly as possible the same conditions, will give results that should aid in determining the fault in the original. Test specimens so made and treated should give practically the same results, and when compared with test specimens made under ideal conditions or

with standard materials, should give the investigator the reasons for the failure.

All means possible should be used by an investigator in making his examination, and his conclusions must be drawn only after he has considered the failure from every probable cause with reason and fairness. The object of the examination is either to place responsibility or to guard against future failures, and right conclusions are the only ones that should be drawn if justice to either objective is to be given.

Coast to Coast

London, Ont.—Six miles are to be added to London's paved street area this year, bringing the total up to 15 miles out of a total of 136 miles of streets.

Galt, Ont.—The installation of the 18-inch water main, the largest contract ever undertaken by the waterworks department of Galt, has been completed.

Sarnia, Ont.—It is rumored at Sarnia that a company of men, mostly of Sarnia and Petrolea, will commence very shortly drilling for gas on the Indian reserve close to Sarnia.

Hull, Que.—A loan of $50,000 to Hull has been received from the provincial bank; and the city is commencing at once to carry out certain local improvements, principally to roads and sidewalks.

Calgary, Alta.—Difficulty is still being experienced at Calgary in the matter of effecting an agreement between the city and Mr. Eugene Coste regarding the supply of natural gas to Calgary.

Irma, Alta.—A report of a further oil strike has been circulated from Edmonton. A small flow was encountered at a depth of 85 feet near Irma, which lies 10 miles east of Edmonton on the G.T.R.

St. Catharines, Ont.—Considerable difficulty is being experienced in reaching an agreement concerning the liability of cost of a pure water supply pipe line from Lake Erie to the towns along the Welland Canal.

Galt, Ont.—A well-grounded rumor is being circulated at Galt to the effect that negotiations are in progress to secure a site for a Union Station for Galt, to be used by the C.P.R., G.T.R., and Lake Erie and Northern Railways.

Fenelon Falls, Ont.—The Seymour Power Company has completed the construction of its new dam at Fenelon Falls. The plant is capable of developing about 1,500 horsepower, and is to serve the purpose of a reserve supply.

Winnipeg, Man.—Construction work commenced on July 8 on the new drill hall in the northwestern portion of Winnipeg city. The building will cost $110,000; and the contract is held by the Brown Construction Company, Limited.

Moncton, N.B.—A gas sand has been struck by the Maritime Oilfields Company in the Albert County gas field, which it is stated is giving a flow of 2,000,000 cubic feet of gas per day. The discovery was made by the deepening of an old well.

Cobourg, Ont.—It is now stated that the Trent Valley Canal will be opened from Peterboro to the Bay of Quinte this fall; and that next spring a regular service will be established. The new section of the canal from Balsam Lake to Lake Simcoe will be deepened.

Woodstock, Ont.—An inspection of the work that has been done in Oxford county in connection with the good roads movement was made by Engineer Huber, of the provincial highways department. Satisfaction with the work has been expressed by the engineer.

Chatham, Ont.—Civil engineers in connection with the Good Roads Branch of the Ontario Department of Public Works are at Chatham making a survey of this section of the country with the object of making recommendations to the Ontario Government regarding plans for improving the roads.

St. Thomas, Ont.—The Hydro-Electric power line from St. Thomas to Windsor will be connected at West Lorne in the course of a few days. The necessary work at the St. Thomas sub-station is practically complete; and it is stated that Niagara power will be available for distribution in Windsor during August.

High River, Alta.—Oil has been found to exist in the well which has been drilled within the limits of High River for the purpose of supplying gas to that town; and the substance is said to be of similar character to that struck in the Dingman well near Calgary. The well at High River has not been drilled below 505 feet.

Assiniboia, Man.—Another oil strike rumor comes from Assiniboia, Man., where it is claimed that the fluid was found in a well being bored for water supply at a depth of 1,000 feet. The discovery was made about 17 miles west of the territory of Verwood, in which district claims are now being filed and further drilling operations commenced.

Toronto, Ont.—Direct connection has now been made between the North Toronto district and the large water supply plant at Yonge and Heath Streets, Toronto. The increased pressure for the supply of water for North Toronto gives 130 pounds per square inch in the mains instead of 50 pounds. The booster pump has a capacity of 750,000 gallons a day.

Fredericton, N.B.—Mr. F. P. Gutelius, general manager of the I.C.R., together with other officials of the railway company, has been making an inspection of the St. John Valley line from Fredericton to Gagetown, with a view to selecting a terminal site for a prospective divisional point. Some announcement is expected as to its location in the near future.

Wallaceburg, Ont.—A report from Wallaceburg advises that satisfactory progress is being made on the new waterworks plant being constructed at that point. Nearly half a mile of the ditching for the main intake from the Suye has been completed; and the pumping stations will be ready for machinery within a short time.

Swift Current, Sask.—The local government board at Regina has authorized an issue of debentures by the town of Swift Current to total $196,000 for the financing of necessary local improvements. Of this amount, one issue will be for sewer construction amounting to approximately $112,000; one for an electric lighting plant at $60,000; and a third to provide for concrete sidewalks totalling $15,000.

Kamloops, B.C.—The drill hall which is to be erected at Kamloops will be what is known as the "class D" building, or the type generally constructed in larger cities. The total length of the new building will be 199 feet; and the overall width 82 feet. The foundations will be built of concrete; and the building proper, of red brick. A considerable amount of structural steel will be used in the gallery surrounding the main hall and for the roof spans; while, in the basement will be located the furnace which controls the one pipe low-pressure steam circuit system, which is to be installed.

Ottawa, Ont.—The Federal Town Planning Commission is now engaged in making a comprehensive study of the question of the location and elevation of the bridges on the Rideau Canal. The report will not be ready until September. It is likely that a deputation will be sent from the city council to ask that the clearance space be allowed to be made only 10 feet instead of having to be 30

feet. This would allow the construction of numerous bridges and provide for the rapid development of the section of the city south and east of the canal, and would do away with the occasional large ship traffic into the centre of the city.

Victoria, B.C.—Recently, the laying of the steel pressure pipe for Sooke waterworks from Humpback reservoir to the city commenced at Manchester road, near the Gorge road, where the work done by the Westholme Lumber Company in 1912 ended. The contracting firm for this work is the Burrard Engineering Company of Vancouver. Pipe laying on the concrete flow line between Cooper's Cove and the lake is being rushed by the contractors, the Pacific Lock Joint Pipe Company, two shifts laying from the Humpback Reservoir end and two from the Sooke Lake end. About 400 or 500 feet of concrete and steel pipe will be laid daily by the gangs of the respective contractors, though the rate will be increased on the flow line by the additions to labor which are being made.

Hamilton, Ont.—The National Steel Car Company of Hamilton expects that by fall, it will be running to capacity day and night, so numerous and promising are the recent orders for rolling stock for which the firm has taken contracts. Also a considerable addition is to be constructed to the passenger car shop, owing to the large number of passenger cars on order with the company; and the contract for this work is in the hands of the Hamilton Bridge Company. The firm expects that, with this addition, it will be able to construct 30 passenger cars at a time, with a capacity of 150 per year. This will be in addition to the output of street railway cars. It is not expected that orders for freight cars will be heavy this year, though next spring is expected to bring with it a very active demand for this stock and equipment.

Victoria, B.C.—The grading of the Marine Depot site and construction of the wharf on the eastern shore of the Songhees Reserve has reached such a stage that the contractors, Messrs. Parks, Tupper and Kirkpatrick, expect that the work will be completed by the end of this month. The excavation is about three-fifths complete, in spite of the fact that this section of the contract has been greatly retarded recently owing to the frequent encounter of solid rock. All the bearing piles of the wharf have been driven and capped, and the "L" portion of the wharf is floored, while practically all the joists are in position on the balance of the structure. The fender piles have yet to be driven after the flooring has been completed. The total length of the wharf will be 650 feet, running 424 feet north and south, and 225 feet inshore. By the time the contract is completed it is estimated that approximately 27,000 cubic yards of material will have been excavated and levelled off on a line with the wharf.

New Glasgow, N.S.—At the present time, the Canadian Provincial Power Company, recently incorporated in New Glasgow, N.S., is awaiting a report from a firm of Montreal engineers, specialists in power development, containing final figures and data in connection with the company's proposed power plant on the East River at Sheet Harbor. It is estimated that the entire cost of development and conveyance of power to towns concerned will be $1,500,000, and that the power lines of the company will cover a length of 42 miles in all in order to serve the towns of New Glasgow, Stellarton, Westville and Trenton. The company expects to have its lines completed and the power generating plant installed in about 18 months; though it is not intended that the development will stop with the towns named. Distribution lines may be carried later into Antigonish and Truro. Another feature of the proposition is that the distribution lines will run directly through the heart of the largest gold mining district in Nova Scotia; and the company expects that when its lines have been finally erected and the electrical power generated; then it will be able to give to these mining companies an abundance of power for the operation of mines at a very low figure.

Patricia Bay, B.C.—The wharf structure which has been announced recently to be constructed without delay at Union (Patricia) Bay by the C.N.P.R. company, will be of a temporary character; although it will be 40 feet long and 64 feet wide, or sufficiently large to accommodate the material which will be utilized in the final work necessary for completing for service the Patricia Bay branch of the railroad. It is to be capable of handling at low water a vessel drawing 24 feet, and to be ready for the shipments of rails, angle bars, bolts and spikes for 115 miles of road, which material is being obtained from the Dominion Steel Company of Cape Breton. The contract will stipulate that the work be completed within 90 days; and in that period, the first cargo, approximating 7,000 tons of steel, will be landed, and the final stage of construction will be initiated. Before the supplies are exhausted, another shipload will have arrived, which will permit the road to be finished to mileage 115. By the time this large section is ready for the inauguration of a regular service, plans will have been completed for the continuance of the line, for its Northern terminal. In connection with the latter point, it is stated that Sir Donald Mann is expected to visit Victoria this month with regard to the company's plans for railway development on the Island.

Edmonton, Alta.—Local reports state that over $10,000,000 will be expended by the C.N.R. in Alberta in 1914. Included in this amount is the $6,500,000 for the construction of the Canadian Northern Western, a subsidiary company to the C.N.R. The amount of work to be done includes the mileage from Onoway west to Pine River Pass, or what is generally supposed to be the main line of the Canadian Northern Railway to the Peace River country. Grading has been completed as far as Whitecourt; and 32 miles of steel have been laid. The rest will be laid this summer. The program includes also the line from Oliver northeast to St. Paul de Metis. This line is guaranteed for 100 miles at $13,000 per mile. Although some of the grading has been completed on this line, no steel has yet been laid. There is the road from Bruderheim by way of Vermilion, Wainwright and Medicine Hat to the boundary with the branch northwest of Vermilion to the eastern boundary. This line has been guaranteed at $13,000 per mile for a distance of 30 miles. Other sections are: Calgary northeast to Brazeau line, which leaves the Calgary-Edmonton line near Calgary; Camrose to Alsask from Camrose to the Saskatoon-Calgary section; Edmonton to Pincher Creek; Blackfalds to Goose Lake. Work has been done on some of these lines and an effort will be made to complete them as early as possible.

PROGRESS OF THE GRAND TRUNK PACIFIC RAILWAY.

Confidence is expressed by Mr. Collingwood Schrieber, general consulting engineer to the Dominion Government, and chief Government engineer inspecting the Western divisions of the Grand Trunk Pacific Railway, that the new transcontinental will be ready for through service this autumn. He claims that the new transcontinental is in excellent condition between Winnipeg and Edmonton, in very fair shape between Edmonton and McBride, and is rapidly being placed in first-class order on the other sections. The G.T.P. is operating regular express trains as far as McBride, 342 miles west of Edmonton, and service trains between that point and Fort George, 144 miles further on. From Prince Rupert, the company is running trains as far east as Priestley, 337 miles east of the Pacific terminal. Ballasting is now rapidly approach-

ing completion on the intervening portion of the line, a distance of about 140 miles. No definite date has yet been set for the opening of through service; but the road is expected to be in good running condition by the middle of August. There is still a considerable amount of ballasting to be done between Prince George and Priestley, but rapid progress is being made with the work.

TORONTO BRANCH CANADIAN SOCIETY OF CIVIL ENGINEERS.

The executive committee of the Toronto branch of the Canadian Society of Civil Engineers has made arrangements for the following accommodation in the new Engineers' Club:

(1) A room for a joint technical library to which members of the societies to which the books belong shall have access.

(2) A small room adjoining the library for the exclusive use of members of the branch.

(3) A lecture room capable of seating one hundred persons.

A library committee of the branch, which has been at work since last January, is building up what should be a useful working library for engineers. While first consideration has been given to series of transactions and proceedings of important engineering societies, a considerable number of books are being added, this summer, to those already on the shelves. It is hoped to have the new additions completely bound, catalogued and ready for use by October 1st in order to extend the privileges of the library to those student members at the University, who desire to use them.

The following companies have kindly consented to allow the members of the branch to visit their works from time to time. Any member or group of members wishing to avail themselves of this opportunity are requested to obtain a card of introduction from the secretary of the branch: Canada Foundry Company, Limited, Toronto; Canadian Pacific Railway Grade Separation, North Toronto; Department of Works, Toronto; Hamilton Bridge Works Company, Hamilton, Ont.; Polson Iron Works, Toronto; Steel Company of Canada, Toronto; Thor Iron Works, Toronto; Toronto Harbor Commissioners, Toronto, and Welland Ship Canal, St. Catharines, Ont.

The secretary, J. S. Galbraith, announces that a programme of the meetings to be held this autumn will be issued shortly.

The Manitoba Gazette announces the following provincial appointments in accordance with the Good Roads Act: Chief Engineer, M. A. Lyons.

Engineers, S. A. Button, T. T. Wilson, J. B. Philips, W. Youngman, R. Whitside and F. Minvelle.

Assistant Engineers, W. R. Bertram, L. Cote, and W. H. Bladock.

Inspector, H. T. Thornby.

Draughtsman, C. N. G. Milne.

BACK COPIES FOR DISPOSAL.

A subscriber, who has copies of *The Canadian Engineer* practically complete from Volume 6 to date inclusive, and who, for certain reasons is anxious to dispose of them, would like to hear from readers who may be interested in the matter Address, in the first instance, James J. Salmond, Managing Director, Canadian Engineer.

PERSONAL.

ROSS H. McMASTER, Montreal, has become a director of the Steel Company of Canada, succeeding in that capacity the late Senator Gibson.

RALPH MODJESKI, Consulting Engineer, Chicago, and a member of the Board of Engineers of the Quebec Bridge, has been retained by the Burrard Inlet Tunnel and Bridge Company to report on the tenders which the company has received for the construction of the Second Narrows bridge, Vancouver. The structures will cost approximately $2,000,000.

W. P. DOBSON, B.A.Sc., has been appointed director of the experimental laboratories of the Hydro-Electric Power Commission of Ontario. The laboratories are located in Toronto. For the past eighteen months Mr. Dobson has been carrying on research work on electrical disturbances in high tension transmission systems, for the University of Toronto Engineering Alumni Association. The work has recently been completed and Mr. Dobson's results form a very valuable addition to the existing information respecting such phenomena as that produced by the switching of heavy loads of high voltage lines.

COMING MEETINGS.

UNION OF CANADIAN MUNICIPALITIES.—Annual Convention to be held in Sherbrooke, Que., August 3rd, 4th and 5th, 1914. Hon. Secretary, W. D. Lighthall, Westmount, Que. Assistant-Secretary, G. S. Wilson, 402 Coristine Building, Montreal.

WESTERN CANADA IRRIGATION ASSOCIATION.—Eighth Annual Meeting to be held at Penticton, B.C., on August 17, 18 and 19. Secretary, Norman S. Rankin, P.O. Box 1317, Calgary, Alta.

AMERICAN PEAT SOCIETY.—Eight Annual Meeting will be held in Duluth, Minn., on August 20th, 21st and 22nd, 1914. Secretary-Treasurer, Julius Bordollo, 17 Battery Place, New York, N.Y.

CANADIAN FORESTRY ASSOCIATION.—Annual Convention to be held in Halifax, N.S., September 1st to 4th, 1914. Secretary, James Lawler, Journal Building, Ottawa.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown, Indianapolis, Ind., Secretary.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—11th Annual Convention; 5th American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau St., New York, N.Y.

The Mayor of Halifax, City Engineer and Controller Hobur will represent the city of Halifax at the Union of Canadian Municipalities to be held at Sherbrooke, Que., early in August.

A weekly paper for engineers and engineering-contractors

DEEP WATER TERMINALS AT HALIFAX

REINFORCED CONCRETE PIER CONSTRUCTION BY DOMINION GOVERNMENT FOR THE INTERCOLONIAL RAILWAY—DETAILS OF PILE CASTING AND DRIVING—OUTLINE OF ULTIMATE DEVELOPMENT.

By T. W. J. LYNCH, C.E.,
City Engineer's Staff, Halifax, N.S.

To such an unexpected extent has the volume of freight passing through the port of Halifax increased of recent years, that the Government Railways' Managing Board has been forced to map out a comprehensive plan of extension by which it is hoped and improvements will be constructed chiefly at Deep Water. Fig. 2, showing the old as well as the contemplated development, gives an idea of the vast improvements to be made at this shipping centre. The plan of improvements includes four piers sufficiently large to

Fig. 1.—View of Pier No. 2 While Under Construction

to care for the constantly increasing traffic on the Intercolonial Railway.

The city has two terminal points, one known locally as "Deep Water" and the other as Richmond. The Deep Water terminal is centrally located in the city proper, while the other piers are located at Richmond at the northeastern extremity of the city. The proposed extension accommodate steamers over 700 feet in length, considerably increasing in this respect the capacity of the terminal. One of these piers, No. 2, has been completed. New piers 3, 4 and 5, shown dotted, are as yet in prospect.

The old piers were all of a much smaller size. Old pier No. 2 was practically rebuilt 15 years ago, having a second story added 6 years ago. This was found in-

adequate for general purposes, as its south side was too short for long steamers and the basin in the north side was too narrow. Old pier No. 3, recently rebuilt, is still in good shape and will probably be included in the completed scheme.

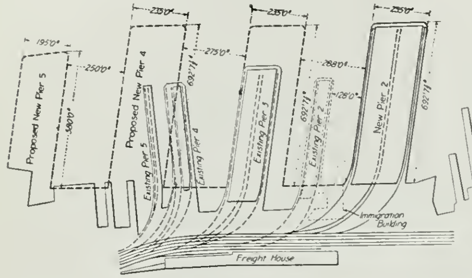

Fig. 2.—General Plan of Development—Existing Piers Shown Dotted.

When these terminals were finally decided upon, Mr. John Kennedy, Hon.M.Can.Soc.C.E., consulting engineer, Montreal, was retained upon the work, and it was under his direction that the contemplated plan was developed and is now being carried out. Mr. A. F. Dyer, C.E., is the resident engineer who is supervising the work, and his assistant is J. Shepherd Lee, C.E.

These improvements make provision for four new piers, pier 2 being 800 ft. by 235 ft., with freight and passenger shed. Pier 3 is for freight purposes only, having the same dimensions as No. 2, and being of similar construction. Pier 4 will also be 800 ft. by 235 ft. with accommodations similar to No. 2. Pier 5 will be 650 ft. by 190 ft. and will be used for smaller steamboat and sailing vessels, as well as for transatlantic steamships. The basin width between piers 2 and 3 will be 280 ft., between Nos. 3 and 4, 275 ft., and between Nos. 4 and 5, 250 ft. These basins will be dredged to a minimum depth of 34 ft. below mean low tide.

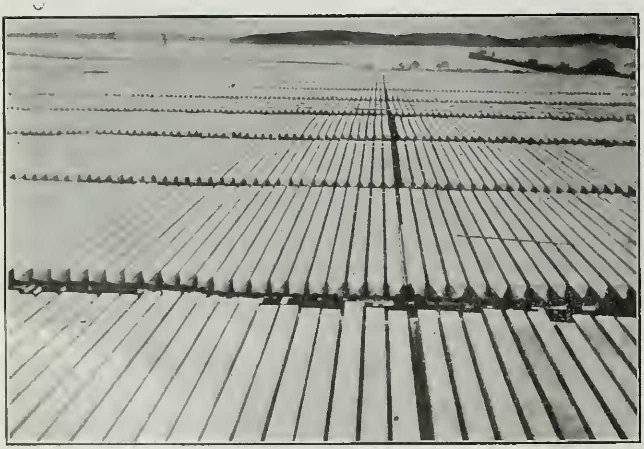

Fig. 4.—View of Pile Casting Yard.

Pier 2 is the first to be constructed and is now complete, the Nova Scotia Construction Company having had the contract at $914,600. This pier is located between the old Immigration Building and the Cunard pier, the latter interfering to a great extent, and now being completely removed.

It was decided, owing to congested yard space, to build a new bulkhead further out in the location indicated. The cribwork of this new bulkhead is to be built in blocks reaching up to about 2 ft. above low water. Above this point the cribwork is to be continuous. The facing of this cribwork is to be of squared timber and made mud-tight. The top of the bulkhead will be finished off with a coping of squared creosoted pine timbers. All timbers over 3 ft. above low water are to be creosoted, the proportions being 12 lbs. of creosote per cubic foot of timber, except for planking, in which case the amount will be increased to 18 lbs.

To strengthen the immigration building wharf where the facing is exposed, sheet piling of squared timber has to be driven along the face and for a distance of 30 ft. beyond the corner. For a further distance of 25 ft. the foundation and cribbing will be protected by round piling. Most of this square sheet piling is to be creosoted, and is to be driven 39 ft.

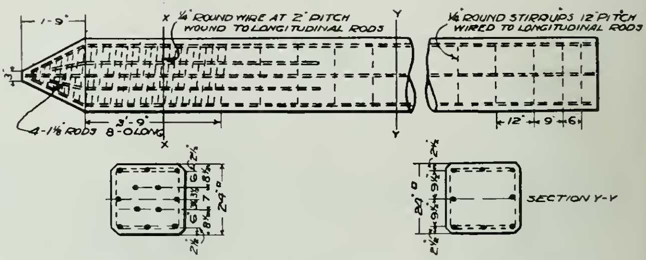

Fig. 3.—Details of Reinforcement of Concrete Piles.

On account of the great depth of water and unevenness of the bottom, there was some difficulty at first as to the mode of construction. The bottom is formed of a substructure of rock, the stratum running nearly perpendicular and presenting a very rough and uneven surface. The rock is covered by a bed of gravel and hardpan varying from 4 ft. to 12 ft. in thickness. This is in turn superimposed by a layer of mud 5 ft. to 25 ft. thick. At the outer end the rock depth is 67 ft., and in shore 44 ft.

Owing to the enormous weight which the supporting piles would be required to carry and owing also to the activity of teredos and limnoria at this point, the use of wooden piles did not meet with favorable consideration, and reinforced concrete piling was adopted instead. The piles are of the construction and size denoted in Fig. 3.

For piles over 70 ft. long the longitudinal reinforcing rods are 1 1/4-in. rounds; between 60 and 70 ft., 1 1/8-in. rounds; and under 60 ft., 1-in. rounds. Four extra 1 1/8-in. longitudinal rods extend up for a short distance from the pointed end. Except near the point of the pile, where the rods are wound with 1/4-in. round wire at a 2-in. pitch, the rods have 1/4-in. wire stirrups, at

a 12-in. spacing. The largest of the piles weigh about 25 tons. The concrete is composed of 1 of cement to 4½ of aggregate, the latter being composed of about 1½ of sand to 3 of broken stone. The cement used was specially selected to resist frost and salt water action, the former causing spalling of the concrete between tide levels and the latter setting up a chemical action with the constituents of the cement causing disintegration. The selected brand has an extremely low percentage of alumina, the specifications calling for a maximum of 6.3%. Used in the proportions mentioned above and carefully graded, a dense and impermeable concrete is produced. To further protect it against frost action between high and low tide levels, the pile is sheathed over a space of 8 ft.

Each pile was made with one filling of the mold, and the concrete thoroughly rammed into place, more particularly at the water line. Fig. 4 gives a view of the pile fabricating yard, which is 600 x 800 ft. in dimensions. The piles, which are 24 in. square, were set in the molds for 7 days at least and were not lifted for 6 weeks or driven in less than 8 weeks. The estimated maximum load to which each pile will be subjected when in use is between 85 and 86 tons, and in order to safely sustain this weight, they are all being driven through the hard-pan to solid rock, steam hammer and water jet being used for the purpose. A floating weight of 180,000 lbs. which, at low tide, will apply itself to the pile under test, is one of the means suggested for testing the bearing power.

The average height of the structure, from solid rock to the level of the tracks on the pier, is 75 ft. Extreme low-water level is 15 ft. 8 in. below track level. Because of the fact that such a difference exists between the distances above and below water through which the piles were to extend the pier was stiffened by reinforced concrete brace piles driven as shown in Fig. 3. This system of bracing is novel and, according to several authorities, this is its first application. As shown in the diagram, three vertical piles and one brace pile support each interior column, while three singly driven intermediate piles carry the floor.

In order to handle these 1,800 extremely heavy piles and to drive them through the hard-pan to solid rock a special pile driver was constructed by the Bucyrus Company, of South Milwaukee, Wis., under the direction of Mr. W. L. Scott, chief engineer of Mussens, Limited, Montreal, who was retained by the contractors in the matter of designing a suitable machine. It is of massive construction, the machinery on account of the weight of the piles being very heavy. The gearing is all of cast steel with cut teeth, and the drums steel castings bronze bushed. The hull is of wood, 108 ft. long, 45 ft. wide and 12 ft. deep at the bow. In order to support the leader carriage tracks, solid timber bulkheads run fore and aft. These, in addition to several transverse trusses, provide a hull of extremely rigid construction.

To facilitate the driving of brace piles without changing the position of the driver, the leads are designed so as to have a transverse motion of 8 ft. across the face of the hull, and a fore-and-aft motion of 7 ft., and a transverse sloping position to an angle of at least 20°, sufficient in all to encompass the driving of a whole cluster of piles without moving the pile driver hull from the position to which it is fixed by the spuds.

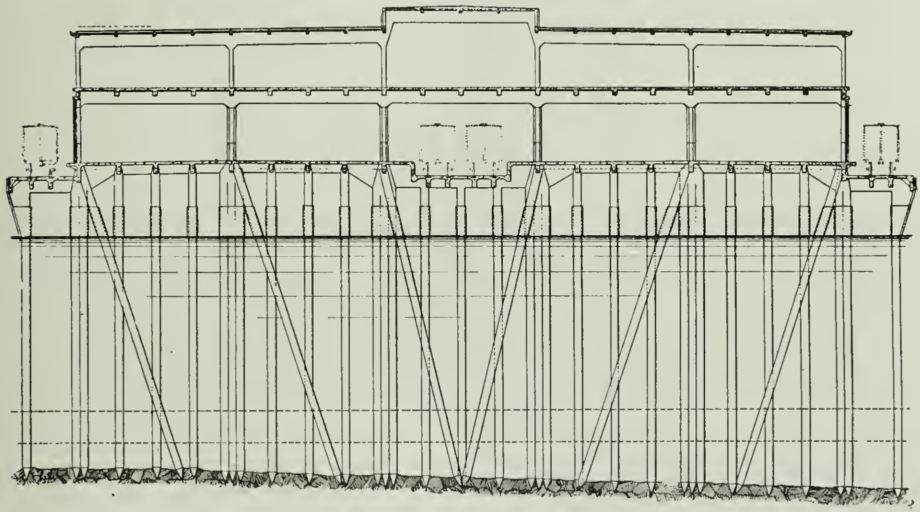

Fig. 5.—Transverse Half-Section of Pier, Showing Arrangement of Brace Piles.

The drums and machinery for hoisting the piles and the hammer and for operating the stern spud are driven by a double-cylinder 12 x 16-in. engine. All this machinery is mounted on a heavy structural-steel carriage, so arranged as to be moved fore and aft. This carriage is in turn mounted on rollers which travel fore and aft on a suitable track. The whole is moved by means of a rack-and-pinion drive from the main engine, the rack being rigidly bolted to the deck. The front of the carriage is provided with two transverse heavy structural-steel girders, one just above the deck level and the other some 30 ft. higher, running across the leads. These two transverse girders are shown in Fig. 6. The upper girder carries a trunnion bearing which supports the weight of the leads.

The lower carries a specially designed crosshead, attached to the leads in such a way that they are held vertically in any position.

The trunnion bearing on the upper girder and the crosshead on the lower girder, are both connected to independent screw shafts driven by 8 x 8-in. double-cylinder engines. When both screws are in gear with the engines, the leaders can be moved transversely across the leader carriage and battered to any angle. In order to batter the leaders it is only necessary to drive the upper or the lower screw alone. The advantage of this screw design is to make the mechanism fool-proof, as no false motion on the part of the operator can turn the leaders over. The forward spuds hold the driver in position when in action. Each spud is provided with an independent spud-handling engine, which raises the spud or "pins up" the driver as is the practice on a modern dipper dredge.

3 feet beyond the end of the piles, the hammer is fitted with a special cap. The leads are provided with a special hammer track, by means of which the hammer when hoisted can be switched in out of the way of a swinging pile. An automatic dog locking device is also provided at the top of the leaders to carry the weight of the hammer while the pile is being placed in position, and also an intermediate stop to hold the hammer when the driver is not in use. The main engine, drums and machinery weigh approximately 33 tons, the leaders 40 tons, the leader carriage 40 tons and the steam hammer 15 tons. The machine was originally intended to drive one pile an hour but it has been found that it can, with ease, handle 20 to 25 in a 10-hour working day.

The character of the material through which the pile is being driven controls the capacity considerably, as it takes from 25 to 30 blows of the hammer to drive the pile

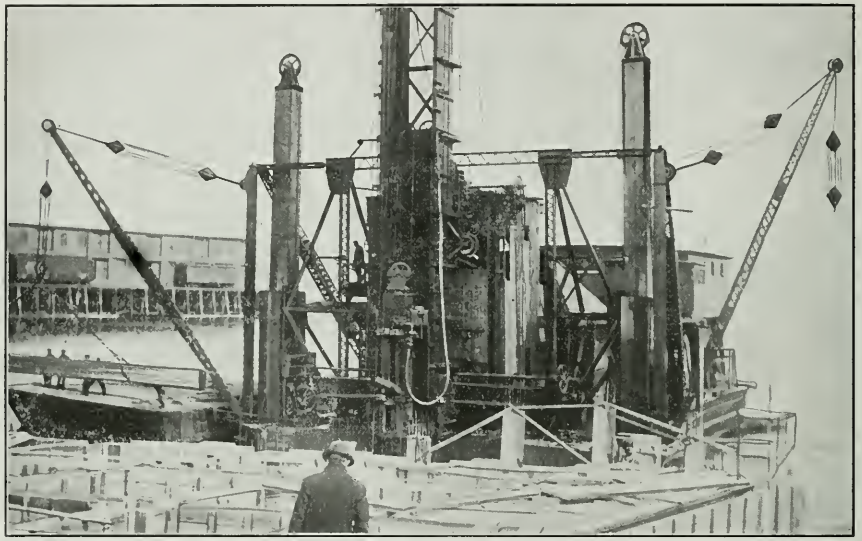

Fig. 6.—General View of Pile Driver and Top of Form Work.

one inch into the hard-pan which is encountered. In actual practice, however, it has only been necessary to drive about 15 piles a day.

Figs. 7 and 8 show the driver with the leads canted and brace pile being driven.

The piles were delivered to the driver loaded on scows. Two derricks were provided for lifting them and swinging them in front of the leads. These derricks were placed one on either side of the driver on the deck and outside of the forward spud guides. The swinging of the derrick was accomplished by manipulating the forward spuds. The pile cable being made fast to the staple projecting from the pile head, the order to hoist was given, and as the derrick fall was lowered the pile was gradually hoisted into a vertical position, the derrick straps being disengaged as they slackened off. The leaders are then moved until the pile, hanging in them, was centered in exact position. Then the pile was lowered, its own weight being sufficient to penetrate the soft mud overlying the hard-pan. When the thickness of the mud was equal to about a third of the length of the pile it was

The spud machinery is placed well aft on the deck and is connected to the spuds by wire ropes leading over the top and bottom of each spud. The levers controlling the movements of the spud engines, are so arranged that the engineer from his position in the traveling leader carriage has full control.

The steam hammer which was designed and built by the Union Iron Works, of Hoboken, N.J., is without question the largest double acting steam pile driving hammer ever constructed. The combined weight of the hammer with follower and follower guide is approximately 28,000 pounds. The diameter of the cylinder is 14 in., stroke 36 in., and the weight of ram alone is 4,000 pounds. With a mean effective steam pressure in cylinder of 80 pounds per square inch, the hammer is rated to develop 3,916,000 foot pounds per minute, when the hammer is striking 80 blows per minute. With a penetration of pile of one inch for each blow, the average force of the blow would be 588,000 pounds. This assumes that the steam follows the piston during the entire stroke. In order to take care of reinforcing bars, which project

found that the pile would stand where placed without any bracing; as a rule, however, the pile was braced while the hammer was being adjusted on its head.

Separate cushions were used between the concrete of the pile and the ram of the hammer. On top of the pile was placed a 3-in. spruce plank. On this rested a cast-steel follower about 4 ft. high consisting of a hollow cylinder or post with top and bottom flanges. The bottom flange was flat, and in it were eight holes through which the projecting rods of the pile reinforcement passed and were protected. The top flange had cast on its upper side a rectangular depression in which was placed a hardwood block about 15 in. thick, bound round with a steel band. This block received the direct blows of the hammer and had to be frequently renewed; sometimes it would last for two piles only, while at other times it would stand the hammering of twenty. Usually the cause of failure was the breaking of the steel bands, but on one occasion the block was found to be on fire and badly charred owing to the heat generated by the force of the blows.

Where the thickness of hardpan was small the pile would often come to a stop after 200 or 300 strokes, while at other places nearly 1,800 blows would be required. The rate of penetration through the hardpan was small, the advance in the last strip being in many cases not more than ¼ in. per blow.

Only two out of 1,550 piles had their heads smashed in driving, and these were among the first dozen driven, the cause being a continuation of the hammering after the pile had reached rock. No harm was done, however, by a few blows after the penetration had stopped. In order to find out what was happening to the point of the piles some of them were pulled out after having been driven to refusal. In only one case was there any damage done to the point, and this damage is believed to have been caused by a projecting rock spalling off a small amount of the concrete.

The bearing power of the piles was tested after driving by one of them being subjected for 3 hours to a load of 120 tons. This caused no settlement whatever.

It is the intention to have two railway tracks extending the length of the pier through the centre of the shed, and two outside, one on each side. The flooring is raised to the car deck level above the tracks to facilitate and expedite the handling of freight. There are two roadway ramps at the Water Street end, one on each side, for the accommodation of dray traffic.

Superstructure on Pier.—The shed will consist of fireproof material having reinforced concrete walls and floors. It is necessarily of substantial construction as upwards of 3,000 immigrants and their effects will be housed in the building when two large well-filled steamships reach port at the same time. The building is a two-story structure. The ground floor is a plain floor for freight purposes, covering the whole area of the building with a series of railway, steamship and custom offices and storerooms at the shore end and in each side of the two central freight tracks. Along each wall, outside of which are the exterior tracks above referred to, there is a series of overlapping doors of sheeted steel frame construction. These can be slid along to form an opening at any desired place in the full length of the building. The upper story of the building is for passenger purposes exclusively. It is divided into three main sections, baggage rooms on the north and south extending the full length, with the exception of a distance of about 100 ft. at each end, and passenger rooms and offices along the whole length of the central part of the shed and across the whole width of each end. The outer wall of each baggage room will have alternate doors and windows at 36 door centres, so that it may receive passengers and baggage from any part of either two short or one long steamer up to the full length of the pier.

The adoption of the plans for the Deep Water terminal improvements means a general shifting of the railway yard arrangements. Other equally extensive changes will likely be necessitated to bring about a completely harmonious arrangement.

MORTAR-MAKING QUALITIES OF SAND.

THE importance of careful discrimination in the selection of ingredients of mortar is a consideration to which attention has been called frequently in these columns. The term "mortar," as defined by the American Railway Engineering Association, is a mixture of fine aggregate (sand or crushed stone screenings), cement or lime, and water, used to bind together the materials in concrete, stone, or brick masonry, or to form a covering for the same. Owing to varying geological conditions, sand, for instance, is one ingredient which may be expected to vary widely in character, and in practice it is found to fully comply with such expectations. In concrete construction the cement is nowadays subjected to careful inspection. The specification requires the sand to be "clean and sharp," although such wide latitude as has heretofore been allowed in its inspection is giving way to closer investigation and scrutiny. This is owing to failures that have been caused by deficiency in both durability and strength, that may be laid only to the inferior quality of sand used.

There is a growing demand for more information concerning the general characteristics of sands, as well as for reliable data on the mortar-making qualities of typical sands. The subject has been very fully discussed in a bulletin recently issued by the University of Illinois, containing a complete account of an investigation undertaken by Mr. C. C. Wiley, with the object of determining the relative value of a number of representative sands in common use in the cities of Illinois. It is of special interest to engineers and contractors, as the methods which it describes and the conclusions arrived at will be found distinctly useful for general guidance.

Description of Tests.—Each sand was tested for cleanness, gradation of size of grains (sieve analysis), specific gravity, voids, and weight. The approximate mineralogical composition and comparative sharpness were also determined. Tests for tensile strength were made on mortars made of each of the sands. In making all of these tests especial care was taken to eliminate the personal factor from the results. There were 576 briquettes prepared and tested, 18 for each specimen of sand. The mixture contained Portland cement, and the various sands mixed in the proportions of 1:3 by weight.

The sands were tested for cleanness as follows: 1,000 grams of the sand were thoroughly agitated in about one gallon of water. The mixture was then allowed to settle for about one minute, experience showing that this allowed sufficient time for the finest sand to settle. The dirty water was then siphoned off, care being taken that none of the sand was carried over with the water. This washing process was repeated until the water showed no discoloration. The sand was then transferred to a pan and as much water as possible drawn off by jarring the sand until the water flushed to the surface, and then removing the water with a pipette. The sand was then re-dried over steam coil and weighed. The loss in weight due to the washing was taken as the amount of suspended matter.

The following standard sieves were used: Nos. 5, 8, 10, 16, 20, 30, 40, 60, 74, 100, 150, and 200. The washed sand was then placed on the top sieve and the whole shaken for forty minutes on an agitator driven by power at 100 r.p.m. After shaking, the sand retained on each sieve was weighed and from these weights the percentage passing each sieve was calculated. In making these calculations the amount of suspended matter, as determined by the cleanness test, was included with the material passing the finest sieve.

The specific gravity of the sands was determined by means of a Schumann flask, consisting of a bulb or bottle into the neck of which a graduated stem fits with a ground joint. The bulb was filled with water and the height of the column of water in the stem read from the graduations. Fifty grams of sand were used and results checked by an additional 50 grams.

The large variation in the percentage of voids in sands as determined by different observers is doubtless due to errors of observation, particularly to a failure to compact all sands to the same extent. For the present series of tests some method of operation was desired which would compact all sands alike, and hence yield reliable results; and, further, a method was desired which would be easy to perform and which could make use of a limited quantity of sand. After a number of trials the following method was adopted:—

A graduated cylinder about 2 in. in diameter and of 500 c.c. capacity was used. About 20 c.c. of sand was placed in this cylinder and compacted by striking lightly with the cylinder on a pad composed of eight thicknesses of heavy cotton flannel. Twelve blows were given at the rate of about two per second with a fall of about one inch, care being taken that the blow was not hard enough to cause the sand to bounce, and also that the cylinder struck squarely so that the sand was not thrown from side to side. Successive increments of the sand were added in this way until the cylinder was filled. The difference between the weight of the empty cylinder and the cylinder full of sand gave the weight of 500 c.c. of dry, compacted sand. Then, knowing the specific gravity of the sand, the percentage of voids was computed from the equation

$$V = 100\frac{S - W}{S}$$

in which V is the voids expressed in per cents. of the total volume, W is the weight of the sand, and S is the product of the volume of the sand, its specific gravity, and the weight of a unit volume of water; i.e., S is the weight of an equal volume of sand containing no voids. In the present case S equals 500 multiplied by the specific gravity. The results obtained by the above method were quite uniform, the maximum variations from the mean averaging only from about 0.8 to 1.5 per cent.

The weight per cubic foot of each sand was computed from the weight of 500 c.c. The results averaged about 3 per cent. higher than the results obtained by other observers on similar sands, due evidently to a difference in the method of compacting the sands.

Mineralogical compositions and sharpness were determined by microscopical examinations.

Conclusions.—Following is a brief discussion of the series of tests and the conclusions arrived at:—

The mineralogical composition of a sand is the fundamental factor in its mortar-making qualities, since not only its durability, and hence the durability of the mortar, but the size and gradation of the grains, the nature of the grain surfaces, the strength of the grains themselves, and all the other factors which affect the strength of the mortar are more or less directly dependent on the nature of the component materials of the sand.

The specific gravity of a sand affords but little information relative to its mortar-making qualities, its principal value being as a factor in certain computations. Quartz has a specific gravity of about 2.65; and the nearer the specific gravity of a sand approaches this value the greater is the content of silicious material. A higher

value indicates considerable quantities of materials other than quartz, which are likely to be hard and durable; while a lower value usually indicates the presence of soft, unsatisfactory material, or of considerable quantities of clay and loam or other foreign matter.

Angularity or irregularity of the sand grains appears to exert no effect on the tensile strength of the mortar. In compression, the sharp sands may show a slight advantage due to the interlocking of the angular grains; but evidently such action is insignificant as compared with the resistance to displacement of the grains afforded by the bond between them, due to the adhesion of the cement to their surfaces, hence the strongest mortars are invariably those in which the cement most readily adheres to the sand grains. Crystalline rocks when freshly fractured generally show surfaces of great smoothness to which the cement does not adhere well; but when these grains have been worn down the surfaces become roughened and the cement adheres much more readily. This is particularly true of quartz, as is evidenced by the fact that rounded silicious sands usually form mortars of greater strength than similar sharp sands. With sands composed of rocks which naturally show a rough, granular fracture this advantage of round grains is lost, but in any case mortars made of round-grained sands will compact more readily than those of sharp sands; hence such mortars in place are likely to be more compact and dense, which conduces to greater strength. The usual requirements of specifications that sands for mortar and concrete shall be sharp is not only useless, but may even be detrimental, and should, therefore, be omitted. Further, since the condition of the grain surfaces does materially affect the strength of the mortar, the specifications should fully cover this point.

The percentage of voids in dry sand is a function of its compactness and the gradation of sizes in the sand grains, hence the effect of the voids on the strength of the mortar is included with that of the gradation of the sizes of the grains. The percentage of voids is valuable in determining the amount of cement necessary to give the densest mortar.

It has been demonstrated, both by experiment and practice, that coarse sands will yield denser mortars than fine sands, and that the maximum density is obtained when the various sizes of grains are present in the proper proportions. Just what the proper proportions are, or in other words, what the ideal form of the sieve analysis curve is, has not as yet been determined. Experiments with materials for concrete indicate that for a mixture of cement, sand, and stone the sieve analysis curve should approximate a parabola, and by analogy it would seem that the same should be true of a mixture of cement and sand as well. Assuming that the parabola is the ideal line for the mixture, and remembering that the cement is very fine, it follows that the ideal line for the sand considered alone must lie below the parabola, and that it would be different for each proportion of cement used. But since the cement is very fine and forms a relatively large proportion in most mortars, the consequent variation in the ideal gradation for the sand considered alone will not be great; and hence it may be said that for the common proportions of cement and sand (1:1 to 1:4) the flatter the sieve analysis curve of the sand the denser will be the mortar made from it.

It has also been demonstrated that, other things being equal, the denser a mortar the greater is its strength; and hence the size and gradation of the grains is indirectly a factor in the strength of the mortar. Unfortunately, the fact that "other things must be equal," has been frequently overlooked with disappointing and sometimes disastrous results. It is only when the various sands are identical in mineralogical composition, condition of the grain surfaces, cleanness, etc., that the size and gradation of the grains becomes the controlling factor in the strength of the mortar and even then it is only relative. Thus, if two sands are exactly alike in all respects except size and gradation of the grains, the better-graded sand will yield the mortar of both greater density and greater strength; but this strength may be decidedly less than that of a mortar from a third sand which may be less perfectly graded than either of the two given sands, but is superior in other characteristics. Consequently, we may have two sands which have identical sieve analyses and yield mortars of the same density, and yet these mortars may differ greatly in strength; or, two sands which differ greatly in their sieve analyses may form mortars of the same strength, although different in density.

Where strength is of the first importance in a mortar the only criterion is a direct test for strength; but after the absolute strength of the mortar from any one sand is determined, the sieve analysis may indicate whether the strength can be somewhat increased by improving the gradation of the sand. In general, this improvement must be accomplished by judicious screening rather than by the addition of other material, since usually the added material will not be of the same general character as the given sand. Where a dense or impervious mortar is required, the size and gradation of the grains is of more importance; and if strength is secondary, may control the choice of the sand. In this case the sieve analysis curves may be of considerable assistance in selecting the proper sand, or in indicating whether the desired results can be obtained either by combining several sands or by screening. In no case, however, should the direct test for strength be omitted, for a certain amount of strength is always required, and a good result for the sieve analysis is not sufficient evidence that the mortar will have sufficient strength.

The maximum size of grain permissible depends on the work for which the mortar is intended. For concrete the maximum size is now taken at 1/4 inch, but certain kinds of masonry, etc., require a much smaller maximum size. The maximum size of grain fixes the limits of sieve analysis, and consequently two sands may differ greatly in average fineness, and yet each one may be more perfectly graded, and hence more suitable for some particular work than the other.

Foreign material in a sand may affect the strength of the mortar by retarding or preventing the hardening of the cement, by preventing the adhesion of the cement to the sand grains, and if present in sufficient quantities by simple "dilution" of the cement. Organic matter is the most common source of trouble, but inert clay and loam may prove deleterious under certain conditions. Experiments indicate that finely divided inert clay or loam may be present in an average sand to the extent of 10 to 15 per cent. without appreciably affecting the strength of the mortar, provided the clay or loam does not adhere to the grains, while a very small quantity may seriously impair the strength of the mortar if it forms a coating around the sand grains.

The tensile strength of the natural sand mortars varied from 140 to 464 lbs. per sq. in. at the age of 90 days. By comparing the tensile strengths with the sieve analysis curves, it is seen that the coarser sands give the mortars of greater strength, and it will be noted that several of the sands show almost identical curves but that their tensile strengths are quite different, while still others, giving practically the same strength, differ greatly in their sieve analysis curves. An examination of the sands themselves shows that this variation is due to

some of the other characteristics of the sands. Only five of the natural sands gave a tensile strength greater than the Ottawa standard sand; and it will be noted that all of these are bank sands with rounded grains, comparatively well graded and containing considerable material other than quartz. The river sands showed less variation in strength than the bank sands, but this is to be expected since they differ less in composition, grading, and cleanness. It may, therefore, be expected that river sands will form mortars of only moderate strength, and that there is likely to be little variation between different sands; and that bank sands will furnish the mortars of greatest strength, but that the strength from different sands will vary through a wide range.

In an experimental investigation there is often a question as to how many individual results are necessary for the accurate determination of the result. It will be found that in any extended series of observed values of a single quantity one value is considerably less than the average, another considerably greater than the average, while the remaining values fill in the interval between these extremes more or less completely. If the values are platted as ordinates in the order of their magnitude with uniform horizontal spacing, the resulting curve will be found to have the form of an ogee or reversed curve, and the average value will lie at the point of reversal of the ogee. If the values are too few in number, the curve will be discontinuous, and the average value cannot be said to be accurately determined. As the number of values is increased the curve will become smoother and more complete; and it is only when the typical ogee form is distinctly and continuously outlined that the average value of the results can be considered as accurately determined.

The selection of the proper proportions for a mortar is essentially a problem in economics, whether the result to be attained is a mortar or concrete of maximum strength, or one of the greatest density and imperviousness, or simply one of sufficient strength for the purpose in hand. The object in any case is to obtain the desired result with the minimum cost. If this fact is kept in mind, it will become clear that it may really be true economy to spend what appears to be a considerable amount of time and money in investigating the available sands and determining the best combinations. Obviously, the saving to be effected varies with the magnitude of the work, and hence the bigger the job the more important it is that the materials be properly selected. If such investigations were generally made it would certainly result in reducing the careless and extravagant use of cement, the most costly material entering into mortar or concrete.

OIL IN JAPAN.

Alberta is not experiencing the entire universal supply of oil-boom excitements. It is reported that the Japan Petroleum Company recently completed a well at Kurokawa, Akita district, which proved to be a gusher, yielding 400,000 gallons a day. The news caused extraordinary excitement on the Tokyo Stock Exchange, and the company's shares rose from 86 to 200 yen in a very short time; and would have gone further, but the Exchange officials ordered dealings suspended.

According to the "Journal of Commerce" of Montreal, the statistics of the exports of iron and steel for the year 1913 show that Germany heads the list, with exports of 6,497,000 metric tons in 1913, against 6,042,000 tons in 1912. Great Britain comes second, with 5,050,919 gross tons, against 4,933,112 tons in 1912. The United States exported 2,760,133 gross tons, against 2,947,597 tons in 1912.

A NOTABLE SUBMARINE GAS SUPPLY.*

THE town of Christiansund, Norway, extends over the mainland and three islands, and, until recently, the question of lighting either by gas or electricity had not resulted in any practical scheme, owing to the unusual difficulties presented. It was optional for the municipality to either build their own works or place the work in the hands of a contractor. They preferred the latter, and the work of erecting gasworks and of further providing the main portion of the town, namely, Kirkelandet, with electricity, was given on the 17th of July, 1907, to Mr. Ferd. G. Juell and Engineer Karl F. B. Pihl. The concession was granted for twenty-five years, but the municipality reserved to themselves the

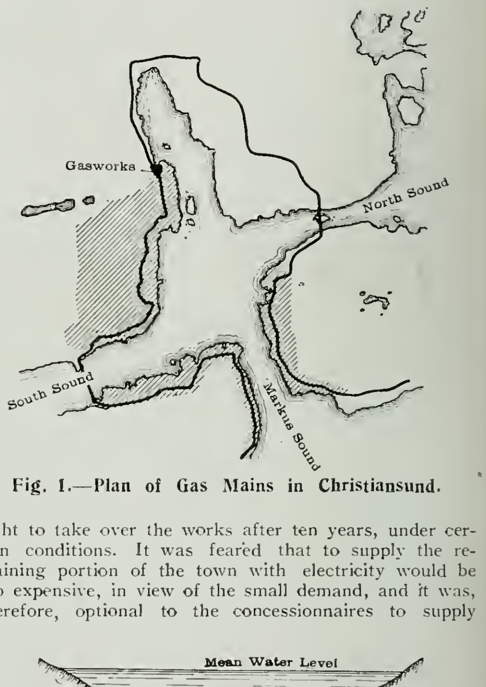

Fig. 1.—Plan of Gas Mains in Christiansund.

right to take over the works after ten years, under certain conditions. It was feared that to supply the remaining portion of the town with electricity would be too expensive, in view of the small demand, and it was, therefore, optional to the concessionnaires to supply

Fig. 2.—Section of the South Sound.

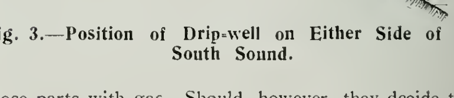

Fig. 3.—Position of Drip-well on Either Side of the South Sound.

those parts with gas. Should, however, they decide that this could not be done owing to the broad and deep Sound, then those parts were to be supplied with electricity.

* Translated from "Teknisk Ukoblad" by "The Gas World."

Preference was given to gas, owing to the advantages which it offered to the inhabitants, in so far as it could be used for lighting, cooking and heating, whereas electricity could practically only be used for lighting, and it was decided to go in for a submarine and long-

Fig. 4.—Sinking Gas Mains.

distance gas main, in spite of the difficulties offered by the Sound.

The main, which is 2½ miles long (half of which distance is without branch mains), is the only one of its kind in Norway, and, furthermore, it is surmised that there are no other submarine gas mains laid at so great a depth. As shown in Fig. 1, the gasworks is situated at Kirkelandet, from which one main goes round the Overvaagen, *via* Gromatlandet, through the North Sound to Nordlandet, and another main is laid from the gasworks through the South Sound to Inlandet. The main crossing the North Sound also supplies the small island situated in this Sound, and, as the depth of this Sound is only 24 feet, no difficulties were encountered during laying. The laying of the main in the South Sound, however, was a more formidable undertaking.

Fig. 2 shows a section of the South Sound. The submarine portion of the main in this sound is over 200 yards long, and its greatest depth below the level of the water is 86 feet. The depth of the Sound would, therefore, involve a maximum external pressure of 86 feet head of water, or 37 lbs. per square inch. In the case of a water main, a small leakage under these conditions would not be serious, or even with a sufficiently high-pressure gas main, but the supply of gas is designed for low pressure, only 15 to 25-tenths, and, therefore, it was necessary, above all, that the joints of the main should be absolutely tight. Furthermore, the difficulty of pumping any drip-well placed at such a depth enhanced the necessity not only of providing securely against leakage of water into the main from without, but also of obviating condensation within. The engineer, Mr. Pihl, appears to have worked on the lines of prevention.

In order to encourage condensation of gas in the main before or after its passage through the Sound, the pipes were laid above ground for a certain distance. Drip-wells were then placed on either side as shown in Fig. 3. Valves also are installed, and the main proceeds to dip under the water without any further provision, either for catching liquid or pumping it out. Four years of practical experience have proved that this bold scheme has been successful.

The submarine gas main consists of weldless Mannesmann steel tubes of 4 inches diameter, in lengths of 33 feet. They are protected against the action of sea water by means of galvanizing. They are also coated inside and out with rust-preventing mixture, and covered outside with strips of hessian soaked in a special tar preparation. The ends are threaded and the tubes connected by means of couplings with tightening cones, which type of joint has already proved satisfactory in a main at Vardo. The tubes were easily jointed up as per Fig. 5. They were bent on land to suit the shape of the banks, the remainder being allowed to adapt itself to the formation of the bottom of the Sound. The main was completely erected on a small island, inspected and tested to the requisite pressure. and was then brought by tugs into position, where it was sunk by divers, as shown in Fig. 4. During laying, a small tug was stationed at the entrance to the Sound to tow incoming steamers into port by another route. The sinking of the main was done quickly and safely, and not a single joint was damaged.

Fig. 5.—Screwing up the Joints of the Pipes.

Both submarine mains have now been in use for four years without interruption, and no accident has happened to them, except directly after laying, when an anchor, which was dropped without permission, got into contact with the main in the North Sound.

All four parts of the town are supplied with gas by these long-distance and submarine mains.

FLOOD PREVENTION.*

By Maj. J. C. Oakes, M.Am.Soc.C.E.,
Corps of Engineers, U.S.A.

FLOODS are caused by excessive rainfall, quick melting of a thick blanket of snow, or a combination of the two, quick run-off, and channels inadequate to take care of the resulting flow of water. The run-off may be hastened by frozen ground, or a ground saturated by previous rainfall so that all of the precipitation escapes rapidly. The natural channel capacities may be, and usually are, reduced by artificial obstructions which prevent free and easy run-off.

Flood prevention measures must reduce precipitation, retard run-off, or increase capacity of the channels. I think that it is generally agreed that it is beyond the possibility of human ingenuity to control precipitation. The only method that has been seriously advanced is by forestation, and even for that method I am not aware that its advocates claim that forests decrease precipitation. It is certain that for all practical purposes the control of precipitation by forests or other means is at present impossible.

Flood prevention must deal, therefore, with the other causes of floods.

Run-off may be retarded by the retention of precipitation on or in the ground, or by the use of reservoirs. Several means of holding the precipitation where it falls have been proposed, such as deep plowing, contour plowing, and forestation. The term deep plowing is self-descriptive and the method is advocated not only for the purpose of retarding run-off, but also as a means of improving the yield of agricultural land. If all cultivated land could be plowed deep and the material well broken up, a considerable amount of precipitation would be retained by the soil. However, as can be readily seen, as a means of flood prevention, it is hardly within the control of the government. Furthermore, with a serious storm it is very doubtful if more than a very small portion could be held in the soil, even if plowed deep. Again, a large part of the country is uncultivated and covered by forests, hillsides and towns. This method, therefore, is very limited in its application and apparently impossible of control.

Contour plowing is a term applied to the method of plowing which creates ridges following the contours of the land and forms, as it were, terraces in such a manner that water will be held where it falls. This method, or perhaps a modification of it by the use of small dikes, is used extensively in foreign countries, such as Japan and the Philippines, where there is an excess of rain in one season to be followed later by a season of drouth. Under such climatic conditions, holding the water on the lands becomes necessary, else no crop can be raised.

In the eastern and middle western states these measures are not necessary for agricultural purposes, and while, if used extensively, they would retard run-off to some extent, they are impossible of control.

Both of these methods, therefore, seem to have advantages within certain limits, and would seem desirable, but they are not feasible means.

This brings us to forestation. This subject was treated at some length in the report of the National Waterways Commission, and the following is quoted from their report:

It is generally admitted that forests exercise such reservoir characteristics and under favorable conditions to a sufficient extent to improve the regularity of stream flow. There is, however, a decided limit to the quantity of water which a forest cover can absorb. The capacity for absorption varies greatly under different conditions, depending upon the depth and character of the forest litter, as well as of the soil underneath, whether pervious or impervious, also upon the condition of the ground, whether frozen or not, upon the steepness of the slope, and numerous other factors. Where the forest litter is destroyed by forest fires, or is removed to prevent them, the absorptive capacity is thereby reduced.

Various experiments have been made to ascertain the amount of water which different kinds of forest litter could absorb and hold. The results show that in general an amount equal to a precipitation of 0.16 of an inch can ordinarily be retained, while under favorable conditions the absorption of an amount equal to 0.24 of an inch or even more is possible. The soil beneath the humus may also be capable of some absorption. As soon as the saturation point is reached, additional rainfall must necessarily run off on the surface just as if the ground were deforested. This explains why forests are powerless to prevent floods, although, to the extent that they do absorb the precipitation, they may mitigate them.

Effects of Forests Upon Floods.—Floods are caused primarily by a heavy and prolonged precipitation, amounting oftentimes to several inches within twenty-four hours. During the heavy rains which caused the disastrous floods in the Passaic Valley in October, 1903, 14 inches fell, according to records taken at New York and Newark. The worst floods usually occur in the spring when these heavy rains fall upon a considerable accumulation of snow, which melts rapidly and augments the amount of water already precipitated. At this time the ground is more apt to be frozen or saturated and its capacity for absorption to that extent impaired.

Forests retard the melting of snow in the spring and by allowing the water from this source to be absorbed, exercise a beneficial influence upon stream flow, but should heavy spring rains fall upon the snow thus preserved and cause it to melt within a few hours the effect of the forest is in such a case to aggravate rather than ameliorate flood conditions. It thus appears that under one set of conditions forests may exercise a beneficial influence upon stream flow and floods, while under another their influence will be harmful.

Assuming that the above is a fair statement of the effects of forest on stream flow, it will be noted that an amount of precipitation equal to 0.16 of an inch can ordinarily be retained, while under favorable conditions the absorption of an amount equal to 0.24 is possible. Applying the factor of 0.16 of an inch to the State of Ohio, and to the storms which created the flood of March and April, 1913, if the whole State of Ohio could be reforested and could retain 0.16 of an inch of rainfall, only 2⅔ per cent. of the total rainfall would have been retained by the storage effect of this forest. The present forest area of Ohio is about 9,000 square miles, or a little less than one-quarter of the State of Ohio. If we could imagine an additional 10,000 square miles of present cultivated land back into forest, this additional forest under the most favorable hypothesis would retain only two-thirds of 1 per cent. of the rainfall of such a storm as that of March 23-27, 1913.

*Address delivered before the Indiana Sanitary and Water Supply Association, Indianapolis, Ind., February 26, 1914.

This subject was very thoroughly discussed in the Transactions of the American Society of Civil Engineers in connection with an article by Brigadier-General H. M. Chittenden, Corps of Engineers, U.S. Army, on the subject of "Forests and Reservoirs in Their Relation to Streamflow, With Particular Reference to Navigable Rivers." As illustrating the bad influence that forests may have upon run-off, he states:

In the first place, forests break the wind, prevent the formation of drifts and distribute the snow in an even blanket over the ground. * * *

The water from the first melting of the snow blanket does not sink into the ground, but into itself. The forest shade thus holds the snow, which gradually becomes saturated from its own melting until the heat and warm rains of late spring and early summer arrive. * * *

The result is that when the final melting begins, the whole body of snow disappears very rapidly, rushing from every direction into the streams, swelling them to their limit and often causing disastrous freshets. * * *

The delay in melting caused by the forest shade has simply operated to concentrate it into a shorter period and increase the intensity of the resulting freshet.

I believe that all of us will agree that the above statements are correct under certain conditions, and that by retarding the melting of the snow, forests have, on occasions, contributed to disastrous floods. Furthermore, even if it could be proven that forests exert on the whole a very beneficial effect, it is impracticable to convert fine agricultural land into forests. This country is certain to be more thickly settled than at present, greater crops will be needed for the support of the people and all tillable land will be ultimately used for the cultivation of crops until timber becomes so scarce that its value will pay the farmer to set aside a portion of his farm for its cultivation. Another objection to this method is that the formation of a humus sufficient to have its maximum effect in absorbing rainfall requires a long period, probably at least a century.

For these reasons it seems to me inexpedient to advocate reforestation as a means of prevention of floods.

The last mentioned and most feasible method of retarding run-off, is by the use of reservoirs. We have heard much on this subject within the last few years, and it has become a popular remedy for the prevention of floods.

If a certain amount of water flows downstream creating damage during its flow, it is apparent to anyone that if that water can be held in a reservoir and allowed to escape slowly, no damage would occur. Therefore, without understanding the immensity of the problem the ordinary man thinks he sees a remedy for floods and proceeds to become an advocate of what has come to be known as the reservoir method of flood prevention.

I desire to dwell on this subject at some length, for the purpose of showing that the problem is not as simple as stated above. There are without doubt many localities that may be protected by a reservoir or reservoirs. For instance, in the study of flood protection for the city of Columbus, O., the engineers were able to show that there were available sites immediately upstream from that city, which could be converted into holding reservoirs sufficient to take care of a flood similar to that of March and April, 1913. If such reservoirs had been in operation and had been controlled properly, releasing only sufficient water to fill the channel and not overflow the banks, no serious damage would have occurred in Columbus. It is also reported that the consulting engineers for the city of Dayton have shown that not only that town, but several others in the immediate vicinity, may be protected in like manner. The Pittsburgh Flood Commission has studied the subject in connection with flood protection for their city, and they have evolved a plan which appears to be ample to provide against future disastrous floods at Pittsburgh, if, however, the control of the reservoirs is possible to obtain results in accordance with the plans.

When one comes, however, to consider the prevention of floods in a river system like that of the Mississippi, the problem becomes exceedingly difficult. In the first place, reservoir sites are not generally found close to the points where the damage will occur, and this is particularly true of the Mississippi.

Col. C. McD. Townsend, Corps of Engineers, U.S. Army, president of the Mississippi River Commission, in an address before the Drainage Congress in the spring of 1913, stated:

To have retained the Mississippi flood of 1912 within its banks would have required a reservoir in the vicinity of Cairo, Ill., having an area of 7,000 square miles, slightly less than that of the State of New Jersey, and a depth of about 15 feet, assuming that the reservoir was empty when the river attained a bank-full stage. Cairo is the logical location for a reservoir to regulate the discharge of the Lower Mississippi. It will not only control the floods from the Ohio, but also the discharge from the Missouri and Upper Mississippi. But if the reservoirs be transferred from the mouths of the tributaries to the headwaters, their capacities must be largely increased.

It is not to be supposed that the people of Illinois and Missouri would be willing to have a portion of their territory as large as the State of New Jersey turned into a reservoir.

In this connection it should also be remembered that at the headwaters of the Mississippi there is the largest artificial system of reservoirs in the world, with a capacity of 93,000,000,000 cubic feet. These reservoirs have been successful in slightly increasing the low-water discharge of the Mississippi River above St. Paul, and also in reducing floods in that portion of the river; but a hundred miles farther downstream it is impossible to detect their influence during either high or low water.

The Ohio River has a very large flood discharge. At Louisville, for instance, the maximum discharge is 790,000 c. f. s. At the mouth of the Ohio the estimated maximum discharge amounts to 1,500,000 c. f. s. Let us see what effect the system of reservoirs proposed for the protection of Pittsburgh would have had at Louisville during the flood of March-April, 1913. The Pittsburgh Flood Commission proposed the construction and operation of seventeen reservoirs whose total capacity is approximately 59,500,000,000 cubic feet. The amount of water flowing past Louisville during the day of maximum height was approximately 67,392,000,000 cubic feet. The proposed reservoir system, therefore, would have been more than filled by one day's flow at Louisville. If we assume that the dangerous flood height at Louisville is 54 feet, then, to have kept the river below that height during that flood, a storage capacity of 7,300 square mile feet, equal to 200,000,000,000 cubic feet, would have been required, or over three times the capacity of the proposed Pittsburgh system.

If there had been a reservoir just above Louisville, with a capacity of 7,300 square mile feet, and if such reservoir had been empty when the flood stage of the Ohio River occurred, the Ohio River at Louisville could have been kept below the flood stage. But anyone can

see that it would not be feasible to construct a reservoir of such capacity between Pittsburgh and Louisville because of the great value of the land, towns, improvements, etc., that would be submerged.

Another illustration may be taken from the Wabash River. To have kept the Wabash within its banks at Mt. Carmel between the date of March 25th and April 21st, would have required a storage capacity of 260,000,000,000 cubic feet, amounting to 9,300 square mile feet. This would have required a reservoir or reservoirs having an area of 930 square miles with water at average depth of 10 feet. It is apparent to anyone who knows the territory along the Wabash River that it would be impossible to find any such reservoir site in the vicinity of Mt. Carmel, and even if found, the cost of such site would be prohibitive.

It is evident, therefore, that on the large rivers like the Mississippi and the Ohio, there will be few reservoir sites close to the main streams that can be used to control floods and that sites must be found on the tributaries and generally at their headwaters. This complicates the problem and makes large numbers of reservoirs of immense capacity.

If reservoirs are to be located on the headwaters of the tributaries, then sufficient capacity must be provided on each of the tributaries to allow for its maximum flood. This capacity will be many times the capacity estimated from the discharge of the main stream, because floods are generally caused by the flow from a number of tributaries, but seldom from the flow of all the tributaries at their maximum stage. Thus each individual tributary must be treated and reservoirs must be so operated that they will be empty when needed and when full they must be emptied slowly so as to prevent the piling up of water in the main stream.

A marked defect of this system is the possibility that one storm may follow another so closely that at the time of the second the reservoirs will be full and not available for storage purposes.

Besides the points mentioned above, there enters the question of costs. Reservoir sites are, in general, extremely costly. The Pittsburgh Food Commission estimated the cost of its proposed system at $21,000,000, but a Board of Engineers, U.S. Army, in reviewing the report found that land and property damage were underestimated by $13,000,000, so, if their other estimates were correct, the cost would be $34,000,000. If a complete system were practicable for the Ohio River, some idea of its probable magnitude may be gained from the fact that the area of the basin of the Ohio Valley is 204,320 square miles, while the drainage area of the rivers above Pittsburgh just referred to is but 18,920 square miles, or 9 per cent. of the whole. Assuming that the cost per square mile would be the same as that for the Pittsburgh system, the total cost of providing reservoirs for the Ohio River would be $378,000,000. It is probable, however, that these costs would be greater, for the territory in question above Pittsburgh is not nearly as valuable as in such States as Ohio, Indiana, and Illinois.

The advocates of reservoirs for flood prevention recognize the enormous cost of this method of protection for a large river like the Ohio, and to offset this very pertinent objection they claim that the water stored in reservoirs may be used to produce power which may be sold to the public, thereby reducing the cost of flood prevention, and may also be used to increase the low-water flow of streams thereby improving navigation.

It is true that reservoirs may be used for flood prevention and the water held therein used for power, or for increasing the low-water flow of a stream, but the full capacity of a reservoir may *not* be used for all three of these purposes at the same time. Reservoirs to be used for flood prevention must retain the water during the possibility of floods, but the instant that possibility passes the water must be allowed to escape as rapidly as possible without doing damage, in order that they may be empty at the time of the next possible flood. The use of reservoirs for increasing the flow of streams at low-water stages is just the reverse of this. They must be kept full as long as possible and the water only allowed to escape when it is absolutely necessary to increase the low-water flow. The use of reservoirs for power, on the other hand, requires a constant flow with a constant head to obtain the best results, and the more nearly these conditions are met the more efficient is the plant and the greater income obtainable from a given expenditure.

A little thought on this subject will convince a reasonable man that the three uses of reservoirs proposed by their advocates are incompatible one with the other, and in my opinion if an endeavor were made to use the same reservoirs for these three purposes it would not be long before the power interests would obtain control, and it would be practically impossible for a government agent to empty a reservoir in anticipation of a flood when the power interests desired the reservoir to be kept full in order to provide uniform power for their plant.

In any case, it will be seen from the above that to prevent floods by the use of reservoirs will require a certain definite capacity; that if these reservoirs are to be used for any other purpose their capacity must be vastly increased, thereby increasing the costs of the system. Before the feasibility of protection by reservoirs in any particular case can be affirmed, available information must be supplemented by extensive, reliable data as to run-off, flood heights and discharges, available sites and costs.

The capacity of streams may be increased by the use of levees, dredging, or auxiliary channels.

With reference to the levee as a means of flood protection, it has been used for many hundreds of years. It is a means available for the immediate protection of sites or areas of varying size. Large areas of the Mississippi basin are protected by levees, as well as many towns on that and other rivers. New Orleans and Cairo are so protected. With this method the solution is simple, and the only important questions are to determine the size of the levees and the cost. An area may be made secure against any flood of similar height to those we have had in the past, or that may be expected in the future. The method is simple and direct and is the only method extensively used for protection in cases of large river systems. The levee system on the Mississippi has been in process of construction many years, and while it is true that breaks occur which cause vast damage, it is due to the fact that such levees have not been constructed to the height necessary for protection against the greatest floods. Where a community felt itself too poor to provide against the highest floods they have built their levees as high as their funds would allow, with the expectation and knowledge that when a higher flood came the levees would be topped.

Dredging may be used for increasing the capacity of channels where the increase required is very moderate, but a radical increase in the capacity of a large stream may not be accomplished by this method without the expenditure of enormous sums of money. A point often forgotten is that dredged material must be placed outside of the river channel if the dredging is to do any permanent good. This requires the purchase of lands upon

which such material may be deposited, and increases the cost of actual dredging very materially.

No instance is known where a radical increase by dredging of the flood-carrying capacity of a river channel has been attempted on any large stream. The low-water channels in streams like the Mississippi oftentimes are dredged to facilitate navigation, but it is believed that the limited application of this method should be apparent.

Auxiliary channels have been suggested, both paralleling long stretches of streams and also to form cut-offs. The cost of providing additional channels for a stream like the Ohio or the Mississippi, of sufficient capacity to carry off the flood waters, is absolutely prohibitive. For the protection of a particular locality short auxiliary channels or cut-offs may be used, but these have the disadvantage that while they may benefit the locality in question by facilitating the run-off past that particular locality they pile the water up more rapidly below, thereby creating more damage at other points, as they necessarily cause steeper slopes, higher velocities, and greater erosion.

The method of prevention of floods have been discussed at some length, and it must be realized that the subject is one of great extent and the problem in the case of large streams very difficult of solution.

We now come to the question of the prevention of damage by floods.

Many towns have grown up on the flood planes of the streams, occupying areas that have been overflowed from the beginning; people have entered the bottom lands and erected their structures with the knowledge that those lands were formed by silt deposited by flood waters; railroads have constructed earthen embankments across these bottoms, leaving only very narrow openings with wholly inadequate capacity for passing floods; city and county officials have built bridges with abutments projecting into the stream, with many piers of insufficient height, thus reducing the discharge area materially; individuals have dumped materials over the banks to increase the area of their property for business purposes. These structures and encroachments have reduced the capacity of the streams, have formed partial dams which raise the water above previous levels and then by the breaking of an embankment or the washing out of a bridge the water held back has rushed downstream under increased head and velocity, destroying everything in its path. Aside from the damage done by the inundation of property, which, while serious, is not destructive, almost all of the damage at the points visited is caused by increased velocities of current due to the backing up of the water, by embankments, bridges, and other structures, the subsequent breaking of these partial dams and the rush of the released waters under increased heads and velocities.

The measures to be taken to prevent such damage are: wherever possible, to remove structures from the flood planes and river bottoms, or to elevate such structures above possible high water; to protect by levees valuable property which it is impossible to remove; to prevent the construction of heavy earthen embankments across flood planes by railroads or counties; to increase the capacity of channels by removing encroachments thereon in the shape of bridges, buildings, etc., and to remove all artificial and natural filling or deposits.

Fire has recently completely destroyed the Oceanic dock at Portland, Ore., and has entailed a damage loss of $150,000. The dock was owned by Balfour, Guthrie and Company. The fire was the third destructive waterfront blaze this spring, all along one section of the Portland waterfront.

SUBURBAN, INTERURBAN AND RURAL ROADS.

SOME valuable suggestions as to the classification of public highways and the proper division of expenditures for their construction and maintenance appears in the 1914 report of the Public Roads and Highways Commission of Ontario. In discussing the subject of supporting areas for cities, the report emphasizes the value to the latter of general rural development brought about by better roads.

Urban centres with good roads are especially benefited by the main roads in their immediate vicinity. It may in a general way be assumed that each city has a special interest in an area immediately surrounding it, sufficient to provide a food supply for the city, and the population within such area.

Attention is called in this report to one or two preliminary points. It is well known that cities are not, even in the matter of home-grown products, supported altogether by their immediate neighborhoods.

It would seem, however, that the most potent influence in preventing such a condition has been the heretofore inadequate means of local transportation in marketing. Improvement in these facilities would induce the abandoning, by nearby farmers, of low-priced crops, which have heretofore carried the bonus of cheap marketing, for high-priced crops upon which marketing charges will decrease as the farmer is brought closer to his market.

Then again, some districts are specially adapted to the production of certain products, such as fruits, and they should, therefore, be properly expected to specialize in the production of these commodities. This factor has its effect in altering any general calculations that may be made for cities and their supporting area as a whole.

Still another point arises with the calculation of a large supporting area. A number of towns of various sizes are found within the area. In this instance, therefore, a special calculation has to be made and the results tabulated. In the case of the smaller cities, however, this difficulty is not incurred.

In all, calculations have been made for the twenty-one largest centres in Ontario. The results appear in the table given on the next page.

The results given are based upon calculations in which both the general items of food entering into the dietary of the average family, and the yield of these items in the various districts respectively, for which estimates are presented, have been taken into account. The "average family" was taken consisting of five members. There was then worked out the acreage required to supply the various food items appearing. The total area required for the support of fifty people for one year was thus found to be 109.14 acres. It is to be noted that this acreage provides only the amounts of each kind of food grown locally and consumed by the unit of fifty people in one year and no account is taken whatever of other foods, such as imported fruits, etc., which are consumed in addition. The 109.14 acres thus represents the area required to provide home-grown products only. It is to be further noted that this acreage represents only the net area required, and this whole area of land would need to be cultivated to provide the required amount of food. In the case of each area for which a calculation was made, therefore, account was taken of the proportion between cultivated or producing land and total acreage.

It will be noted that when the circles designating the supporting areas are placed upon a map, certain of these, if carried through, would intersect; the conclusion being that the supporting areas of various cities are found to

overlap each other. It therefore becomes necessary to make allowances in these cases. The smaller city is favored in that the amount of overlapping, when taken from the larger area, makes but a slight difference in its total, whereas the same amount taken from the smaller area would make a very appreciable difference. Furthermore, the areas where overlapping takes place lie, with one exception, closer to the smaller than to the larger urban centre.

Name of City	Population	Total supporting area. (Sq. miles.)	Radius of circle or part of circle of total supporting area. (Miles.)	Radius of area of immediate support. (Miles.)
Toronto, city only (Census 1911)	376,538	1676.8	....	32.7
City, 1913 (Assessment figures)	445,575	2591.9	....	35.3

Woodstock	9,320	53.69	4.2	3.7
Niagara Falls	9,248	69.56	6.6	5.1

Road Classification.—It has been pointed out that while municipal responsibility should be encouraged, there is a point at which, in order to obtain results, the influence of a central authority must bear directly upon road administration. A consideration of the classification of roads will assist in determining the point at which the forces of a central administration should be applied.

Roads should be built to meet the needs of traffic. For example, there are roads which, lightly traveled, by an initial expenditure of $1,000 a mile, will remain in good condition for ten years; on the other hand, there are other roads which, because of heavy traffic, demand an outlay of $1,000 per mile annually for maintenance alone. For this reason, roads admit of classification according to traffic for purposes of construction and maintenance, revenue and administration. They must be constructed and maintained adequately; revenue must, in equity, be derived from those who are benefited and organization must be commensurate with the work.

Cities and Suburban Roads.—The opinion is frequently advanced in the cities that the provision and support of good reads should fall upon the farmer, inasmuch as he must use them to market his products. The farmer, however, is fully justified in maintaining that the cities are equally interested in the roads over which their food supplies reach them. In point of fact, the city and country are necessary to each other, with the advantage somewhat on the farmer's side; for, while he could manage without the city, the city could not exist without him.

About each city there exists, as stated, a belt of rural territory which is knit to it in the closest fashion. Much of the city's food is grown in this belt; more would be if the means of communication were better. Sundry industries, due to the presence of the city, are prosecuted in this area. The residents for some miles out are valuable customers of the city's shops. In every way the city stands to gain by the equipping of this belt with a system of roads able to carry a heavy traffic with speed and economy. The speed of the motor bus and motor truck would extend the city's influence—that is, the area from which it could draw food and direct trade. Opportunities would be afforded for a specially beneficial development, the rapid moving of workers out into the countryside after their daily task is over. It is understood that in Belgium one-third of the industrial workers live outside of the towns, cultivating small holdings of land, under conditions of health which surpass those of residents in the crowded streets. From the standpoint of the city's food supply alone, the improvement of the roads is of great importance to the town dwellers.

Economically speaking, distances are measured by time, and if men trespass too much on the early morning hours in order to reach distant markets, nature makes her claim on them later on. If the constant, regular supply to city markets is limited to points, say, two hours therefrom, it would mean leaving the farm at 6 a.m. in order to be on the market stand at 8 a.m. It is easy to realize, therefore, that by cheap motors and good roads the supply area can be greatly enlarged, as compared with the present districts surrounding most cities, in which supplies are sent into town by horse-drawn vehicles on indifferent roads. Further, the widening of the belt means enhancing the profits per acre, to the advantage of the farmer.

Again, the countryside has suffered for several decades from certain inevitable developments. Forty years ago a considerable amount of industrial work was carried on in nearly every small town, in nearly every village, and, indeed, in many rural communities too small to aspire to the name and style of village. This caused a wholesome diversity of industry, increased the interest of country life, and was in most respects a beneficial social influence. The march of progress has swept that state of things away. The tendency of the age is toward centralization. Those small industries, which meant much to the small towns, have been absorbed into those operating in larger centres. The countryside must specialize in farming. Why, then, should cities—to a certain extent built up by rural districts, which have lost taxable property to those cities—not be prepared to contribute to the road system by which both benefit?

Interurban Roads.—In dealing with interurban roads it is necessary to glance at one aspect of the problem created by the motor. The greatest asset of some European countries is their scenery; it attracts tourists, and the money they spend is of great importance to the community. Bearing in mind that the tendency to reach summer resorts by motor is increasing, it is not difficult to realize that, with a system of main arteries penetrating country regions in the United States and Canada, a more important tourist traffic would be developed. This traffic is of little benefit to the people of the intervening districts traversed; it throngs the roads, and there is a tendency

to over-rapid driving, with its accompanying nuisances, of which the dust evil is but one. However, the traffic is of great value to the summer resort region, which would be the goal of most of these hurrying wayfarers, and the interests of such regions must be considered as well as those of the more strictly farming districts.

Along the interurban roads many persons will pass who do not live in the municipalities in which they are situated. This is perfectly natural; from time immemorial the King's highway has been for the use of the traveler, regardless of his residence. It is necessary, of course, to see that the burdens of constructing and maintaining such a road are equitably adjusted, so as not to impose an undue proportion of them on the people of the locality. Indeed, if measures of this sort are not taken, the situation will work itself out, and disadvantageously to all concerned; for the motorists will search out and appropriate to their use the best stretches, and there will be motor routes which at once will give dissatisfaction to the motorists and inflict a sense of injury upon the farmers and ratepayers along them.

At the same time, a road which constitutes an artery of this sort is not exclusively an affair for the traveller from a distance. It is a series of links—market roads necessary for the needs of local people, and it will be the strictly local road for those who dwell along it. In short, it discharges functions at once local, provincial, and in some cases even national, and in consequence it demands assistance from more than local administrations.

Rural Roads.—It can hardly be doubted that there is impending a revolution in farm operations. Two centuries ago or less the European farmer used the pack-horse to take his products to market. A revolution in methods occurred, and he came to employ wagons, which were hauled along roads much better than the tracks his ancestors had known. The self-propelled vehicle has come to stay, and the successful solution of the problem of good roads in some part depends upon a recognition of that fact. Indeed, the motor, to no small extent, creates the problem, for it has proved so destructive to main highways which resisted the wear and tear of horse-drawn vehicles that means must be devised to guard against a deterioration which now proceeds with a rapidity formerly unknown. Opportunities as well as difficulties are created by this new method of transportation. It prevents some, at least, of the features essential to profitable use by farmers; it conveys loads of a size so moderate that a single farm can furnish one or more than one, yet so large as to out-class the old horse-drawn wagon; it requires, not specialized tracks, like railway, but a common highway, albeit improved to a standard within the reach of the community; it is free from the difficulties of traffic adjustment which have made the conduct of railways a business by itself, and a peculiarly difficult business. In short, it is an individualistic method of transportation, and this commends itself to farming, the most independent and individualistic occupation in the world. Already there are cheap motor cars and trucks to be obtained; the farmer of to-day can procure one of these with as little straining of his resources as his grandfather could a top buggy; and it is but reasonable to expect a further lowering of the price. In this beneficent revolution, good roads must play a necessary and important part.

Increasing attention must be given, not only to the important market roads, but also to the township roads, those gravel or earth highways which pass the doors of the great mass of farmers and afford them access to the country or market roads, which lead to the centres where they sell their products and make their purchases. In Ontario these township roads are estimated at 85 per cent. of the whole of the highways.

It is proposed that township councils should provide for and control the roads of local travel, with the proviso that to encourage better methods and organization the province will grant a subsidy of 20 per cent. of their annual expenditures for a limited period of years. Such aid should not, however, be given to townships until the county has assumed a system of market roads; otherwise, as alternative plans, they might seriously interfere with the installation of a proper system of such county roads. It is felt that provision for a system of good market roads in each county is of first importance and that aid to townships should not be in any way allowed to take the place of such roads. As to the division of cost for rural market roads, it is suggested that 60 per cent. of both construction and maintenance expenses be paid by the county, and 40 per cent. by the province.

Future Development and Maintenance.—In the present circumstances, the general condition of rural roads being so indifferent, interurban and market routes have a tendency to shift, as one stretch of road is improved or another allowed to deteriorate, so that the volume of traffic borne by a particular route is not an absolute proof that under a proper organization of the road system it would not be a main traveled road. A road census would show what amount of travel is furnished to-day by a given district, and the channels which it now takes; but considerations such as the density of population, the productivity of the land, railway construction, possible or probable developments, the distribution of road-making material, and so forth, would have to be taken into account.

One such consideration is the possibility of future urban growth which will lead to the places concerned sending out and attracting to themselves a greatly increased volume of traffic; should this occur, the place so developing would need additional market and interurban routes, striking out from it at varying angles, and in some cases cutting diagonally across the present rectangular road-patterns. It is suggested that tentative plans for such diagonal roads be drawn up with regard to certain prominent centres, and some arrangement—such as the prohibition of the erection of buildings in their track—be made to ensure the possibility of their being constructed at the lowest possible cost, if need should arise in the future.

It is the opinion of the Ontario Highways Commissioners that if due care is taken in studying the situation, the county roads, those taking care of the heavy non-local traffic, need not greatly exceed fifteen per cent. of the whole. Thus they view the problem in Ontario as that of bringing 42,500 miles of township roads to a reasonably fair standard, and of fitting 7,500 miles of county roads to bear the severe demands made upon them.

The first principle in connection with road expenditure is that money secured by bond issues should only be put into permanent roads. The future should not be called upon to pay for the present, unless the present creates something that will be useful to the future. The maintenance of permanent roads is made necessary through the wear and tear of the present generation, hence that burden should be met by the users. As bond issues must eventually be redeemed, and as the roads will wear out and call for renewal from time to time, the bonds should not run for a longer period than the natural life of the road with proper maintenance. It is believed, therefore, that the bond should preferably be redeemed within twenty years, and should not exceed thirty years.

Maintenance would become increasingly heavy as stretch after stretch of standard roadway came into existence; from the moment a permanent road is constructed, a properly organized system of repair and upkeep must be applied to it if the first expense is not to be wasted and the project to issue in disappointment.

An intelligent system of records and cost-keeping is a basic requirement in an undertaking such as road construction and maintenance, for the guidance of those in charge of the work, as well as for the information of the public who supply the funds. Economy of expenditure, and public confidence and support, will be greatly aided by adequate records of work done with a corresponding and lucid statement of expenditure.

A NEW EXPLOSIVE.

TITANITE, a new explosive, which has been invented recently in Vienna, and for which many advantages are claimed, is an ammonium-nitrate and turmeric powder compound. The turmeric root is nitrated by boiling in water to extract coloring substances, drying, grinding, treating with a mixture of sulphuric and nitric acids, washing and drying the product of the reaction. Carbonized turmeric powder may be similarly nitrated. Ammonium-nitrate explosives usually contain carbonaceous material and carbonized turmeric powder and carbonized sandalwood are recommended as excellent for this purpose, the sandalwood hastening the speed of combustion. As a formula for an explosive compounded along these lines, the following is suggested: Ammonium nitrate, 88 per cent.; carbonized turmeric powder, 1.05 per cent.; carbonized sandalwood, 0.95 per cent.; nitrated turmeric powder, 10 per cent.

It has been found, however, that the carbonized material is unnecessary when the nitrated turmeric powder is used, and a simpler formula offered is: 80 to 90 parts of ammonium nitrate and 20 to 10 parts of the nitrated turmeric powder, carefully dried, intimately mixed and finely ground.

The addition of trinitrotoluene and gelatin, the latter consisting of collodion cotton and dinitrotoluene, results in an explosive of greater strength. A formula for such a compound would be: Ammonium nitrate, 82 parts; nitrated turmeric powder, 4 parts; trinitrotoluene, 10 parts; gelatin, 4 parts (the latter to consist of 0.17 part of collodion cotton and 3.83 parts of dinitrotoluene.)

It is claimed that these explosives are stable when stored, the hygroscopic quality of the ammonium nitrate being overcome; that they are entirely safe, being insensitive to blows, shocks and fire, and exploding only from an initial explosion as by a powerful detonator; that they are powerful in their effect, and that they yield only a small amount of noxious gas. As a matter of fact, according to the Engineering and Mining Journal, these claims have been pretty well borne out by trial at one of the largest mines in America. The difficulty in the way of the general introduction of the explosive, which is called titanite, seems to be that ammonium nitrate cannot now be obtained quite cheap enough to enable the titanite to compete in price with the other high explosives in common use.

The great dry dock in Japan at the Maidzura naval station on the western coast, has been completed after 8 years' work. It will accommodate warships up to 35,000 tons displacement.

MODERN METHODS OF STADIA SURVEYING.

By J. A. Macdonald, Ottawa, Ont.

ONE of the reasons why the stadia is growing rapidly into more general use is that fewer men are required for a stadia party than for an ordinary transit party. This particular advantage of the stadia over the transit and chain for the traversing of lakes has caused the Topographical Surveys Branch of the Department of the Interior at Ottawa to adopt the stadia almost exclusively for lake traverses. In the Lands Survey Branch the stadia is used almost entirely, also for all lake traverses necessary to be made in the subdivision of townships. This article embodies the best methods to adopt for surveying by means of the stadia rather than the chain and transit or compass. By reference to Fig. 1 it will be seen that the rays of light proceed from a point so distant that in the stadia the rays may be considered parallel, and these are refracted and converged to a point in the axis of the lens called the focus, or the principal focus, at a certain distance, depending upon the radii of curvature of the surfaces of the lens. The image is formed at the distance, F, in front of the object glass owing to the image of the cross-hairs being projected beyond the objective to the extent of the focal length of the latter. The rays converge at that point, and the measurement must be taken from it. Therefore, in order to obtain accurate results a constant must be added to the reading from that point, which constant is equal to the focal length of the objective, plus the distance from the objective to the centre of the instrument. The focal length is shown by the dotted line, f, while the distance from the objective to the centre of the instrument is shown by the dotted line c. The rod-reading gives the distance only from the point, F, to the rod, so that to get the total distance from the point over which the instrument is set the values of c and f must be added. The distance, then, is the rod-reading (assuming it reads 1 in a 100) of the rod plus $(f + c)$ in all cases. Each instrument has an individuality of its own, and must be adjusted by actual trial at a mean distance. The difference of focal length for an 11-inch transit telescope of 30 magnifying power at a change in distance from 100 to 300 feet would be but 0.0027-ft., so that it is possible to read all lengths of sights with an almost perfect degree of exactness.

Traversing with the Stadia.—In a combination of hydrographic and topographic work, such as the traversing of lakes and other bodies of water, the party usually consists of surveyor, transit-man, two rodmen, and canoe. The traverses of a lake or other body of water is usually made from one or more instrument-stations at or near the shore, the rodman following the bank and giving side-shots at suitable distances apart. For rivers and lakes there is an advantage in keeping one rodman on each side and surveying both sides at the same time, the rodmen following the shore in opposite directions till they meet at the far side. The survey will, however, generally be made on one side only, the front rodman travelling away from the surveyor, while the rear rodman travels towards the surveyor. The rear rodman having reached the surveyor and the front rodman the next instrument station, the surveyor moves his instrument to the next station, while the rodmen are waiting in their places. Upon the arrival of the surveyor the front rodman shows him his new station and the instrument is set up. The rear rodman places his rod upon the last station for orienting the transit, and the survey proceeds as before. It is well to remember that

when the sun is shining and the distance is great, a rod cannot be read unless the sun is shining upon its face, and so only one of the rods can be used for measuring side-shots, according to the direction of the sun. The rodman who is not giving side-shots along the shore can be engaged taking soundings from the boat, while he also gives side-shots to stations on islands.

When no astronomical observation is taken, the instrument is oriented by means of the compass, or rather by the magnetic needle, reading the azimuth of magnetic North deduced from previous readings or from astronomical observations taken from a magnetic map.

It is highly important for the rodman to understand the significance of holding the rod vertical; to ascertain if it is hidden; and how to select a new instrument station. The face of the rod should be turned slightly towards the sun when by so doing the sun can be made to shine on the graduations. A system of signals should be arranged with the rodmen for directing them to stop, or to start again, or to indicate that the rod is hidden. Some signals can be made with the arms, or a flag may be necessary at great distances. Before the rodman leaves the instrument it is well to indicate to him as nearly as possible where the next station is to be. It is more important that the surveyor himself act as front rodman, or at least be with him at instrument points or stations, and leave the transit-man at the instrument. I is also well to read the three wires for both the front and rear instrumental stations as a precaution against errors.

When the instrument is but a few feet above the water it is not necessary to record vertical angles along the shore; when, however, the inclination exceeds 1°-30′, the vertical angle should be recorded and the proper correction applied to the distance read between instrument stations always, and frequently on side-shots if the vertical angle is large.

Reading the Rod.—For reading distances, set the lower wire on an even chain or foot-division on the rod, count the number of feet, tenths and hundredths to the upper wire and estimate the fraction. Distances read by means of the whole interval are twice as accurate as with the half-intervals. The length of courses between stations should always be measured with the whole interval when the distance is less than 1,300 feet, or 20 chains; the readings with the half-interval will necessarily have to be made at distances greater than 20 chains, as the limit of any 13-foot rod is but 1,300 feet with the whole-interval reading, and 2,600 feet reading with the half-interval. When the sum of the readings of the half-intervals equals the reading of the whole interval, the check is significant. The constant of each instrument is anywhere between one and two feet, and this sum must be added to the reading.

As an example of instrument No. X., for which the wire interval factors are: Upper interval 197.19, lower interval 211.53, whole interval 102.18; a reading of 200 ft. with the upper interval corresponds to 197 ft., to which has to be added the constant. With the whole interval, a reading of 1,000 ft. corresponds to 10.22 + .02 (constant). A reading of 2,000 ft. with the lower interval corresponds to 21.15, to which the constant .02 must be added. The correction to the reading is, therefore, + 115 + 2, or + 117; that is to say, the reading both of the rod and the constant is 117 greater than the actual distance.

These directions are tabulated and used for plotting when extreme accuracy is demanded. Usually they may be overlooked. In inclined sights the reductions of distance may be quickly reduced by means of the slide-rule. When the difference between the starting and closing corners differs more than 5 % from the distance in an original survey, if any, the error should be located by retracing with the stadia.

For Soundings.—For obtaining contour lines on lakes, or shore lines 5 ft. deep, 10 ft. deep, etc., procure a quarter-inch hemp rope, attach a 2 or 3-lb. lead to the end and mark every 10-ft. with a strip of red and every 5-ft. with a strip of blue bunting. Always tie the loose end of the rope to the boat before leaving the shore. Soundings can be made in shallow water with the rod, though this method of taking soundings is not recommended. After completing the survey of a lake enter in the notes the nature of the water, whether fresh or alkaline, the sources of supply, the outlet, and such other

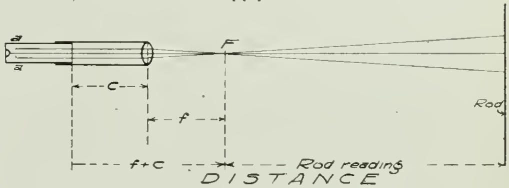

Fig. 1.

data as may be of interest. A determination of the magnetic meridian should be made if the weather permits making an astronomical observation, but this will not always be necessary.

Plotting the Survey.—A rough sketch of the survey should be made or plotted on the right-hand page of the field book before leaving the locality, or as the work proceeds. Two field books may be used consecutively, one being left in the office or camp while the other is in use on the survey. Make the plot, first, at least, in pencil, preferably on paper ruled to a scale of 10 chains to the inch. Commence plotting carefully the instrumental stations and work in pencil the north and south points of each station.

Plot the side-shots by means of the protractor. Then enter on the plan the soundings taken, and all other information that has been collected.

The Field Book.—The left-hand page of the field book is for the notes; the right-hand page for a sketch of the survey. Two stations are designated by numbers; the side-shots by letters. In the first column of the left-hand page enter the letter of the side-shot or the number of station sighted upon. The second column is for the distance read or estimated; the third column for the bearing; the fourth column for the vertical angle, and the remainder of the page for remarks.

Stat. No. or side-shots.	Distance.	Bearing.	Vert. angle.	Remarks.
(1)	...	....	....	Inst. set Comp. north.
(a)	150	307.00	6.40	Top of bank.
(b)	350	115.30	82.45	Foot of bank.
(c)	457	31.25	....	....
(d)	1423	224.51	....	Creek, 10 feet wide, 2 feet deep.
(2)	1343	122.26	85.50	Marshy shore. Water—
Stat. 2—				
(e)	918	46.40	....	....
(f)	987	238.12	....	....
(g)	1423	224.51	....	....

At each instrument-station enter in the notes the nature of the shore, the rise of the ground from the water's edge, the depth of the water as determined from soundings in the boat by one of the rodmen, the estimated distance to the foot or top of the slope when the lake lies in a valley, and such other data as may be considered useful.

SAND SPECIFICATIONS.

In connection with the conclusions arrived at by the Engineering Experiment Station of the University of Illinois, following the extensive tests to ascertain the mortar-making qualities of various sands, the specifications, given below, are proposed:—

It is generally acknowledged that the specifications most frequently used for sand are inadequate in that they are too brief or two indefinite to secure the desired results. Recent specifications have overcome these defects in some respects, but most of them are objectionable in that they are too inflexible, i.e., fail to allow variations in the quality of the sand to meet varying conditions or different requirements, or else by placing undue stress on some particular requirement bar from use sands which would prove entirely satisfactory. The following specifications have been prepared with the idea of giving this necessary flexibility and at the same time making them sufficiently rigid. It is not intended, however, that these specifications should be used indiscriminately for all purposes, but rather that they should serve simply as a guide in preparing the specifications for any particular piece of work. In preparing these specifications both the specifications proposed by the national engineering societies and the results of the test described in the bulletin have been taken as guides.

Definition of Sand and Screenings. — The term "sand" shall be understood to mean natural sand which will pass, when dry, a screen having ¼-in. clear openings. Similar material which is the product of artificial crushing shall be known as "screenings," and shall conform to the specifications for sand.

Suggested Classification of Sands.—Sands shall be classified as No. 1, No. 2, No. 3, plastering sand, and grout sand, the several grades being suitable for the following classes of work:—

No. 1 sand is that required in reinforced concrete and in other work requiring a mortar of maximum strength and density.

No. 2 sand is that required in work not demanding maximum strength or density, but still requiring a mortar of high quality.

No. 3 sand is that required where high strength or density is not a controlling factor.

Plastering sand is that for use in ordinary plastering over masonry, concrete, and wood or metal lath. Either No. 3 sand or plastering sand is of high enough quality for use in lime mortars. The latter sand should be used where the thickness of the mortar joint is such as to require grains of small size.

Grout sand is that for use in pavement fillers and other work requiring a thin, smooth, free-running grout.

Specifications for No. 1 Sand.

Composition.—No. 1 sand shall consist of grains from hard, tough, durable rocks, and be free from soft, decayed, or friable material.

Cleanness.—The sand must be free from lumps of clay, loam, or other foreign material. It shall not contain more than 2 per cent. by weight of finely divided clay, loam, or other suspended matter when tested by washing in such a manner as to remove all such material without removing any of the finest sand; provided, that if the strength of the mortar made from the sand is greater than 110 per cent. of the strength of a similar mortar made with standard Ottawa sand, the amount of suspended matter may reach 3 per cent. This suspended matter must not form a coating around the grains to such an extent that such coating is not entirely broken up and removed from the grains by sprinkling with water or in the mixing of the mortar or concrete. The sand shall be free from oily or greasy matter in any form and must contain no organic silt.

Roughness.—The grains shall have rough, unpolished surfaces to which the cement paste will readily adhere.

Size of Grains.—The grains shall be well graded in size from the finest to the coarsest. For the greatest density not more than 8 per cent. by weight, including the suspended matter, shall pass the No. 100 sieve, and not more than 60 per cent. the No. 16 sieve. If maximum density is not essential and the mortar yields the required strength, these quantities may be increased to 12 per cent. and 75 per cent., respectively.

Voids. — The voids in the dry sand, when well shaken, shall not exceed 33 per cent. of the total volume of the sand.

Tensile Strength.—Mortar, in the proportions of 1:3 by weight, when tested at an age of 28 days, shall develop a tensile strength at least equal to the strength of a similar mortar made of the same cement and standard Ottawa sand tested at the same age.

Specifications for No. 2 Sand.

General Requirements.—No. 2 sand shall meet the requirements for No. 1 sand in all respects except as follows:—

Cleanness.—The suspended matter shall not exceed 6 per cent. by weight when tested in the same manner as described for No. 1 sand.

Size of Grains.—Not more than 15 per cent. by weight, including the suspended matter, shall pass the No. 100 sieve, and not more than 80 per cent. the No. 16 sieve.

Voids.—The voids shall not exceed 35 per cent. of the total volume.

Tensile Strength.—The tensile strength shall equal at least 80 per cent. of that of the standard Ottawa sand mortar when tested as described for No. 1 sand.

Specifications for No. 3 Sand.

No. 3 sand shall meet the requirements of No. 2 sand, except that the suspended matter may reach 8 per cent. and the tensile strength be as low as 65 per cent. of that of the standard Ottawa sand mortar.

Plastering sand shall meet the requirements for No. 3 sand in all respects, except that for the finishing coat it shall be of the requisite fineness to give the desired finish.

Grout sand shall meet the requirements for No. 3 sand except as follows:—

It shall all pass a No. 16 sieve. The voids shall not exceed 38 per cent. of the total volume. The tensile strength shall be at least 40 per cent. of that of the standard Ottawa sand mortar.

The firm previously known as the Caradian Contractors, Limited, of Winnipeg, has recently changed its name to "Joseph Macdonald and Company, Limited."

SPECIFICATIONS FOR DRAIN TILE.

Among the committee reports that were presented at the recent convention in Atlantic City of the American Society for Testing Materials, that of Committee No. C-6, on standard tests and specifications for drain tile, contained something more definite and valuable than has heretofore been published. The following considerations, relating to strength tests, quality and recommended practice in design and construction are extracted therefrom:

Proposed Specifications for Strength Tests.—1. The specimens shall be unbroken, full-size tile. They shall be carefully selected so as to represent fairly the quality of the tile.

2. A standard test shall comprise five individual tests. The result for each specimen and the average of the five shall be given in the report of the test.

3. The materials of the tile shells shall, at the time of testing, be in a thoroughly wet condition, such as may be obtained by covering with sacks kept wet for 8 hours.

4. No test specimen shall be exposed to water or air temperatures lower than 40° F. from the beginning of artificial wetting until tested. Frozen tile shall be completely thawed before artificial wetting begins.

5. Each specimen shall, if practicable, be weighed on a reliable scales just prior to testing.

6. The load shall be applied by any machine or hand method which will apply the load continuously, or in uniform increments not exceeding 0.05 of the total load necessary to break the tile. The tile shall not be allowed to stand any considerable time under load. All solid parts of the bearing frames or bearing blocks shall be so rigid that the distribution of the load shall not be appreciably affected by the deflection of any part. All bearings and the test specimens shall be so accurately centered as to insure in every direction a symmetrical distribution of the loading on each side of the centre of the tile.

7. The inspector, in specifying test requirements for drain tile, shall prescribe in advance one of the three following kinds of bearings: sand bearings; hydraulic bearings; three-point bearings.

8. The test results shall be reported in terms of the ordinary supporting strength. This term shall be defined to mean the supporting strength of a tile when the load is applied with such a distribution as to produce a maximum bending moment of $0.20 \frac{RW}{12}$, where W = the ordinary supporting strength, and R = radius of middle line of tile shell, in inches. The ordinary supporting strength shall be obtained by multiplying the test breaking loads, by the following factors: For sand bearings, 1.00; for hydraulic bearings, 1.25; for three-point bearings, 1.50.

The ordinary supporting strength shall be reported in pounds per linear foot.

9. The modulus of rupture shall be calculated from the maximum bending moment prescribed in Section 8 by the formula

$$p = \frac{6M}{t^2}$$

where p = modulus of rupture in pounds per square inch, M = maximum bending moment in shell in inch-pounds per inch of length, calculated as prescribed in Section 8, and t = thickness of tile shell in inches.

Five-eighths of the weight of the tile per lineal foot for sand bearings, or three-fourths for hydraulic or three-point bearings, shall be added to W in computing the maximum bending moment, when such addition exceeds 5 per cent. of W.

10. Where sand bearings are used, each specimen shall be accurately marked in quarters, with pencil or crayon lines, prior to the test. Specimens shall be carefully bedded, above and below, in sand, for one-fourth the circumference of the pipe, measured on the middle line of the pipe shell. The depth of bedding above and below the pipe at the thinnest points shall at each place be equal to one-fourth the diameter of the pipe, measured between the middle lines of the pipe walls.

The sand used shall be clean sand which will pass a No. 4 screen.

The top bearing frame shall not be allowed to come in contact with the pipe or with the test load. The upper surface of the sand in the top bearing shall be carefully struck level with a straight edge, and shall be carefully covered with a heavy, rigid, top bearing plate, with lower surface a true plane, made of heavy timbers or other rigid material, capable of uniformly distributing the test load without appreciable bending. The test load shall be applied at the exact centre of this top bearing plate, in such a way—either by the use of a spherical bearing or by the use of two rollers at right angles—as to leave the bearing free to move in both directions. In case the test is made without the use of a machine, and by piling on weight, the weight may be piled directly on a platform resting on the top bearing plate, provided, however, that the weight is piled in such a way as to insure uniform distribution of the load over the top surface of the sand.

The frames of the top and bottom bearings shall be composed of timbers so heavy as to avoid appreciable bending by the side pressure of the sand. The frames shall be dressed on their interior surfaces. No frame shall come in contact with the pipe during the test. A strip of soft cloth may be attached to the inside of the upper frame on each side along the lower edge to prevent the escape of sand between the frame and the tile.

11. Where hydraulic bearings are used, each specimen shall be accurately marked in halves, with pencil or crayon lines, prior to the test.

A hydraulic bearing shall be composed of a wooden platen to which is attached, as hereinafter described, a section of rubber hose. The hose shall lie against the tile, and the pressure shall be applied to the hose through the platen.

The platen shall be built of yellow pine, and shall be at least 4 by 4 in. in section, and its least length shall be the length of the pipe plus 8 in. One-inch quarter rounds with their convex surfaces facing shall be firmly attached to each edge of one side. The straight portion of this face shall extend at least the length of the pipe, and the platen beyond this length may be cut to the arc of a circle.

Between the quarter rounds shall be laid a piece of 2½-in. hose, which shall be closed in a water-tight manner at each end by clamps. The hose shall contain a volume of water not less than one-half nor more than two-thirds its capacity, when completely distended. This hose may be attached to the platen at either end in any satisfactory manner which will not induce wrinkling when under test pressure.

The test load shall be applied at the exact centre of the top bearing, in such a way as to leave the bearing free to move in the vertical plane of the axis of the pipe.

It is recommended that stops be screwed to the platen symmetrical with the point of application of the load, and at a distance apart not greater than the length of the tile plus ½ in. This will help centre the load coming upon the pipe.

12. Where three-point bearings are used, each specimen shall be accurately marked in halves, with pencil or crayon lines, prior to the test.

The lower bearings shall consist of two wooden strips having a corner rounded to a radius of approximately ½ in. They shall be straight and shall be securely fastened to a rigid block in a position such that the bearing lines of a cylinder of 24-in. diameter laid along the rounded edge of the strips shall be 2 in. apart.

The upper bearing shall be a wooden block, straight and true from end to end.

The test load shall be applied through the upper bearing block in such a way as to leave the bearing free to move in a vertical plane passing between the lower bearings.

In testing a tile which is "out of straight," the lines of the bearings chosen shall be from those that appear to give most favorable conditions for fair bearings.

Proposed Specifications for Quality.—1. Specimens to be tested shall be selected by the inspector from the tile to be used on the work; these specimens to be selected at the factory, shipping destination, or at the trench location. The tile shall be measured, sounded and examined by inspection. Five specimens of each materially different class noted shall be selected for a test. If, in the judgment of the inspector, it is necessary either before or after the testing of the specimens, additional specimens may be selected, but in no case shall these additional specimens exceed 1 ft. in length for each 100 linear feet of tile to be laid. These additional specimens shall be furnished by the contractor free of charge at the point of selection, provided that, in case the specimens tested meet the specifications, not more than 1 per cent. shall be required to be furnished free.

2. Each tile shall be of a cylinderical section, the size being designated by the interior diameter. The average diameter shall not be more than 3 per cent. less than the specified diameter. The maximum and minimum diameters of the same tile or average diameters of adjoining tile shall not differ more than 80 per cent. of the thickness of the wall.

3. The minimum length of the tile shall not be less than 12 in. In tile 12 in. or above in diameter, up to 30 in. in diameter, the length shall not be less than the diameter. Tile above 30 in. in diameter need not have a greater length than 30 in.

4. Tile designed to be straight shall not vary from a straight line more than 3 per cent. of its length.

5. Tile shall be reasonably smooth on the inside, and free from cracks and checks extending into the body of the tile in such a manner as to appreciably decrease the strength.

Tile stood on end and tapped with a light hammer when dry shall give a clear ring.

Tile shall be free from chips or broken pieces which will decrease its strength or admit earth into the drain. The end shall be regular and smooth and admit of the making of a close joint when properly turned and pressed together.

6. In a standard test, if one or more specimens fall more than 25 per cent. below the required strength as specified, the class of tile represented by the failing specimens shall be rejected, and other specimens tested to complete the standard test.

7. *(a) Class No. 1B.*—No. 1B tile are intended to be suitable for supporting the load in the worst material in a trench having a grade line 5 ft. deep. They shall have minimum average ordinary supporting strengths calculated as prescribed in Section 8 of the proposed Standard Specifications for Strength Tests of Drain Tile, in accordance with the following table:

Required Average Ordinary Supporting Strength for Class No. 1B Tile.

Diameter of tile, in.	Lb. per linear foot.
10	600
12	700
14	800
16	900
18	1,000
20	1,100
22	1,100
24	1,200

(b) Class No. 1A.—No. 1A tile shall be made of good materials by the most approved method, and are intended to be suitable for supporting the load in the worst material in a trench having a grade line 7 ft. deep.

The inner surface of the tile shall be free from defects. The outer surface shall be free from broken blisters, lumps or flakes which are thicker than 20 per cent. of the thickness of the tile, or whose diameter is greater than 15 per cent. of the inner diameter of the tile, and such defects as are allowed shall not be of such nature as to appreciably weaken the tile when laid in the ditch.

The tile shall have minimum average ordinary supporting strengths (calculated as prescribed in Section 8 of the proposed Standard Specifications for Strength Tests of Drain Tile) in accordance with the following table:

Required Average Ordinary Supporting Strength for Class No. 1A Tile.

Diameter of tile, in.	Lb. per linear foot.
12	900
14	1,000
16	1,200
18	1,300
20	1,400
22	1,550
24	1,700
26	1,800
28	1,900
30	2,000
32	2,050
34	2,150
36	2,250

(c) Class No. 1 Extra A.—No. 1 Extra A tile shall be extra good, and are intended to be suitable for supporting the load in the worst material in a trench having a grade line 10 ft. deep. They shall be either vitrified, salt-glazed, clay tile, or thoroughly seasoned concrete tile, made of the best materials, by the most approved method.

The inner surface of the tile shall be free from defects. The outer surface shall be free from broken blisters, lumps or flakes which are thicker than 16 per cent. of the thickness of the tile, or whose diameter is greater than 12 per cent. of the inner diameter of the tile, and such defects as are allowed shall not appreciably weaken the tile when laid in the ditch.

The tile shall have minimum average ordinary supporting strengths (calculated as prescribed in Section 8 of the proposed Standard Specifications for Strength Tests of Drain Tile) in accordance with the following table:

Required Average Ordinary Supporting Strength for Class No. 1 Extra A Tile.

Diameter of tile, in.	Lb. per linear foot.
12	1,000
14	1,200
16	1,500
18	1,700
20	2,100
22	2,300
24	2,500
26	2,600
28	2,800
30	3,000
32	3,200
34	3,300
36	3,500

8. Tile not meeting the above specifications shall be rejected.

Proposed Recommended Practice in Design and Construction of Tile Drains.—The selection of a class of tile suited to a particular case requires a knowledge of the pressures to which the tile will be subjected. This in turn depends upon the character of the soil and the manner of laying the tile as well as upon the depth and width of ditch. The following is recommended as good practice in design and construction:

Methods of Tile Laying.—1. Three grades of work are recognized, namely, Ordinary, First Class, and Concrete-Cradle. Generally the engineer will specify the grade of work required, but in some cases it may be advisable to allow the contractor a choice between using a superior method of laying, or a stronger tile.

2. In Ordinary tile laying the contractor shall shape the bottom of the ditch approximately to fit the lowest one-quarter of the outside circumference of the tile, taking pains to secure an extra firm bearing near the outer edges of the bearing area.

In hard material he shall bed the tile in a thin layer of granular earth where, in the judgment of the engineer, it is necessary to secure a good bearing.

After the tile is bedded truly to line and grade, the contractor shall carefully place the earth around and over the tile by hand to the depth of at least 1 ft. over the tile, using shovels or other suitable tools to work the earth filling down the sides, and underneath the tile so far as practicable.

Whenever the ordinary supporting strength of the tile, as determined by actual tests, and calculated as prescribed in Section 8 of the proposed Standard Specifications for Strength Tests of Drain Tile, is 50 per cent. or more in excess of the strength specified, the bottom of the ditch need not be shaped to fit more than the lower one-eighth of the outside circumference of the tile.

3. In First-Class tile laying in hard material, the contractor shall shape the bottom of the ditch approximately to fit the lowest one-quarter of the circumference of the tile, taking pains to secure an extra firm bearing near the outer edges of the bearing area. Upon the concave surface so prepared the contractor shall spread a layer, 1 to 2 in. thick, of pulverized soil, or sand free from pebbles larger than ¼ in. diameter, and shall firmly bed each tile truly to line and grade thereon.

Where the bottom of the ditch is so wet and soft as to enable the thorough bedding of the lowest one-quarter circumference of the tile without the use of the layer of pulverized earth or sand, and still is firm enough to afford good, safe support to the tile and its load of ditch filling, the engineer may authorize the omission of the layer of granular material, but such authorization shall not excuse imperfect bedding.

The space between the tile and the bottom and sides of the ditch shall be filled with selected earth, thoroughly tamped as fast as placed, up to the level of the top of the tile. The side filling shall be carried up as rapidly on one side of the tile as on the other.

The tile shall then be covered by hand with earth to a depth of at least 1 ft. above the top of the tile.

No tile laying shall be considered as First-Class unless the laying and tamping of each tile are watched and directed by an inspector kept constantly on the work for that purpose.

4. Two grades of Concrete-Cradle tile laying shall be recognized, one for solid material and the other for yielding material.

(a) Solid Material.—Solid material shall be defined as that which is as solid as average, firm, clay sub-soil. Concrete-Cradles, Solid Soils, shall be made as follows:

The contractor shall shape the bottom of the ditch to fit approximately the lowest one-fourth of the circumference of the tile. Upon the concave surface so prepared there shall be spread at least 2 in. of soft concrete, stiff enough to sustain the weight of the tile, and the tile shall be firmly bedded truly to line and grade thereon.

The space between the tile and the bottom and sides of the ditch shall then be thoroughly tamped or spaded full of soft concrete, up to a level one-quarter of the diameter of the tile above the mid-height. The thickness of the concrete at any point shall not be less than 2 in.

Each joint shall be promptly cleaned on the inside of the tile, as soon as the concrete is in place for that joint.

The concrete used in this method of strengthening tile shall be made of 1 part Portland cement and 8 parts of gravel, or 1 Portland cement, 5 parts sand, and 8 parts broken stone. No pebbles or stone shall exceed in size 1 in. less than the thickness of the concrete.

(b) Yielding Materials.—Yielding materials shall be defined as including all materials not solid, as defined above.

Concrete-cradles for yielding material shall be designed by the engineer to carry safely to the soil foundations both the vertical load on the tile from the ditch filling and a side thrust at the mid-height of the tile, such as would exist if the tile were cracked at the top, bottom and each side. The thickness of the concrete at the lowest part of the bottom of the tile shall be at least one-eighth, and on each side at the mid-height at least one-fifth the internal diameter of the tile, and the side concrete shall extend about one-quarter of the diameter above the mid-height of the tile. Each joint shall be promptly cleaned on the inside of the tile as soon as the concrete is in place for that joint.

The concrete used in this method of strengthening pipe shall be made of 1 part of standard Portland cement and 5 parts of good, coarse, clean gravel, or 1 part of standard Portland cement, 3 parts clean, coarse sand, and 5 parts broken stone. No pebbles or stone shall exceed 2½ in. in greatest diameter, nor exceed 1 in. less than the thickness of the concrete.

5. Tile in the trench shall not be subjected to freezing weather during construction without a sufficient depth of cover to prevent cracking.

6. In Table I. are given the approximate values in pounds per linear foot of the ordinary maximum loads on drain tile and sewer pipe from common ditch-filling materials, as determined by tests[1] at Ames, Iowa, and Bos-

[1] For both the tests and the data of actual drains and sewers, see the Report of Committee C-6 on the Investigations on Drain Tile, American Society for Testing Materials, published as Bulletin No. 36, Iowa Engineering Experiment Station.

ton, Mass., and by study of the detailed data of about 90 actual tile drains and pipe sewers, part sound and part cracked.

It is recommended that for clay and all common material except sand and loam, the values under clay be used, and for sand and loam, the values under sand.

Strength of Tile Required.—6. It is recommended that where tile are to be laid according to the description for the Ordinary method, a factor of safety of 1½, applied to the average strength, shall be used when the results of the tests are reported in terms of the ordinary supporting strength, calculated as prescribed in Section 8 of the proposed Standard Specifications for Strength Tests of Drain Tile, and loads estimated according to Table I.

7. Where the tile are to be laid in accordance with the method denominated First-Class, in consideration of the increased support furnished by the improved foundations, the nominal factor of safety to be employed shall be 1¼, applied to the average strength, and with loads estimated according to Table I.

8. In this case it is intended that the concrete-cradles shall furnish the strength necessary to carry the load from the ditch filling. It is recommended, however, that only Class No. 1 A or Class No. 1 Extra A tile shall be used in this case.

Table I.—Maximum Loads on Drain Tile and Sewer Pipe from Ordinary Ditch-Filling Materials—Ordinary Sand, 120 lb. per Cu. Ft.; Thoroughly Wet Clay, 120 lb. per Cu. Ft.

Loads in Pounds per Linear Foot.

Height of fill above top of tile, ft.	Breadth of Ditch a Little Below Top of Tile: 1 ft. Sand.	1 ft. Clay.	2 ft. Sand.	2 ft. Clay.	3 ft. Sand.	3 ft. Clay.	4 ft. Sand.	4 ft. Clay.	5 ft. Sand.	5 ft. Clay.
2	180	190	410	420	650	660	890	900	1,110	1,130
4	270	300	710	750	1,170	1,220	1,640	1,690	2,100	2,150
6	310	360	910	1,000	1,590	1,680	2,270	2,400	2,970	3,100
8	340	400	1,070	1,190	1,910	2,070	2,820	3,000	3,720	3,930

PROPOSED STANDARD ROAD TERMS.

By the Committee on Standard Tests for Road Materials, appointed by the American Society for Testing Materials, the following terms applicable to materials for roads and pavements were submitted at the recent convention of the society as proposed standard definitions:

Asphalts.—Solid or semi-solid native bitumens, solid or semi-solid bitumens obtained by refining petroleum, or solid or semi-solid bitumens which are combinations of the bitumens mentioned with petroleums or derivatives thereof, which melt upon the application of heat and which consist of a mixture of hydrocarbons and their derivatives of complex structure, largely cyclic and bridge compounds.

Asphaltenes.—The components of the bitumen in petroleum, petroleum products, malthas, asphalt cements and solid native bitumens, which are soluble in carbon disulphide but insoluble in paraffin naphthas.

Blown Petroleums.—Semi-solid or solid products produced primarily by the action of air upon originally fluid native bitumens which are heated during the blowing process.

Carbenes.—The components of the bitumen in petroleums, petroleum products, malthas, asphalt cements and solid native bitumens, which are soluble in carbon disulphide but insoluble in carbon tetrachloride.

Cut-back Products.—Petroleum or tar residuums which have been fluxed with distillates.

Tars.—Bitumens which yield pitches upon fractional distillation and which are produced as distillates by the destructive distillation of bitumens, pyrobitumens or organic materials.

Coal Tar.—The mixture of hydrocarbon distillates, mostly unsaturated ring compounds, produced in the destructive distillation of coal.

Coke-oven Tar.—Coal tar produced in by-product coke ovens in the manufacture of coke from bituminous coal.

Dehydrated Tars.—Tars from which all water has been removed.

Gas-house Coal Tar.—Coal tar produced in gas-house retorts in the manufacture of illuminating gas from bituminous coal.

Oil-gas Tars.—Tars produced by cracking oil vapors at high temperatures in the manufacture of oil gas.

Pitches.—Solid residues produced in the evaporation or distillation of bitumens, the term being usually applied to residues obtained from tars.

Refined Tar.—Tar freed from water by evaporation or distillation which is continued until the residue is of desired consistency; or a product produced by fluxing tar residuum with tar distillate.

Water-gas Tars.—Tars produced by cracking oil vapors at high temperatures in the manufacture of carburetted water-gas.

Editorial

JOHN GALBRAITH, ENGINEERING EDUCATIONALIST.

With engineering in Canada will always be prominently associated the name of John Galbraith, who gave the fullness of his life to the building up of an institution devoted to the teaching of the scientific principles which, when inculcated, formed the basis of many engineering careers. The loss which engineering has sustained at his death will never be fully realized. So brightly has shone the personality of the Dean through so many years that it will continue to shine.

Nearly forty years of a whole-hearted application of one of the most observing, resourceful and judicious intellects, to the problems before it, have left an impress that nothing can obliterate. His tremendous ability, his remarkable alertness to the difficulties of others and to the cause to which he had devoted his life, his unceasing vigilance and prompt yet cool and masterful disciplinary powers, his keen sympathies for the student and his work, for his staff and its worries, for the country and its needs, raised him high above his fellow men, yet nestled him into their hearts.

The encomiums which are being so abundantly and so deservedly accorded him, come with double aptitude, in the light of the fact that death found him in the harness, to the last, never lingering, never slipping, and always in the hearts of his School men, always with them in his heart.

ETHICS IN COMPETITIVE DESIGN.

Competitive designing may be a good thing, providing the rules of the game are observed. Its goodness is altogether contingent, however, upon close adherence to the conditions by which the competition is governed. Otherwise it is apt to come within the category of "skin games."

Recently the council of a western city took a flier into the sport and launched a competition, which is very slow at righting itself to the general satisfaction of all concerned. For even the judges should observe the rules with exactness.

The city employs an engineer. (It may be that our readers will remember a reference in these columns last year to a city engineer, taken suddenly ill, being indiscreet enough to be hustled to the hospital without first bending his knee and asking permission—thereby almost forfeiting his job. It is the same city engineer, and the same city. The incident was commented upon to show the absolute lack of fairness which the city council displayed in dealing with the case.)

Competitive designs were received this spring for a piece of engineering work of interest to engineers and architects. The conditions of the competition, with which we are especially concerned, stipulated that the competitors were required to submit fully detailed drawings to enable the city engineer to check over the design, as regards strength and stability, as well as specifications, quantities, prices, etc.; that designs were required to conform in line and grade with location plans supplied by the city engineer, and that, should any of the conditions be ignored, the plans, being disqualified, would not receive consideration.

Some 29 designs were submitted by 23 engineers and architects. They were referred to the city engineer. The city engineer also prepared a design, which, it is stated, was not presented at the same time as the others. Later he prepared a second design.

The special committee of the city council took his design No. 2 into competition with the others and recommended it.

The other competitors thereupon held a meeting and protested against the recommendation on the grounds that, (1) the city engineer acted in a triple capacity, viz., as compiler of the regulations governing the competition, as technical expert in judging the designs, and as a competitor; (2) the city engineer's design was contrary to his own regulations, and did not conform to the lines and grades as laid down by himself. Therefore it was not eligible for competition. Having spent considerable time, labor and money on the competition, the competitors (21 of whom had signed the protest) hoped that the council would take a stand which would allow it to be closed with satisfaction to all and honor to the council.

The city has a branch of the Canadian Society of Civil Engineers, who protested against the procedure; so did the Provincial Architectural Institute.

The city council adopted the design No. 2 submitted by the city engineer.

In view of the disturbance which resulted from the proceedings, the city engineer, in a letter to the mayor, stated that the modification of design No. 1, which was embodied in design No. 2, had been conceived and prepared before examining the individual plans submitted by the various competitors. He explained that the choice of design was not made by him or upon his recommendation but by the committee; and that he was not present when the decision was reached. He made it clear that since his own designs were in competition with the other twenty-three, he would prefer to be relieved of all responsibility for advising the city council in the matter.

It is stated, further, by one of the aldermen, that no one knew of the design No. 2 until a day or two before the committee met to go over the plans. According to the city engineer's letter to the mayor, his report dealing with the engineering features of the various plans had been prepared prior to this. The sub-committee to go over the plans and city engineer's report was not appointed until six weeks after the competition had been closed. It is very evident that as the city grows older its council is not improving in the matter of fairness. But there is an engineer connected with the unfairness, whose case should be clearer than the circumstances indicate. We have been hoping that our information is inaccurate, but supplementary advices from other sources strongly bear it out. Is it a case of absolute devotion to his employers, in right or wrong, with an equally absolute disregard for engineering ethics?

JOHN GALBRAITH

DR. JOHN GALBRAITH, Professor of Engineering and Dean of the Faculty of Applied Science and Engineering, University of Toronto, died at Go Home, among the islands of Georgian Bay, on July 22nd, 1914. It was known by an intimate few that his health had been seriously impaired, but death came with appalling and unexpected suddenness, even to the members of his family close to him at the time.

His early career, until the founding of the School of Practical Science in 1878, is briefly told. Born in Montreal, September 5, 1846, and coming with his parents a few years later to reside in Ontario, his early and high school education was received in Port Hope. At the age of 17 he entered the University of Toronto. Here, despite his modest and retiring nature, his desire for a liberal education, and for the uplifting of others as well as of himself, created a pronounced interest in undergraduate activities. The annals of the University record him as a participant in the foundation of several of the earlier organizations, including the first National Science Club.

His graduation with the degree of B.A. was marked by a singular appreciation of his ability, in the award to him of a double scholarship in mathematics and general proficiency. He acquired the gold medal in the former, and in 1868 his unparalleled qualifications earned for him the Prince of Wales' prize. Characteristic of the genius and of his insatiable desire for knowledge, the education which had been accompanied by these distinctions was regarded by him as very ungratifying. Though young in years, he had a remarkable conception of the future of the country and of its inevitable development. His explorations into the forest-covered confines of Upper Canada had revealed to him the dependency of this development upon the training in applied science of young men. Throughout the years which followed his convictions were augmented by the primitiveness of many of the methods then in vogue in engineering work. During his connection with the building of the Midland, the Intercolonial and the Canadian Pacific railways his resourcefulness and comprehensive grasp of fundamentals earned for him the prophecy of his chiefs, that in the open field of civil engineering his would be a most notable career. But the yearning for the application of science to the problems of engineering triumphed over the call of the wild. In 1875 he returned to the University of Toronto for the degree of M.A. and strongly voiced his convictions, now a part of himself, that the direst need in education at that time was the need of a technical training for young men, to enable them to become engineers. His persistent and potent arguments resulted in the Legislative Assembly of 1877 sanctioning the establishment of a School of Practical Science in Toronto. His scheme of organization included an arrangement whereby the students of the proposed institution were to enjoy full advantage of the instruction given by the teaching staff of University College in all the departments of science which would be embraced in the work of the School. John Galbraith assumed the full personal responsibility of instruction in Engineering Thus opened the gateway through which have passed a multitude of technically trained engineers—one of the outstanding and epoch-making events in the history of the Dominion of Canada.

The progress of the School of Practical Science through the intervening years, until 1906, and its development since, as the Faculty of Applied Science and Engineering of the University of Toronto, is as well and truly written over, and under, the surface of this country as it is in the archives of Parliament or the University. Better! It bespeaks, as writings cannot do, the long-drawn strife and indefatigable devotion of the force behind the institution. The history of the institution is the biography of the man. Its success has been to his sacrifice. The story of the battle of a life-time will never be told in full. The conscientious engineer carried his self-unrevealing troubles under seal to his grave.

The arduousness of the academic work which he had set himself to do, took him, during the summer months of each year, into the field of engineering to acquire first-

---

Dr. Galbraith was one of the greatest men of his age, for he has been instrumental in producing the men who are now so strong a factor in the development of our Dominion.

I shall always cherish his memory with sincere affection.

H. G. Tyrrell, '86,
Consulting Engineer.

Evanston, Ill., July 24th, 1914.

Dean Galbraith was the greatest practical engineering educator of his time and, through his graduates, he has influenced all parts of the engineering world. I count it a great privilege to have studied under him, and the friendship which has since continued makes me mourn his loss most keenly.

Louis L. Brown, '95,
Vice-President The Foundation Co.

New York, July 25th, 1914.

Dean Galbraith possessed, I believe, more of the Christian virtues than any other man I have known. He was of a most kindly disposition and was considerate, almost to a fault, of the feelings of all with whom he came in contact.

For over twenty years he has been my most intimate friend, and in this long period I cannot recall his ever having spoken uncharitably of anybody, although he occasionally expressed righteous anger at manifest wrong doings. He practiced to the fullest extent the Golden Rule, "Do unto others as you would have others do to you."

He was extremely happy and content in his home life and had practically no outside interests, other than those connected with the University and the School of Science.

R. F. Stupart,
Meteorological Service.

Toronto, July 25th, 1914.

hand knowledge of its progress and its requirements. Always on the alert, years went by with no cessation of engineering activity. His extensive knowledge of the geographical and geological nature of the country was acquired by canoe and trail, years before the faces of other white men had penetrated into the Indian's domain. The various tribes committed their dialects to his mastering, his friendships among the red men were many, and more than one tribe has hailed him as the "Chief of all the Whites." His foot trod over the mineral fields between civilization and Hudson Bay a score of years before the intrusion of the pick, and the northern waterways familiarly bore his canoe when geographical map there was none. He saw it all as a field for the engineer, and as the horizon receded, he saw to it that his purposeful labors, with their attending trials and responsibilities, expanded accordingly. The sun set with his shoulder still to the wheel.

> He has left his mark in Canada through his great influence. He was beloved and revered by every student who studied under him and few men will be more widely mourned.
>
> T. R. Deacon, '91,
> Mayor.
>
> Winnipeg, Man., July 27th, 1914.

A noted writer has already said of him: "In a world where men are crowding and pushful, it is gratifying to see, now and then, a man who is quiet and retiring brought out whether or no, and placed in front, where his attainments entitle him to be." In 1907, he was appointed a member of the Royal Commission to investigate and report upon the collapse of the Quebec Bridge. In 1909 he was elected president of the Canadian Society of Civil Engineers, for which he had long acted as councillor and in the establishment of which, in 1887, he was one of the founders. Back in 1902 the University of Toronto conferred upon him the honorary degree of LL.D., and in the following year Queen's University, Kingston, likewise paid tribute to his ability. For many years he had been an associate member of the Institution of Civil Engineers of Great Britain.

> For 32 years I had the great good fortune of the acquaintance, advice, instruction and friendship of Dean John Galbraith.
>
> The late James Ross, a thorough judge of men, said in 1883, that Galbraith was an exceptionally capable engineer and teacher, and that any boy who was fortunate enough to graduate under his instruction would need no further collegiate training in Europe or America.
>
> The advice given me by Dean Galbraith has been repeated to many young men, as I have felt sure that it would benefit them as it has benefited me.
>
> There is no man living whom I respect, admire and love as much as I did Dean Galbraith.
>
> T. Kennard Thomson, '86,
> Consulting Engineer.
>
> New York, July 25th, 1914.

In his earlier manhood, Dr. Galbraith was a military as well as a civilian engineer. He was present at the mustering of the garrisons near Montreal in the sixties, upon the occasion of a visit from the then Prince of Wales, later King Edward VII. The story has been told of the call for volunteers during the Fenian raids. At that time he was an assistant on the railway survey party. When news of the call reached the party in the forest, the chief, desirous of enlisting, designed to leave the work in charge of John Galbraith. His assistant, however, advanced his own sense of duty at such a time of need, arguing that the better surveyor should stay and the better fighter should go. The acknowledgment of the respective qualifications was somewhat unbalanced and the latter accomplishment required vindication. This was adjusted out behind the tent. Galbraith went.

To the graduates of the institution known familiarly as "The School," the record of his death has come with appalling suddenness. He was dearly loved by all; by some as the Dean, by others as the Principal, by many others by the more familiar and genuinely brotherly appellation of "Johnny." The age of 67 found him with his energies ebbing, spent in the pursuit of his life-work, to a greater degree than any but his closest friends surmised. After a strenuous year, full of characteristic endeavor to bring his institution to that degree of efficiency that has always been his ideal, he had repaired with his family, only a few weeks ago to Go Home, a quiet and beautiful spot established by himself more than twenty years ago on the shores of Georgian Bay. His lowered

> For a long while I have known him—33 years—and in all that time, first as a pupil and afterwards as one of the many who had the good fortune to possess his friendship, I grew to respect more and more and admire those rare qualities of heart and mind which so endeared him to all who knew him well.
>
> His personality was extremely attractive. He appealed to all sorts and conditions of people, to young and old, to the plain workman as well as to the educated college man.
>
> He had all the qualities of a truly great leader. He had wonderful tact and intuition and was very, very kindly. His modesty and genial good nature, keen sense of humor, and charity for human weaknesses, gained him friends everywhere, and yet when necessary, he could be very strong, but he ruled through love and not through force.
>
> He possessed the faculty to a remarkable degree of imparting knowledge to others, and of stimulating a desire for thoroughness. I have met none who were his equal in this respect. There was something in him which unconsciously brought out the best in his pupils. I do not remember that he ever lectured his class on conduct or ethics; but his influence somehow stimulated the best that was in us. He was not only a great teacher of Applied Science—he was an upbuilder of character—he made Men as well as Engineers.
>
> His loss to Canada and to the University is very great. To his wife and family and to his many devoted friends, it is irreparable; but he had lived to see the fruition of his life's work, and it gave him much joy in his later years to see the bountiful return which his early strenuous and loyal work had produced. The influence of his life will long survive him. The world is better for John Galbraith having lived.
>
> Eugene W. Stern, '84.
> Consulting Engineer.
>
> New York City, July 24th, 1914.

vitality failed, however, to respond, as usual, to the recuperative environments.

Dean Galbraith was not a seeker of renown. His world-wide reputation is of the kind that will wear through ages, gathering as it has done from without the horizon of his sphere of labor. He merely sought to do his part, faithful to himself, loyal to his profession, a friend of every student, and every man a student like himself. With the close of his career the continent loses the person of one of its greatest educators, but one who had accomplished so much in the upbuilding of the engineering profession that the personality behind it all will go down through the ages an archetype of the life of the engineer as it should be lived to do the most good to mankind.

LETTERS TO THE EDITOR.

Concrete Arches.

Sir,—I note with considerable interest, in your issue of June 11th, 1914, the five conclusions drawn from the paper on concrete arches in Proceedings of the American Society of Civil Engineers for Vol. 39, page 1193.

The writer of your article has not referred to the discussion which followed in subsequent numbers of Proceedings. Some recognition of the same should be made, for, in the writer's opinion at least, these discussions, made by the most eminent engineers of the country, are of great value.

As I am at present away from Toronto and have not these numbers of Proceedings with me, I am unable to give names or figures, but the following general discussions are, I believe correct:—

* (1) and (2) are generally confirmed.

(3) This statement is questioned by a large number of engineers. In the first place, there will not be very much more concrete in a fixed rib than in a three-hinged rib, if both are properly designed, and the cost of forms will be very nearly the same. Consequently, the saving in using a three-hinged rib will be only in material, and the estimate should be so prepared. On the other hand, the cost of the hinges is very considerable, and will usually offset, or even outweigh, the saving in concrete.

Secondly—The fixed ring is without doubt more rigid and stable than the hinged ring.

Thirdly—The greater reliability which is attributed to the hinged ring is largely a matter of facility and certainty of design. A fixed ring is susceptible of a very rigid and accurate design, and can be carried to a scientifically fine point. Of course, the labor of designing a fixed arch is somewhat greater than of a hinged arch.

The value of a hinged arch ring is its greater adaptability to small motions of the abutments. But in the general condition of rigid, immovable abutments the fixed ring is generally considered not only better design, but more economical.

Permit me to refer your readers to the last chapter in David A. Molitor's "Kinetic Theory of Structures," which the writer holds in high esteem.

(4) The rib of I-section is not in general favor, since any small settlement which may occur before forms are removed tends to crack off the flanges. (For want of a better word I employ the term flanges, which will at least be understood.)

In addition to this, the extra amount of formwork which is necessitated by this form of arch ring will reduce, or even eliminate, the economy of concrete material.

(5) The value attributed to the form of pier mentioned in the article is also somewhat questioned, chiefly on account of the agitation and obstruction of the current of the stream. This difficulty can, no doubt, be overcome by carrying a solid pier to above high water.

These remarks can be amplified and verified by an examination of the numbers of Proceedings in which these discussions are published. I trust they will be of some interest to your readers.

Ernst G. Kaufmann, C.E.

Schomberg, Ont., July 21st, 1914.

Improved Roofing Materials.

Sir,—We have read with interest a paper by W. E. King, C.E., published in your July 16th issue under the title of "Economical Design of Industrial Works," and we note therein a paragraph referring to the roof.

We would like to inform your readers that we have had a series of experiments with two styles of roof, which have proven very efficient and permanent. A great many industrial establishments in Montreal and elsewhere in Canada have been covered with a thin slab of fine cinder concrete, ordinary cement mortar, and finished with felt or asphalt material.

The idea of construction is to attach to the roof small shapes for purlins at 5-ft. centres, and to these purlins attach ¾-in. or 1-in. channels at 12-in. centres and transverse, and to these channels apply a 24-gauge expanded metal lathing. To this lathing apply a fine cinder concrete, and when the slab is dry finish the exposed side with a roofing compound and plaster inside with ordinary cement mortar. This makes a permanent roof, and by the use of the two different compounds condensation is reduced to a minimum.

Another very superior style of fireproof and permanent roof is procured by the use of ferro-dovetail plates. The idea is to attach purlins from 4 to 6 ft. centres, and to these purlins attach the plates in the same manner as you would attach corrugated sheets. When these sheets are affixed, cover with cinder or fine stone concrete, applied to a thickness of 1 in. above the plates, and then apply your roofing compound. The underneath side of the plates can then be plastered with ordinary lime mortar, cement mortar or gunite.

The Pedlar People, Limited,
Per W. E. Ramsay.

Montreal, July 17th, 1914.

Two books have been published dealing with the proceedings of the Fifth National Conservation Congress, held in Washington, D.C., last November. One of them treats of Water Power subjects exclusively, and is an important contribution to constructive literature in this subject. The other book contains the Forestry reports and addresses, which were conceded to be the most valuable ever presented at a similar meeting in this country. The books may be had through N. C. McLoud, Treasurer and Recording Secretary of the Congress, 1201 Swetland Building, Cleveland, Ohio.

BOOK REVIEWS.

Insulation and Design of Electrical Windings.—By A. P. M. Fleming and R. Johnson. Published by Longmans, Green and Co., London. Canadian Selling Agents, Renouf Publishing Co., Montreal; 224 pp.; 102 diagrams; size 6 x 9 ins.; cloth. Price, $2.25. (Reviewed by Prof. H. W. Price, Department of Electrical Engineering, University of Toronto.)

Relatively there are very few books on insulation which attempt to treat the subject generally. The authors of this volume have offered a valuable addition to this literature, and in it have included a large collection of data in tabular and curved forms on mechanical and electrical properties of insulation for rotating and static electrical machinery. It is difficult to predict with exactness the service to be expected of insulation, because in so many situations it is subjected not only to fairly definitely-known electrical stress and frequency, but also to variable and imperfectly-known punishment or fatigue from mechanical strain in construction and operation, dirt and moisture, overheating, high frequency, etc. Therefore trial and error is largely depended upon for advice. The authors have made many tests to find individual effects of these variables in operating life of insulations, and their results are interesting as an aid toward good judgment in design.

The first three chapters are devoted to an account of physical characteristics of gaseous, liquid and solid dielectrics, the nature and extent of electrical stresses to be met in practical work and properties of many insulating materials when subjected to electrical stress, fatigue from continued over-stress or abnormal frequency, effects of oil and moisture on both electrical and mechanical characteristics, properties when dried out in various ways after abuse, etc. The authors have evidently made many investigations themselves, have also collected data from other sources, and with many curves, tables and discussion, offer a good assembly of information.

A large section is devoted to "design of insulation and windings," insulation tests, etc. Various windings for motors, generators, and transformers are discussed from the insulation point of view, and many sketches are offered showing actual materials and thickness provided for specified service. This information is extensive and valuable, but in view of titles of book and chapter one wonders why no attempt is made to explain how the authors would proceed with their data to choose insulation other than by copy-cut-try methods, which their preface states they desire to make less necessary.

The last two chapters concern drying and handling of windings in factory and in service, and causes of failures in service. Such matters as drying of transformer oil, which have been fully dealt with by others, are given little space. Here, as in several other places in the book, the authors have wisely preferred definite references to their selections from literature now available on the point in question.

Sanitary Engineering.—By Francis Wood, M.I.C.E., F.G.S. Published by Chas. Griffin and Co., Exeter St., Strand, London; 306 pp.; 181 illustrations; size 5½ x 7½ ins.; cloth. Price $2.25 net.

This is the third edition of a practical manual of town drainage, sewerage and refuse disposal. It contains a number of additions covering improvements and alterations, which have developed in the design and construction of sewers, particularly in the application of concrete; also in the ventilation of sewers or oxygenation of the sewage, and other subjects which have been given great attention since the publication of the first edition 13 years ago.

The book contains 20 chapters, the first three of which are of an elementary nature and deal lightly with hydraulics together with formulæ for the velocity of flow in pipes, etc. Following, 12 pages are devoted to a technical consideration of earth pressure and retaining walls. Chapter V. is on power, and a few facts are given concerning water-power, steam, electricity and compressed air. In the reviewer's opinion, the six pages devoted to the subject of power might well have been omitted as the subject matter is so elementary as to be entirely lacking in practical information respecting the subjects mentioned. Mere definitions of horsepower, ohm, ampere, volt, etc., seem quite out of place in a book written specially for the sanitary engineer.

The subject of house drainage has been well and thoroughly treated, both from the standpoint of the urban and rural dwelling. Chapter VII. has to do with land drainage, evaporation, rainfall, etc. The subject of sewers and sewerage systems are taken up in a capable and comprehensive manner in some 70 pages, under the headings of Sewers, Separate System, Sewage Pumping, Sewer Ventilation, Drainage Areas, Manholes, etc. A chapter of 20 pages is devoted to trade refuse and river disposal. The titles of the remaining chapters are Sewage Disposal, Bacterial Treatment, Sludge Disposal, Construction Materials and Cleansing of Sewers, Refuse Disposal, Chimneys and Foundations. The book is well indexed, the illustrations are particularly clear and the whole subject is treated in such a way as to render the book a valuable one to sanitary engineers, architects, inspectors, contractors and students.

Metallurgy of Copper.—By H. O. Hofman, E.M., Met.E., Ph.D., Professor of Metallurgy, Massachusetts Institute of Tecnology. Published by McGraw-Hill Book Co., New York City; 556 pp.; 548 illustrations; 130 tables; size 6 x 9 ins.; cloth. Price, $5 net. (Reviewed by Geo. A. Guess, Metallurgical Engineer, Toronto.)

To write the metallurgy of copper is unquestionably a difficult undertaking. Progress in the art is so rapid, each year seeing new developments, that a book can hardly be written before new metallurgical features are in successful use.

Dr. Hofman in his "Metallurgy of Copper" has, however, given us a book that is up-to-date, and which covers the field as no other book does. The work is essentially a compilation of the published literature on the metallurgy of copper, supplemented by data obtained from several of the larger American smelters and refineries. The work is clear, concise and free from padding. It is difficult to find anything but praise for the book. If inclined to be critical one might object to descriptions and cuts of roasting furnaces hopelessly antiquated, or of descriptions of smelting operations which recall the days when an air of mystery surrounded the metallurgist. Such a description is given in the smelting in of a reverberatory furnace bottom. Under leaching methods considerable attention is paid to wet processes for treating copper mattes, a practice which is extinct in America. It is to be hoped that, in view of the rapid development of wet methods of ore treatment, the author will rewrite in a year or two bis chapter on the leaching of copper ores. The book quite correctly does not deal with any form of wet concentration or flotation. It is written for the profession and the advanced student of metallurgy.

The work is purely descriptive. The author refrains from criticizing furnace or plant design. He states without comment, conditions as they exist, as to equipment of plant, and scheme of operations. He reviews the evidence and leaves the case with his readers.

Practical Iron Founding.—By Jas. G. Horner, A.M.I., Mech. E. Published by Whittaker & Co., London and New York. 409 pages; 285 illustrations; size, 5 x 7 ins.; cloth. Price, $1.25 net.

The principles and practice of iron founding are depicted in this work for the special guidance of the student and of the practical man, relating particularly to the two branches of machine molding and the melting of iron. This is tbe fourth edition of Mr. Horner's treatment of the subject, and it has been thoroughly revised and enlarged to conform with the great changes which the industry has experienced since the first edition was published. In it the portion devoted to machine molding has been entirely rewritten and new chapters prepared with additional examples of molds introduced. The volume has outgrown the stage of elementary treatise and its value has increased accordingly.

Its scope may be briefly summed up by an enumeration of the subjects of the 16 chapters. They are as follows: Principles; Sands and their Preparation; Iron-Melting and Testing; Cupolas, Blast, and Ladles; The Shops, and their Equipment; Molding-boxes and Tools; Shrinkage, Curving, Fractures; Faults; Principles of Green Sand Molding; Examples of Green Sand Molding; Dry Sand Molding; Cores; Loam Work; The Elements of Machine Molding; Examples of Molding Machines; Machine-molded Gears; Miscellaneous Economics; Weights of Castings.

Foundry workers will find in this new edition a wealth of material quite up-to-date and in keeping with the present stage of iron founding.

Electrical Practice in Collieries.—By Daniel Burns, M. Inst. M.E., Professor of Mining and Geology, Royal Technical College, Glasgow. Published by Chas. Griffin & Company, Limited, London. 353 pages; 207 illustrations; size, 5 x 7 ins.; cloth. Price, $2.00 net.

In this work the three previous editions have been carefully revised and brought abreast with the latest developments of the industry, as well as the alterations of the laws of Great Britain pertaining thereto. Its publication is justified by the increasing of electric power in mines, particularly in the improvements with respect to coal-working machinery.

The book as a manual of information will be found useful, particularly in the author's native country, by colliery managers, under-managers, and students going up for certificates as such. The purely scientific aspects of the subject are ignored with the exception of a portion of the opening chapter, which has to do with elementary details of electric currents and units of measurement. The chapters following discuss the dynamo, the electric motor, and the applications of electricity to lighting, pumping, haulage and coal-cutting, while the closing chapter of over 50 pages deals with miscellaneous electrically-operated appliances of service in mining operations. Several chapters are concluded by arithmetical examples for the benefit of those students who may peruse the volume.

As a work generally descriptive of the application of electrical power with a minimum of technical discussion this book will be found of considerable assistance to those for whom it was especially written.

Elementary Principles of Illumination and Artificial Lighting.—By Arthur Blok, published by Scott, Greenwood and Son, London, Eng. Illustrated; size, 5 x 7 ins.; cloth. Price, $2. (Reviewed by H. W. Price, Associate Professor of Electrical Engineering, University of Toronto.)

For a small book, the treatment given principles of illumination and lighting is really good. The author has not only explained how to attack many practical problems, but has presented here and there actual cases with the solution completely carried out as he would advise.

Chapters I. and II. cover general principles, selective radiation, effect of light color on color of body illuminated, color matching, etc. The meaning of and methods of using in calculations the units of light and intensity are well explained. Only flame standards of candle power are mentioned in detail. One wonders why electric incandescent secondary standards and their proper use are given seven lines only, when a thousand of them are in use in industrial photometry for every flame standard in service.

Chapter III. gives illustrated description of various commercial photometers, followed by four pages of excellent advice on the use of them in field work. Chapters IV., V., VI., devote 60 pages to all sorts of calculations on lighting and illumination. Explanation of each method is followed by examples from practice completely solved as the authors would recommend. Numerous diagrams and tables are arranged to assist the reader. Chapter VII. is devoted to typical distribution curves from gas and electric light sources, and the science of converting these as efficiently as possible to any other form desired by reflectors, globes and shades. Chapters VIII. and IX. are specially upon problems of indoor and outdoor illumination. Examples are included showing how to value actual requirements of practice. The last chapter deals specially with the properties of illuminants.

The book is pocket size, yet it has a complete contents, list of tables, five useful appendices, a list of symbols employed, a reference list of 20 equations used, a cross index,

and a list of other authors referred to in the text. Our opinion is that this small book is most useful to any requiring assistance in work on illumination.

Motorcycles, Side Cars and Cycle Cars.—By Victor W. Page, M.E. Published by the Norman W. Henley Publishing Company, 132 Nassau Street, New York. 550 pages; 339 illustrations; size, 5 x 7 ins.; cloth. Price, $1.50.

This book is a comprehensive, non-technical treatise, defining all forms of the lighter self-propelled vehicles, principles of operation, construction and practical operation of components in the leading machines. It contains detailed advice on management, maintenance, and repair of all representative types.

Undoubtedly the growth of the motorcycle industry has created a field for a book of this nature. The motorcyclist has heretofore been obliged to acquire his knowledge by much research and reading because the books on motorcycling have been in the nature of elementary pamphlets rather than works of any pretensions. He will find in the work at present under discussion some very useful material, easily understood and up-to-date.

Memorials of Henry Forbes Julian.—By Hester Julian. Published by Chas. Griffin & Company, Limited, London. 310 pages; illustrated; size, 6 x 9 in.; cloth. Price, $1.50 net.

These memorials of Henry Forbes Julian, a member of the Institution of Mining and Metallurgy of Great Britain, joint author of "Cyaniding Coal and Silver Ores," and who perished in the Titanic disaster of April, 1912, have been written and edited by his wife, the author of a number of widely-known biographical works. In the course of his profession as a mining engineer the subject of these memorials was called upon to travel in many countries, and his prominence in the metallurgical industry resulted in a widespread reputation and recognition. He was one of the pioneers of metallurgical work in South Africa, as well as having taken an active part in the development of mining in Germany, Mexico and the United States. The text affords ample indications of his scientific acquirements, his patient industry and adaptability to varied circumstances.

Clean Water and How to Get It.—By Allen Hazen, consulting engineer, New York. Published by John Wiley & Sons, Inc., New York; Canadian Selling agents, Renouf Publishing Company, Montreal. 196 pages; illustrated; size, 5 x 7 ins.; cloth. Price, $1.50, postpaid.

This is the second edition of Mr. Hazen's book dealing with matters of general policy, pressure, fire service, sale of water, and the financial management of waterworks. The volume describes a number of plants and their methods of operation, to illustrate the principles involved. The second edition contains chapters upon the disinfection of water and the "red water" trouble, as well as a general bringing up to date the treatment of the subject in general. The problems of water supply from large and small lakes, from rivers, and of ground water are concisely dealt with in separate chapters. Chap. 6 is devoted to a discussion of the action of water on iron pipes and the effect thereof upon the quality of the supply, together with an outline of the recognized methods for the elimination of trouble in connection with the same.

The development of water purification in America is historically dealt with in a very concise yet comprehensive chapter. The questions of tastes, odors, coagulation and filters are clearly explained. Chap. 9 deals to some length with the nature of purification methods, classifying the processes into mechanical separation, coagulation, chemical purification, disinfecting processes, biological processes, aeration, and boiling. Chap. 10 deals entirely with disinfection, Chap. 11 with the application of the methods of water purification, arranged according to the matters to be removed by the treatment; Chap. 12 with storage of filtered water; Chap. 13 on the required sizes of filters and other parts of waterworks; Chap. 14 as to the pressure under which water is to be delivered; Chap. 15 on the use of measurement of water; Chap. 16 on the financial aspects of the water supply problem; Chap. 17, the laying out and construction of works, and Chap. 18, on the financial management of publicly-owned water supply systems.

The book is very carefully indexed and will be found useful by engineers and waterworks superintendents.

A Glossary of Road Terms.—By H. Percy Boulnois, M. Inst. C.E., city engineer of Liverpool, etc. Published by St. Bride's Press, Limited, London, England. 71 pages; size, 5 x 7 ins. Price, 50 cents net.

The convenient manner in which this glossary has been prepared will receive an enthusiastic welcome from highway engineers. The author's attempt to standardize the nomenclature of road terms appeared last year in the columns of The Surveyor, London, and has resulted in a number of valuable suggestions and criticisms which the author has subsequently incorporated in his work. The glossary follows closely the road terms of the Engineering Standards Committee, the author taking this step advisedly and refraining from technical and geological terms of various rock materials in use.

Oil Fuel: Its Supply, Consumption and Application.—By Edward Butler, M.I.M.E. Published by Chas. Griffin & Company, Limited, London, Eng. 328 pages; 150 illustrations; size, 5 x 7 ins.; cloth. Price, $2.00 net.

This is a third and considerably enlarged edition, and comprises an exhaustively and systematically classified record of the development and progress made in the application of oil fuel for marine and naval purposes, locomotives, road vehicles, lighting, domestic, metallurgical, and other purposes. The relative advantages of steam, compressed air and mechanical action as an atomizing addition for liquid fuel-burners is treated carefully in thirty pages, which include the results of a number of tests. The technical composition of fuel oils, their thermodynamic properties and a history of combustion methods are each treated to some length, while the origin, production and sources of supply of liquid fuel are dealt with in an interesting and authoritative manner. The production of petroleum in the chief oil-producing countries covering a period of a number of years is also given.

The book will be found of distinct value to engineers and manufacturers who encounter various problems connected with the combustion of oil fuel.

Report of a Plan of Sewerage—City of Cincinnati.—By Harrison P. Eddy, Consulting Engineer; H. M. Waite, Chief Engineer, Department of Public Works, and H. S. Morse, Engineer-in-Charge. 730 pages; plates, maps, diagrams, and tables; size, 6 x 9 ins.; cloth.

This is one of the most complete reports on the sewerage of a city that has ever been published. The general report, of 32 pages, outlines the matter treated and the conclusions reached. The treatment of the development of the sewerage system, an account of the detailed underground survey of the existing system; a topographical survey for future plans; data on rainfall and runoff, the planning of relief sewers, of intercepting sewers and creek mains, and the

disposal and treatment of sewage are subjects that are very fully discussed. Although the greater part of it is of purely local interest, there are many theories of general application and matters of similar interest to municipal and sanitary engineers.

PUBLICATIONS RECEIVED.

Annual Report of the City Engineer of the city of Halifax, N.S., for the civic year, 1912-1913.

Labor Organization in Canada.—Third Annual Report for the year 1913, issued by the Department of Labor at Ottawa.

McGill University Calendar, 1914-1915, containing full information regarding all departments and faculties, details of courses, etc.

Proceedings of the Union of Nova Scotia Municipalities at the eighth annual convention, held at Bridgewater, N.S., on August 27th, 28th and 29th, 1913.

Monthly Bulletin of the Canadian Mining Institute.—Edited by H. Mortimer Lamb, Secretary. This bulletin represents the proceedings of the Institute for the month.

28th Semi-Annual Report of the Sewage and Water Board of New Orleans.—This mid-year report consists of brief financial statements and synopsis covering the previous six months.

Notes on Radium-Bearing Minerals.—A 26-page handbook, listed as Prospectors' Handbook No. 1, issued by the Geological Survey Branch, Department of Mines, Ottawa. Compiled by Wegatt Malcolm.

Summary Report of the Geological Survey, Department of Mines, for the calendar year 1912. A 544-page summary of the operations of the Geological Survey for 1912, including the reports of the various officials on the work accomplished by them.

Progress Reports of Experiments on Dust Prevention and Road Preservation, 1913.—Bulletin No. 105, issued by the United States Department of Agriculture, Washington, covering experiments made at Chevy Chase, Md., with supplementary reports.

Year Book, 1913.—Issued by the Swedish Chamber of Commerce in London. The contents include the first annual report of the council, transactions of the year, and various lists, statements and reports; in addition several plans, maps, and full-page illustrations.

Flumes and Fluming.—By Eugene S. Bruce, expert lumberman. Issued as Bulletin No. 87 by the United States Department of Agriculture, Washington. This bulletin discusses the use of flumes in lumbering operations and tells how to build them. Of special value to lumbermen and log-drivers.

Permissible Electric Lamps for Mines.—Written by H. H. Clark, and issued, as Technical Paper No. 75, by the Bureau of Mines, Department of Mines, Washington. This paper deals with safety as a feature of miners' electric lamps, permissible tests, and specifications suggested by the Bureau of Mines for portable electric lamps.

Serpentine and Associated Rocks of Southern Quebec.—Compiled by John A. Dresser. A preliminary report, dealing, primarily, with the economic resources of Southern Quebec, with some attention given also to the petrography and structural geology of the district. Issued as Memoir No. 22 by the Geological Survey Branch, Department of Mines, Ottawa.

Precise Levelling.—By F. B. Reid, D.L.S., and issued by the Dominion Observatory, Department of the Interior, Ottawa. This publication is a continuation of two that have already been issued—Appendix No. 5 to the Chief Astronomer's report for 1910, and the 1913 publication on precise levelling. The present publication is arranged in the same general form, with the results of the levelling set forth in three tables.

Ohio State Board of Health—27th Annual Report, 1912.—Voluminous report, comprising 880 pages. Size, 6 x 9 ins.; bound in cloth. It contains the minutes of board meetings and complete discussions of the subjects taken up. Reports on proposed new water supplies and purification plants for various cities are included. Another section is devoted to reports upon communicable diseases, and another to hygienic laboratories.

Brass-Furnace Practice in the United States.—Compiled by H. W. Gillett, and issued as Bulletin No. 73 by the Bureau of Mines, Department of the Interior, Washington. The bulletin deals with the object and results of an extensive investigation conducted to ascertain the melting and fuel losses on present brass-melting losses, and to indicate, as far as possible, methods by which such losses might be reduced.

Portions of Portland Canal and Skeena Mining Divisions, Skeena River, B.C.—By R. G. McConnell. Memoir No. 32, issued by the Geological Survey Branch, Department of Mines, Ottawa. This memoir includes reports on four neighboring areas, all portions of the Skeena mining district. The main report deals with Portland Canal mining division; the others describe the results of preliminary work in the Salmon River valley, portions of Nass valley, and on observatory inlet.

Tests of Bond between Concrete and Steel.—Compiled by Duff A. Adams, and issued as Bulletin No. 71 by the Engineering Experimental Station, University of Illinois. The tests reported in this bulletin were made in the Laboratory of Applied Mechanics, and formed a part of the investigations of reinforced concrete and other structural materials which were conducted by the Experimental Station. The tests cover the experiments which were designed with special reference to a study of bond between concrete and steel during the period of 1909-1912.

The Tractive Resistance of a 28-Ton Electric Car.—By Harold H. Dunn, and issued as Bulletin No. 74 by the Engineering Experimental Station, University of Illinois. The first part of the bulletin describes the purpose, methods and final results of tests conducted by the Engineering Department to determine the resistance offered to the motion of a 28-ton electric car running on a straight, level track, in still air at uniform speed; and to asertain the relation existing between the resistance and the speed of the car. In the three appendices details are given concerning the apparatus, the methods of calculation, the test data, and the intermediate results.

CATALOGUES RECEIVED.

Merritt Sewage Disposal Apparatus.—A 16-page, illustrated booklet descriptive of the various features of Merritt sewage apparatus. Issued by the Merritt Hydraulics Company, Philadelphia, Pa.

G-E Flow Meters for Measuring Steam, Water, and Air.—Bulletin No. 46501, containing 52 pages descriptive of flow meters manufactured by the Canadian General Electric Company, Limited, of Toronto.

Electric Cable-making Machinery.—A fine, cloth-bound, 84-page catalog descriptive of electric cable-making machinery and accessories. Issued by W. S. Glover & Company, Limited, Manchester, Eng.

Lighting of Business Streets.—A small folder illustrating the adaptability of G. E. ornamental luminous arc lamps for the attractive lighting of business streets. Issued by the Canadian General Electric Company, Toronto.

Small Motors.—A well-written 20-page booklet issued by the Westinghouse Electric and Manufacturing Company, East Pittsburg, Pa., descriptive of the construction, application, and utility of electric ventilating outfits.

Heavy-Duty Corliss Engines.—Bulletin No. 1529, 20 pages, containing a brief description of the more important features of the Corliss engine designed for heavy duty. Issued by Canadian Allis-Chalmers, Limited, Toronto.

Priestman Sewage Pumping Equipment. — A 16-page booklet issued by the Merritt Hydraulics Company, Philadelphia, consisting of a complete description of the Priestman method of sewage pumping, its advantage, cost of operation,, etc.

Heat-Treating Furnaces.—A handsomely-illustrated and well-designed 40-page booklet issued by Tate, Jones & Company, Inc., Pittsburg, Pa. This booklet is descriptive of heat-treating furnaces for annealing, hardening and tempering of steel, and all heat-treating operations.

Steel Chain Belt.—Catalogue No. 54, illustrated, 32 pages, descriptive of Chabelco chain belt, manufactured by Chain Belt Company, Milwaukee, Wis. A few pages are devoted to chilled steel sprocket wheels and the application of the two to conveyer systems, paving-mixers, etc.

Tiffin Motor Trucks.—An attractive 24-page booklet issued by the Tiffin Wagon Company, Tiffin, Ohio. This booklet is fully illustrated with fine half-tones, and gives a very complete and comprehensive description of the design, construction, and utility of Tiffin motor trucks.

Recent Developments in Machine Stoking.—A 40-page, illustrated booklet issued by Ed. Bennis & Company, Limited, London, Eng. This booklet gives a complete description of modern machine stoking by the Bennis method. The text is freely illustrated with interesting photographs.

Flushtank Siphons and Water Regulators.—A 16-page, 6 x 9-in. booklet, by Merritt Hydraulics Company, Philadelphia, dealing with water flushing and control, and containing details of construction and operation of the Morse and Merritt flush-tanks, automatic and semi-automatic.

Bermudez Road Asphalt.—A 16-page booklet descriptive of some roads made from Bermudez asphalt and the wide adaptability of the latter. Many illustrations are given of some of the 12,000,000 sq. yds. of these roads in the United States. Specifications for bituminous road-binder are included. Published by the Barber Asphalt Paving Company, Philadelphia.

Gurley Scientific Instruments.—1914 Catalog, 6 x 9 ins., of W. & L. E. Gurley, Troy, N.Y., for civil, hydraulic and mining engineers' and land surveyors' instruments, including transits, levels, compasses, current meters, and all supplies for field and engineering office work. The catalog, which comprises 224 pages, is very carefully and handsomely illustrated, many of the descriptions of instruments being accompanied by full-page plates.

The Exhaust Steam-Heating Encyclopedia.—The Harrison Safety Boiler Works, New York, have issued their new 207-page edition of the Exhaust Steam-Heating Encyclopedia. This unique and beautifully-designed volume contains a complete compilation of facts and statistics concerning the improved Cochrane Steam Stack and Cut-out Valve Heater and Receiver, and its application in connection with commercial systems of exhaust steam and hot water heating. In addition, there is much other information and tables useful to heating and ventilating engineers and contractors. Canadian Allis-Chalmers are the Canadian agents.

Coast to Coast

Deseronto, Ont.—A flow of natural gas has been struck at Deseronto at a depth of 60 feet; and it is stated gives promise of heavy pressure.

Regina, Sask.—It is now expected that the street railway deficit at Regina will amount this year to only half of the estimated amount, which was $100,000.

Ottawa, Ont.—On July 20, the government steamer "Minto" sailed for Hudson Strait and Hudson Bay, to install 12 lighthouses for the protection of navigation.

Owen Sound, Ont.—As an endeavor to solve its paving problem, the council of Owen Sound has authorized the construction of a block of tarred road, as an experiment; and if this proves satisfactory, more of this road will be built.

Leamington, Ont.—It is expected that before fall, the harbor at Leamington, planned by the Canadian Government, will be ready for the use of vessels drawing not more than 26 feet. Soundings are now being made by engineers; and a breakwater will be built 300 feet out in the lake west of the present dock, which will provide a commodious and safe haven during bad weather.

St. Catharines, Ont.—In addition to the question of a water supply which is now being confronted by the town of St. Catharines, there is the question of the effect of the raising of the river level upon the sewerage system of the town. An endeavor is being made at present to solve both problems and to reach an agreement with the Department of Railways and Canals for the defraying of new expenditures that will be involved.

Sault Ste. Marie, Ont.—Such progress has been made in connection with the construction of the third lock at Sault Ste. Marie that it is expected by lock officials that it will be in use by September 1. Water has been turned into the approach at both ends; and only minor touches remain to be given to the entrance channels. The depth of the new lock will be 25 feet. A year later, it is planned to have a new fourth lock ready for traffic.

Montreal, Que.—Due to the fact that more small buildings are being erected and a correspondingly smaller number of large structures are being undertaken this year in Montreal, figures obtained from the office of the city building inspector show that for 1914, from January to June 30, the estimated value of new buildings was $8,521,910; while for the same period of 1913 the value of buildings erected was $9,942,286, or in other words a decrease for the current year of $1,400,000.

Weyburn, Sask.—The laying of steel on the new Weyburn-Lethbridge branch of the C.P.R. has been completed as far as the Alberta boundary line. This work has progressed steadily all summer at the rate of 3 miles per day, leaving only some 80 miles of its 410 miles in length to be completed. A passenger service is already being run from Weyburn to Shaunavon, which it is expected to extend to Covenlock on September 1, this latter point being practically situated on the boundary line between Saskatchewan and Alberta. In addition to the construction work on the Weyburn-Lethbridge line, the C.P.R. is also double-tracking the main line between Regina and Broadview. This work will be completed by September 1, giving a double track run practically all the way across Saskatchewan.

Montreal, Que.—The plans which are to be prepared, and have almost been completed by the architects of the Mont-

real Harbor Board, provide for a new extension to the No. 1 elevator which will be an almost exact duplicate of the addition which was completed last winter and put into operation this spring. The original elevator had a million bushels capacity, its first extension increasing this by one and a half millions, and the new extension to add a similar amount, so that the two additions will be three times the capacity of the original elevator. This new extension will cost about $750,000, and will be completed for use, it is hoped, by next September. Little beside the elevator itself will be required in the construction. It will be of the same type as the extension at the east side of the original No. 1, with huge concrete tanks to hold the grain, while the machinery in the original elevator will be sufficient to handle the grain in the whole series of bins. When this addition is completed, the Montreal Harbor Board will directly own no less than 7,000,000 bushels of elevator capacity, which will give the Montreal port an elevator equipment of well over 9,000,000 bushels, including the Harbor Commission's 7,000,000, and the Grand Trunk elevators with a capacity of 2,160,000 bushels.

Victoria, B.C.—The first section of tunnel in connection with the northwest sewer construction at Victoria has been completed. The south tunnel from No. 1 shaft, near the outfall, was pierced to meet the drift in from the open cut at McLoughlin point, the connection being made without the slightest difficulty. It will be some time, however, before the tunnel northwards under Smith Street hill will meet the tunnel work being commenced at the outfall point. Preparations are being made for driving tunnel Y, the intention being to drift in from an opening at Sea terrace as well as from the ends. Work in the open trench is also in progress at Hereward road. At the Sunnyside tunnel, where the engineers are working in from Selkirk water, about 270 feet have been completed. This tunnel will be 1,800 feet long. It is the intention to have as much of the open excavation done as possible before the rains of winter. Sewer work is also in progress in the King's road ravine, and at Oxford Street. At the latter place, the collapse of the brick surface drain proved an expensive item; but the worst of the work has been repaired. It is proposed to insert steel ties at each side of the brick work, and brace the sewer, filling in with concrete, in place of the bricks, the base where further danger threatens. It is believed that by that means it will be possible to save a considerable amount of money, and also to secure a drain which will last the lifetime of the paving.

PERSONAL.

A. M. NANTON, who succeeded Sir William Whyte on the directorate of the Canadian Pacific Railway has been elected to the vice-presidency held by Sir William on the Winnipeg Electric Railway Board.

T. R. PERKINS, assistant manager of Toronto branch of the Pedlar People, Limited, has been appointed Western manager, beginning August 1st. He will make Winnipeg his headquarters.

THOS. TURNBULL has been appointed assistant chief engineer of the Canadian Northern Railway, with headquarters in Winnipeg. For the past four years Mr. Turnbull was with the C.P.R. in the West, and with the Hudson Bay Railway, previous to which he was connected with the C.N.R. in Ontario.

A. F. HATCH, formerly president of the Canada Steel Good Company, of Hamilton, Ont., has been appointed general manager and treasurer of the Hamilton branch of the Steel Goods Company, of New Britain, Conn., the latter company having absorbed the former. Operations will be commenced without delay on the erection in Hamilton of an extensive new plant.

ARCH. CURRIE, C.E., city engineer of Ottawa, has tendered his resignation owing to ill-health. Mr. Currie assumed his duties in July, 1913, going to Ottawa from Westmount, Que., where he had been city engineer for two years. Previous to that Mr. Currie had been engaged in municipal work in Great Britain, and in railway work for 12 years in China and 10 years in South Africa. In January last Mr. Currie suffered a severe illness, and since that time, despite his many efforts to attend to civic duties, he has not succeeded in regaining his health.

OBITUARY.

The death occurred on July 19th of Mr. W. N. Allan, a third-year student in mining engineering, University of Toronto, at an age of 26. Mr. Allan was at the time resident in Oakville, Ont., being in the employ of the Ontario Public Roads and Highways Commission, making a survey of the Lake Shore Road between Toronto and Hamilton. Upon noticing a canoe overturn, throwing its occupants into the lake, Mr. Allan swam to their rescue, but death, due to heart failure, intervened. High tribute is being paid to his heroic action, and his untimely death has occasioned much sorrow among his class mates and many others who knew him. Deceased was a native of British Columbia.

COMING MEETINGS.

UNION OF CANADIAN MUNICIPALITIES.—Annual Convention to be held in Sherbrooke, Que., August 3rd, 4th and 5th, 1914. Hon. Secretary, W. D Lighthall, Westmount, Que. Assistant-Secretary, G. S. Wilson, 402 Coristine Building, Montreal.

WESTERN CANADA IRRIGATION ASSOCIATION.—Eighth Annual Meeting to be held at Penticton, B.C., on August 17, 18 and 19. Secretary, Norman S. Rankin, P.O. Box 1317, Calgary, Alta.

AMERICAN PEAT SOCIETY.—Eight Annual Meeting will be held in Duluth, Minn., on August 20th, 21st and 22nd, 1914. Secretary-Treasurer, Julius Bordollo, 17 Battery Place, New York, N.Y.

CANADIAN FORESTRY ASSOCIATION.—Annual Convention to be held in Halifax, N.S., September 1st to 4th, 1914. Secretary, James Lawler, Journal Building, Ottawa.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown, Indianapolis, Ind., Secretary.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—11th Annual Convention; 5th American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau St., New York, N.Y.

KANANASKIS FALLS HYDRO-ELECTRIC DEVELOPMENT

WATER POWER ON THE BOW RIVER—CALGARY POWER COMPANY'S NEW PLANT AND EXTENSIONS TO THE HORSESHOE FALLS DEVELOPMENT — STREAM FLUCTUATION AND STORAGE POSSIBILITIES.

THE Calgary Power Company Limited, of Montreal, has recently practically completed the construction of a new hydro-electric power plant at Kananaskis Falls, on the Bow River, in Alberta, about 50 miles west of Calgary. This plant adds materially to the power previously developed by the company at Horseshoe Falls, two miles distant, and built several years ago.

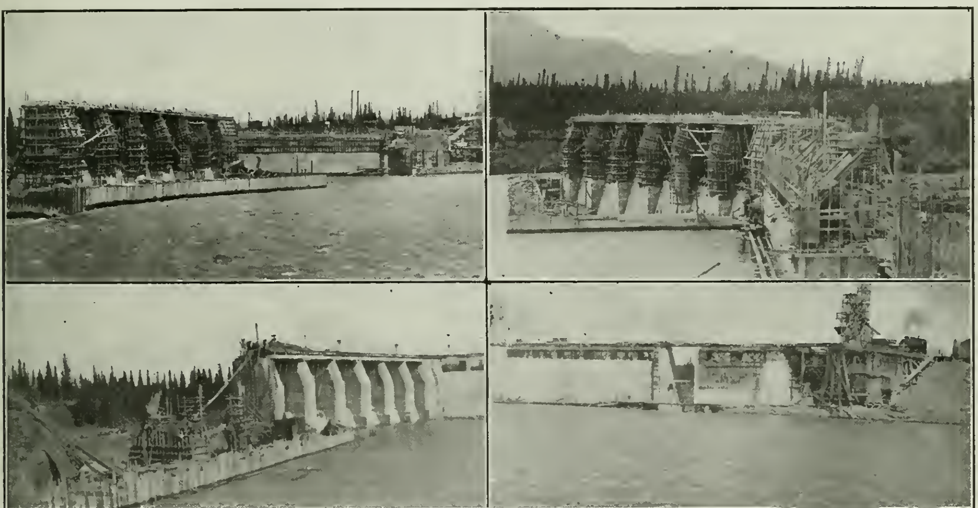

Fig. 1.—Kananaskis Dam, Showing Sluices and Spillway During Construction.

The Bow River.—The Bow River rises in the Rocky Mountains and drains an area of 3,138 square miles, 1,710 of which are above Kananaskis Falls and wholly in the mountain region. It is a typical mountain stream, rising at an altitude of some 6,500 ft. This slope is unusually steep and several falls occur. Its flow, like that of other mountain streams, is subject to sudden variations and is greatly affected by the temperature. During the hot summer months the melting of the snow in the mountains develops floods, while in the winter the cold reduces the flow to a very small proportion. There is, accordingly, a wide variation between high and low water, as evidenced by levels taken by the Canadian Pacific Railway at their bridges over Bow and Kananaskis Rivers, in the immediate vicinity of the development to be described. A flow as high as 45,000 cu. ft. per sec. has occurred at Horseshoe Falls, while a winter discharge of less than 500 cu. ft. per sec. has been recorded at the same place. The section of the river suitable for power development is some 30 miles in length and is well within economic transmission distance of Calgary. The river and the storage possibilities connected therewith, necessitated by the great fluctuation in the discharge, have occasioned very thorough investigation on the part of the water power branch of the Department of the Interior. A study of the power and storage possibilities of the river and its tributaries included the acquirement of copious information respecting run-off, rainfall and stream gauging. Mr. C. H. Mitchell, C.E., of Toronto, acted as consulting engineer to the government in connection with this work.

It should be stated that the direction of flow of the river is southeast from the mountains as far as the foot hills and thence east as far as Calgary. It then flows south and east to its confluence with the Belly River. Its many tributaries, most of them small, include the Kana-

naskis River, which runs into it at a point 53 miles west of Calgary.

Before entering upon a description of the Kananaskis Falls development, the attention of our readers should be called to the reference in *The Canadian Engineer* of June 4th, 1914, to the proposed hydro-electric plant of the Dominion Government at Banff, Alta. The storage possibilities of Lake Minnewanka were outlined therein. During the winter of 1912 the Calgary Power Company entered into an agreement with the Department of the Interior whereby the former was given the right to create a storage at this point. This involved the construction of a dam in Devil's Canyon, the outlet of the lake. The dam is a solid concrete structure about 100 ft. in length

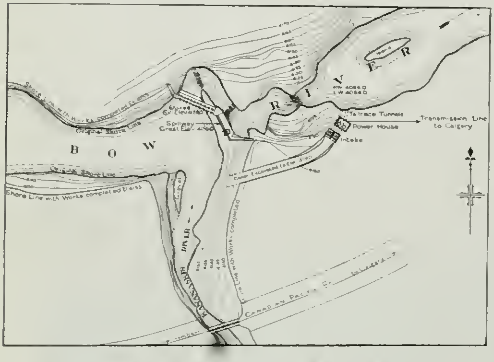

Fig. 2.—General Layout of Power Development.

and 55 ft. at its highest point. It is provided with three stop-log sluiceways and a low level sluice controlled by a gate valve, as illustrated in the article previously referred to. The dam was completed in May, 1912, and storage commenced.

Kananaskis Dam.—In the same year the Calgary Power Company was given the right to develop power at Kananaskis Falls, about $2\frac{1}{2}$ miles above the then almost completed Horseshoe Falls plant. A total drop of about 40 ft. existed at that point and, by the use of a dam at the top of the falls a total head of 70 ft. is gained. Surveys of the site were carried out in considerable detail in the late fall of 1912, and designs for the plant were worked out forthwith. The layout shows a dam across the head of the falls immediately below the point at which the Kananaskis empties into the Bow, a canal

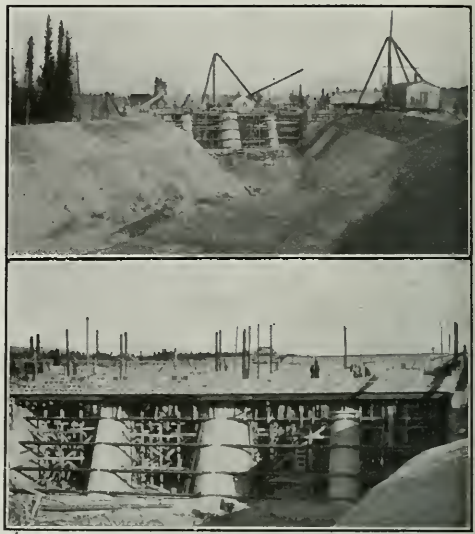

Fig. 3.—Canal and Head Gates Under Construction.

along the south side of the river, an intake, wheel pit, power house, and tailrace tunnels to deliver the water back to the river below the falls. The arrangement is illustrated in Fig. 2. The dam, construction views of which appear in Fig. 1, has a total length of over 800 ft., including wing walls. It is $57\frac{1}{2}$ ft. in extreme height and has eleven stop-log sluiceways 18 ft. in width and 14 ft. below the spillway level. It will raise the water level about 59 ft., backing it up into the Kananaskis River and necessitating the raising of a two-span bridge of the Canadian Pacific Railway on its line from Banff to Calgary

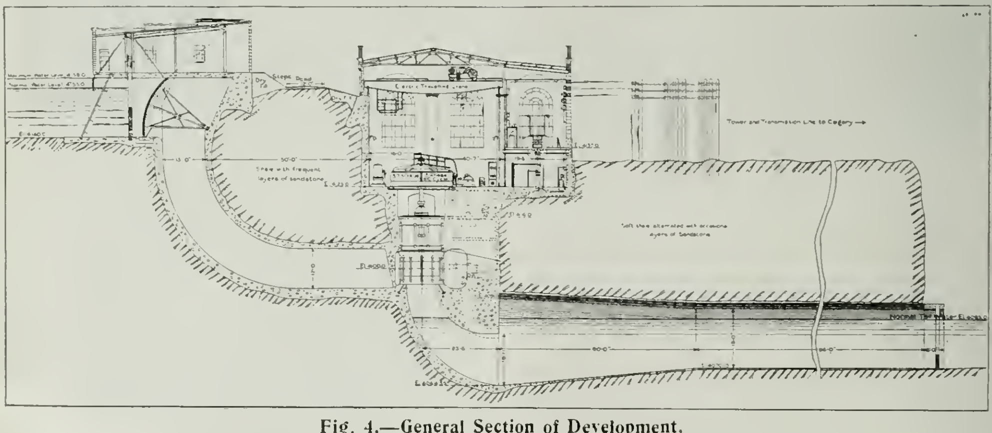

Fig. 4.—General Section of Development.

with a corresponding elevation of 4 ft. in grade. The spillway section of the dam is divided into twelve 17-ft. openings and there is in addition a low-level sluiceway controlled by a 72-in. valve. This provides for a flood discharge of over 47,000 cu. ft. per second with a 3-ft. overtop on the spillway section. There is 215 lineal ft. of free overflow in the length of the dam, high-level water being 20 ft. above the lowest stop-log opening. The wing walls, which add to the dam proper a length of 75 ft., run well into the banks at either side.

The sluiceway and stop-log sections are furnished with a deck 20 ft. in width, narrowing to 10 ft. in width over the other sections. This deck carries an electrically operated winch for the handling of stop-logs.

Owing to the earth structure below the dam being of soft shale and very seamy in spots, in order to prevent seepage the foundation was grouted. Two-inch holes were drilled about 20 in. apart on both sides of the dam and were filled with cement grout under pressure. In some places the foundation structure was so seamy as to require a very large quantity of grout before leakage ceased.

Canal and Head-works.—The canal itself has been constructed sufficiently large to carry the amount of water necessary for the maximum of the plant at low velocity. It is over 700 ft. in length and is of trapezoidal cross-section, 50 ft. wide at the bottom, 80 ft. wide at the top, with an operating depth of 15 ft. This is where it passes through gravel, as shown in Fig. 3. The canal section in rock is rectangular and approximately 50 ft. wide with a depth of 15 ft. The former portion has been lined with concrete from the forebay to the head-works. The rock portion forms a natural dam for the canal. It is in general of a seamy shale nature and alternating with occasional beds of sandstone. From the head-works two 60-ft. concrete penstocks 35 ft. wide by 13 ft. high at the head gates and 12 ft. by 12 ft. at the wheel-case, feed directly to the scroll chambers. These tunnels are located in solid rock, as are also the draft tubes, tailrace tunnels, etc.

The head gates, which are riveted steel Tainter gates, operated by electric winches in the gate house above, are equipped with stop-logs to allow for repairs to the main gates, as well as with gratings to prevent intrusion of floating debris. Fig. 3 shows them under construction. The concrete-lined pressure tubes leading from the gates develop into scroll chambers formed in concrete in which are set the turbines. The forms and method of reinforcing of these chambers are shown in Fig. 5. The draft tubes into which the turbines discharge are 30 ft. in length, varying in cross-section from 9 ft. square at the wheel pit to 16 ft. by 13 ft. at the tailrace tunnels, from which point the water flows directly into the river, as shown in Fig. 6.

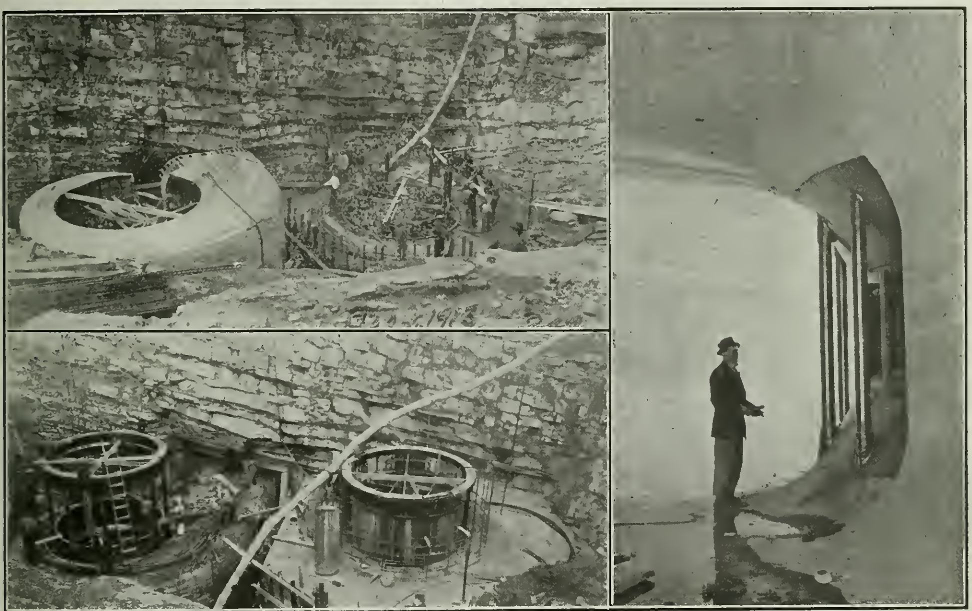

Fig. 5.—Scroll Chambers During Construction. Also Interior View of One with Forms Removed, Showing Turbine Frame in Place.

Construction Details.—The building itself is 90 ft by 60 ft., and is placed on a solid concrete foundation over rock. The lower 15 ft. of the walls are of concrete, while the structure is finished in clay brick. Sand and gravel for the concrete was obtained quite near the site. Mixing was done by steam-driven one-yard mixers in both the construction of the dam and head-works. The building of the dam itself was effected by the construction, during the winter season with low-water level, of a temporary discharge channel cut through the rock, built up with concrete and furnished with stop-log apparatus. A cofferdam was then constructed extending into the river as the current would permit. The flood season, however,

discouraged attempts to divert the whole river through the temporary runway. Accordingly a natural opening was left at the north bank until the following winter season with its decreased flow. The construction, owing to the isolated location of the development, necessitated the building of several miles of sidings as well as quarters for 600 men. A steam plant consisting of two 100-h.p. Leonard boilers supplied steam for the pumps and air compressors, as well as for the work-shop and lighting systems. As the work developed, and power requirements increased, the company's transmission line from Exshaw to Calgary was resorted to and transformers installed for the stepping down of the current from 12,000 volts to ordinary working voltage.

The gravel was obtained, as stated, close to the power works. It was moved by a Marion steam shovel with a one cubic yard dipper. From the pit it was

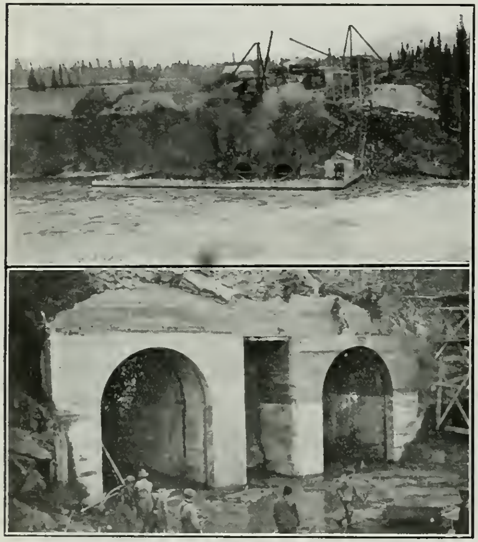

Fig. 6.—Outlet of Tailrace Tunnels.

hauled to the concreting plant in side dump cars of 6 cu. yds. capacity, drawn by Vulcan steam locomotives. The concrete mixers were equipped with hoisting towers and distribution system. They were placed about 30 ft. below the track level. Wooden hoppers with a capacity of 125 cu. yds. received the gravel from the dump cars, and discharged it through sheet metal delivery tubes with arc gates directly into the charging hoppers above the mixers. Cement, in sacks, was received at the mixers through a chute from the storage shed at the top of the bank. The hoisting and distributing towers were two in number, each equipped with Insley hoisting buckets and hoppers. One of them, 40 ft. in height, was used on the construction of the main dam, and the other, 60 ft. high, on the balance of the concreting. Side dump cars, of one cu. yd. capacity conveyed the concrete from the mixers along the deck to the towers. The plant had a capacity of 35 cu. yds. per hour.

An important feature of the construction was the excessive amount of rock excavation necessary. In the canal section a Marion steam shovel with a 1½ cu. yd. dipper loaded into two 12-yd. and eight 6-yd. Peleter side dump cars. Eight Holman compressed air drills were used in rock excavation in the canal section and in the wheel pit and tailrace tunnels. From the latter, excavation was removed by the use of hoisting engines and 5-ton stiff-leg derricks.

The construction of the tail-race tunnels required a heavy timber cofferdam to be constructed in the river.

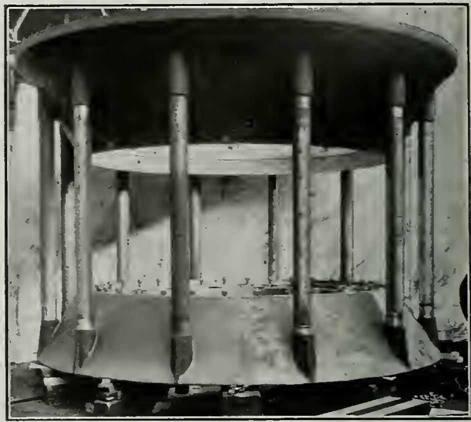

Fig. 7.—Turbine Rings and Supporting Columns. Shop View.

Excavation was then proceeded with from the river base at the same time that the penstock and wheel pit excavation was in progress.

As illustrated in Fig. 5, the forms for the scroll chambers (and the same applies to the forms for the draft tubes and tunnels) were lowered into position from the ledge of rock above.

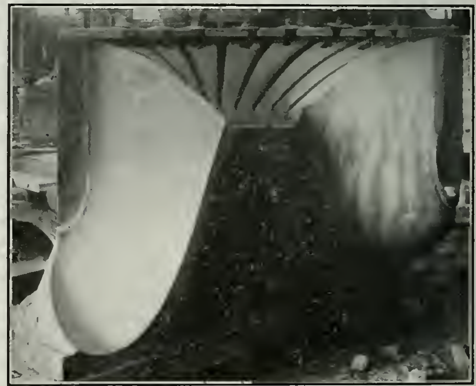

Fig. 8.—Setting Core of Cast Iron Runners for Turbine. Shop View.

The Power House.—The station contains two main turbine units and exciter turbine built by Canadian Allis-Chalmers, Limited. The main turbines are of the low-pressure vertical type set into the concrete spiral casing, described above, the local conditions of the power plant site being most suitable for such a layout. They were

constructed for 6,000 h.p. at 164 r.p.m., operating under 70 ft. head. The additional exciter turbine was built for 150 h.p. at 600 r.p.m.

In order to eliminate distortion of any castings due to the heavy shrinkage stresses in concrete work, the designers applied heavy foundation rings bolted together by means of heavy steel columns, as shown in Fig. 7. These rings were installed during the first stage of the concrete work. After all those parts, together with the concrete around it, had settled properly, the wooden forms were removed and the turbine proper was installed.

The turbines in general consist of a solid speed ring and a guide wheel with bearing. The speed ring holds the bottom and top plates, which are designed to hold the cast steel guide vanes. This guide wheel is of the outside gate rigging type. Each guide vane swivels around a heavy shaft which is cast together with it.

is placed upon a rigid cast iron spider, which is resting upon the upper foundation ring already mentioned. All bearings, as well as the spider, are adjustable.

Fig. 8 is a construction view showing the core for the runners prior to casting.

The generator turbine, as well as the exciter turbine, is regulated by means of oil pressure governors. For the generator turbine the oil system is so laid out that any of the motor-driven oil pumps can feed any of the governors alone or both at the same time. Special attention may be drawn to the fact that the oil pressure tanks are of ample design to store enough energy for both governors for the severest conditions, without having the pump working always to its full capacity. The pump is automatically cut out and put into operation by means of a specially designed unloading valve. A hydraulic hand regulation is placed near each governor actuator,

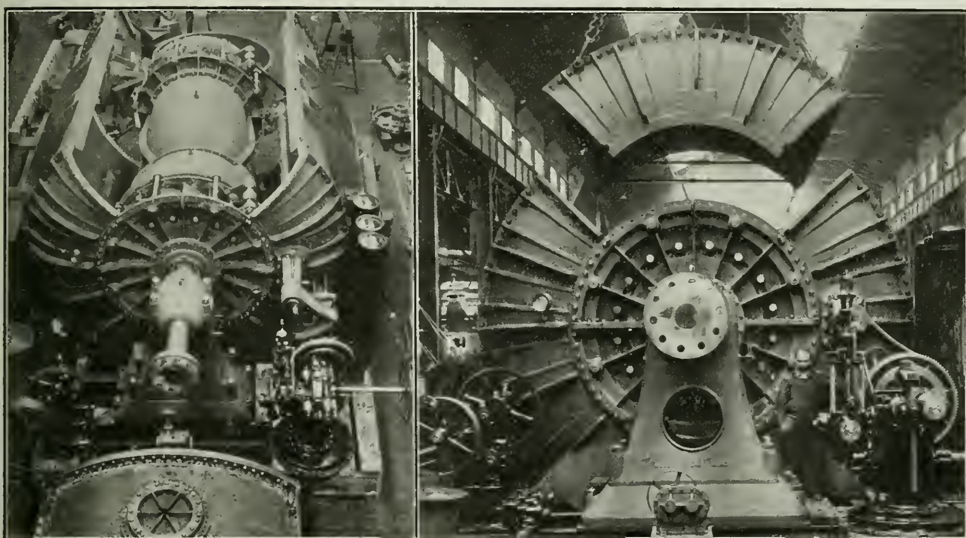

Fig. 9.—Shop Views Showing Construction of Horizontal Turbine for the Horseshoe Falls Extension.

On the upper projecting end a cast steel crank with patented breaking coupling is clamped to the shaft, and the connection to the steel regulating ring is accomplished by means of heavy steel connecting links. All bearings are bronze-bushed and adjustable. The regulating ring is placed around the heavy cast iron frame holding the water-lubricated lignum vitæ bearing for the main turbine shaft. The whole weight of this heavy ring is taken up by a set of steel balls set into oil-lubricated seats and held in place by means of a bronze cage.

The regulating ring, further, is connected to the two oil pressure cylinders by means of the shortest possible connection. These two cylinders are of heavy construction and placed diametrically opposite upon the bearing housing.

The turbine shaft is held in place by two heavily constructed guide bearings, one placed near the turbine runner, and the other immediately under the thrust bearing. This latter bearing is designed for oil lubrication, a small oil pump taking care of proper oil circulation. The thrust bearing is of the pressureless Kingsbury type, and

so as to enable the operator to regulate the machine in case of a shut-down of both oil pumps. All oil pipes for the complete oil system are made of extra heavy brass with bronze flanges.

To the turbines are connected directly two vertical, 12,000-volt, 60-cycle, 4,250-kv.a. generators of Swedish General Electric type. A motor-generator exciter and a turbo-exciter, each of 75 kw., 220 volts, 600 r.p.m., and of the same make, have been installed. The switching equipment was installed by the Canadian Westinghouse Company, and includes a vertical type, remote controlled switchboard of eleven panels, a station and service board, a lighting and a storage battery charging panel. The 12,000-volt bus-bars and electrolytic lightning arresters are situated on a gallery above the switchboard. Above them in turn the five outgoing transmission lines are run through the wall.

The installation of power house equipment was managed by a 50-ton electrically operated crane working over a 40-ft. span. The main floor of the power house has a machine shop at one end.

Capacity.—The new plant generates approximately 12,000 h.p. The station is tied with the 18,000 h.p. plant at Horseshoe Falls by two 3-phase copper-aluminium circuits. At Horseshoe Falls the voltage is stepped up to 55,000 volts for transmission to Calgary.

The Kananaskis development has cost in the neighborhood of $750,000. Mr. H. A. Moore, general manager and chief engineer of the company, has been responsible for its design as well as the entire construction. Mr. H. A. Johnston was resident engineer and had a staff of ten assistant engineers at the site. The superintendent of construction was Mr. A. W. Allen. The installation of the electrical equipment was under the supervision of Mr. E. Barnes, general superintendent.

Horseshoe Falls Plant and Extensions.—In connection with the Kananaskis Falls development, which is now known as No. 2, it is interesting to note the main points of the Horseshoe Falls plant, known as No. 1, and to mention the extensions which the Calgary Power Company has made to it. The plant consists of a dam, intake, power house, etc., all of permanent construction. The head developed is 70 ft., part of which is due to the actual fall and part to the slope of the river.

The dam is of solid concrete construction of the spillway type, measuring 140 ft. in length on the crest. Apart from the spillway, it is provided with four stop-log openings and four sluiceways controlled by Stoney sluice gates, making ample provision for discharging any flood liable to occur. In its construction the same precautions were observed to prevent leakage as have been mentioned in connection with the later development and, whatever leakage there may be is taken care of by a drainage tunnel. The intake, provided with racks and ice-clearing devices, supplies the water to four penstocks, two of which are 12 ft. in diameter and the other two 9½ ft. in diameter. The power station was designed for four units and two exciter units. At first only two units were installed, a 3,750 wh. h.p. Then, upon the storage development at Lake Minnewanka, the third unit was installed. The fourth has recently been under construction, a new 6,000 h.p. Wellman-Seaver-Morgan horizontal turbine, controlled by a Lombard governor, having been installed in connection with a 4,500 kv.a. Canadian General Electric generator, direct connected. For this increased capacity two 3,000-kw., 3-phase transformers have been placed in operation by the Canadian Westinghouse Company, together with the necessary switching apparatus. This installation has brought the Horseshoe Falls plant up to a capacity of 18,000 h.p. This, according to the 1912 report of M. C. Hendry, chief engineer, Water Power Branch, Department of the Interior, cannot be considered as continuous output owing to the wide variation of flow mentioned above. From the records available it is believed, however, that the storage at Lake Minnewanka can be very materially added to by the creation of additional storage at other points in the basin. The chief users of power from the Calgary Power Company are the city of Calgary and the Canada Cement Company, at Exshaw. The city has been, of course, the largest consumer but the extreme fluctuations in the Bow River flow, which preclude the continuous operation of the plants to their full capacity during a portion of the year, have prevented the company from guaranteeing continuous power throughout the entire year to the many users requiring it. The completion of the Kananaskis development, however, in addition to the other storages, will enable the company, it is believed, to give a guarantee of a continuous output sufficient to meet the needs of its customers.

COST OF HAULING WITH TRACTOR OUTFITS.

The following data from the Fourth Report of the Illinois Highway Commission on the cost of hauling road construction material should be of interest to contractors engaged in this class of work:—

Data on Cost of Hauling with Tractor Outfit at Hinsboro, Ill. Average Length of Haul, Three Miles.

Number of cubic yards of stone hauled by engine	2,590
Number of cubic yards of stone hauled by team	3,980
Number of days outfit was on job	120
Number of days outfit hauled (fractions counted as full)	40

Costs.

Cost to Illinois Highway Commission of engine operator (salary and expenses, straight time)	$340.00
Cost of fireman (actual time worked)	66.20
Coal, oil and supplies for outfit	181.81
Cost of maintenance of hauling outfit (one-half season)	53.00
Total	$641.01
Total cost per cubic yard for hauling	$0.247
Total cost per cubic yard to township for hauling	.096
Total cost per cubic yard to state for hauling	.151
Actual cost per cubic yard for team hauling (on same work and same length haul)	.560
Cost of hauling by engine per cubic yard mile	.082
Cost of hauling by team per cubic yard mile	.186

Detailed Costs of Engine Hauling per Cubic Yard Mile.

Operator	$0.043
Fireman	.008
Coal, oil, etc.	.024
Maintenance	.007
Total	$0.082

Data on Cost Hauling with Tractor Outfit at Mattoon, Ill. Average Length of Haul, One Mile.

Number of cubic yards hauled by engine	674
Number of cubic yards hauled by teams	2,170
Number of days outfit was on the job	22
Number of days outfit hauled (fractions counted as full)	13½

Costs.

Cost to Illinois Highway Commission for engine operator (salary and expenses, straight time)	$ 66.00
Cost of fireman (actual days worked)	27.00
Coal, oil and supplies	51.00
Maintenance of outfit	26.00
Total	$170.00
Total cost per cubic yard for hauling	$0.258
Cost per cubic yard to township for hauling	.115
Cost per cubic yard to State for hauling	.143
(Actual cost of team hauling on same work and same haul)	.435
Cost of hauling by engine per cubic yard mile	.258
Cost of hauling by teams per cubic yard mile	.435

Detailed Costs of Engine Hauling per Cubic Yard Mile.

Operator	$0.098
Fireman	.042
Coal, oil, etc.	.077
Maintenance	.041
Total	$0.258

GROUTING AND PENETRATING METHODS OF ROAD SURFACES.*

By George Green, M.Inst.C.E.,
Borough Engineer, Wolverhampton, Eng.

THE ideal road would be one suitable for general traffic, which could be made in a satisfactory manner at less expense than an ordinary tar-macadam road, at a quicker rate, and independently of weather conditions, and which would last longer than a tar-sprayed water-bound road. Such a road would be within the more limited means of local authorities who are not blessed with too much money to spend annually upon their roads.

While the author does not pretend that he has found the long-looked-for means of satisfying all these requirements, he desires to draw attention to some results which indicate how partial satisfaction may be obtained; but he more particularly hopes to be able to obtain additional information and experience on this subject which will be of advantage to those who have the somewhat thankless duty of making roads for the public with a too limited supply of funds.

It would not be out of place, and it might be helpful in considering this subject, to note a few points which the road maker is bound to consider, and which sometimes the road users and the public at large do not thoroughly appreciate.

Provision must be made to keep road surfaces, where the gradients are exceptionally steep, with sufficient foothold for horses, and in frosty and muddy weather when the surfaces are greasy, an adequate supply of grit must be at hand. At the same time, these surfaces should be kept waterproof and as free from mud and dust as possible on account of the ever-increasing motor traffic. If motor traffic was all of one kind, a well tarred, sprayed macadam would meet the case in many areas and for many miles of roads; but this traffic again is divided into various classes—e.g., heavy motors, light motors, vehicles driven by steam with broad rough tyres and heavy loads.

These various kinds of traffic require special and often expensive treatment to keep our roads in a satisfactory condition.

This paper does not deal with main roads or county roads, but more particularly with secondary roads in towns and suburbs, which, at the same time, have considerable traffic, and occasionally are liable to have to carry all sorts and conditions of vehicles and tractors.

From a maintenance point of view it has been found that one of the most difficult roads to keep in good condition is the level road, which, on account of its want of proper longitudinal fall, particularly in wet weather, absorbs a large amount of moisture. Even a waterproofed road is more or less liable, partly owing to its position, to retain moisture in its foundations or in the subsoil if the district around is of a low-lying, insufficiently drained character.

A road that has a good gradient is generally self-cleansing with every shower of rain, and has a chance of a much longer life, in addition to being more easily kept clean and in a satisfactory condition. The margins of roads where tram lines are in the centre will not be dealt with. These have caused enough anxiety, and will continue to do so, to their surveyors as long as tram lines exist, and must always require more or less special treatment. Another reason for calling particular attention to the grouting and penetrating methods is the great difficulty, which it is believed is not uncommon, experienced in obtaining the necessary supplies of tarred road materials of various kinds in the quantity and at the times when they are most urgently needed.

One frequently has the misfortune to have a long and important road undergoing reconstruction, and to be hampered and harassed with the difficulty of obtaining a sufficient quantity of these materials to continue and complete the work in anything like a reasonable time.

All these difficulties make it desirable and necessary for road makers to have more than one string to their bows, and to be able to turn to fresh sources of supply and to use various materials and methods when emergencies of this nature occur, in order to complete their road making and repairs in a reasonable time with as little inconvenience to the public as possible.

Two points that road engineers have to deal with must be emphasized: Road surfaces must not only be able to stand the suction which is the result of rapid motor traffic, with indiarubber tires, which removes the dust, grit, sand, mud and water out of the water-bound roads, and sooner or later the small and then the larger stones themselves as they become loosened by disintegration, but consideration must be given to the provision of surfaces which will withstand the vibration from heavy vehicles—horse-drawn, steam-driven, and otherwise—which, with the continual hammering of the horses' hoofs and the solid iron tires, often shake the crust of the road and also its foundations.

It is obvious that a tar-sprayed road cannot last long under all these conditions. If the traffic were uniform, the problem would be simpler, and less expensive methods might be more easily adopted. All these points have to be considered in the construction or reconstruction of any road, and, as a rule, a road crust has to be constructed on such foundations as will be able to withstand all these conditions in a thoroughly satisfactory manner.

So far, difficulties common to all road engineers have been dealt with, among which that of an adequate supply of materials is by no means the least at the present time.

It no doubt arises largely from the fact that tarred materials of one sort or another have been recognized as one of the chief and best methods of road making, and road authorities—county, urban and rural—are all, without exception, making great efforts to meet the road problem of the day, and partly also on account of the fact that tarred materials can best be laid in dry weather, as most of these new surfaces and reconstruction of roads are done in the few months in the summer which can be relied upon as most suitable for this purpose.

If anyone can discover a material which can be used as satisfactorily in wet weather as in fine, or in winter as easily as in summer, no difficulty would be found in obtaining a ready sale for it.

It seems almost superfluous to reiterate here the great advantage of tar-spraying on well-constructed macadam roads. Most engineers have found that this is of immense advantage not only in the prevention of dust and mud in main roads subject to heavy and rapid traffic, but also that it adds considerably to the life of those roads, and is a distinct advantage from a health point of view in second-rate residential roads made of macadam in which many of the poor in our towns have to live. These streets often swarm with children who use them

*Paper read at the annual meeting of the Institution of Municipal and County Engineers at Cheltenham.

as their playgrounds. The sanitary advantage of tar-spraying in these roads can hardly be over-estimated.

Leaving the difficulties of the situation generally, stress must be laid on the great importance of having proper foundations and good drainage to all roads which are to be treated with waterproof surfaces and have to bear heavy traffic. Many roads which have for years been subject to heavy traffic have been found to consist almost entirely of a number of coats of macadam laid one upon the top of the other, the whole mass resting on a clay underbed without foundation or drainage of any kind. It is impossible for roads constructed on such lines to last, and in such cases the old macadam has invariably had to be removed, and below that, to the required depth, the surplus soil excavated and removed, and in its place a foundation of 6-in. or 8-in. slag pitchers laid upon a properly formed and well-rolled bed consisting of several inches of rough, hard clinker. The advantage of this layer of clinker is to prevent the clay or underbed working through the pitchers towards the surface, and consequently causing the foundation to give way and become uneven. This usually forms an excellent drainage, and remains of lasting benefit to the newly constructed road. Upon this foundation several types of grouting or penetrating methods have been tried, the first which naturally suggested itself being that of ordinary tar. The first trial of this kind was made some five or six years ago on a road which had a natural and sufficient gradient longitudinally; there were tram lines in the centre, the whole surface on either side of the tram lines was scarified and regulated, and after that coated one stone thick with cold blast-furnace slag, carefully and sufficiently rolled in dry. After this a mixture of 40 gallons of gas-tar (not distilled), 6 cwts. of pitch and 4½ gallons of creosote oil, as the constituent parts of the grout, was poured on the surface through cans and rubbed in with squeegees; the surface was then coated with a thin layer of slag chippings and gently rolled in with a 10-ton roller, after which a second and thinner coat of the tar mixture was spread over the surface and another layer of finer grit to spread upon the top. This road surface, which is subject to a fair amount of traffic of various kinds, has lasted up to the present time with hardly any repairs except for trenches and occasional small repairs.

This class of road, provided it is constructed in dry, suitable weather, answers a very useful purpose, and, of course, is more lasting than tar-spraying and very little more costly than ordinary water-bound macadam, provided the same road material is used. Of course, a road of this kind could only be made in suitable weather, and should a period of wet weather follow the commencement of the work, completion might be delayed for a considerable time.

Experiments have been made on a similar form of road, with other forms of binding material, with varying success; in some places the earlier work has stood for a number of years, and has a very satisfactory surface, in others there have been less satisfactory results owing to the heavier nature of traffic and to a level surface. A year ago a more elaborate experiment was made with this material. The road in this case was laid in two coats; the first coat was treated similarly to the one made of slag referred to above, and after it had been thoroughly grouted and rolled in, a second coat, one stone thick, of basalt was laid upon the top, and the process repeated with the binder and chippings until the final surface was finished.

This was only done a year ago, and the length of its life cannot be estimated. The carriageway is narrow, the surface is a level one, with hardly any gradient, and the traffic of a heavy nature, mostly with iron tires, such as railway drays and vehicles of that kind. The surface today is almost as good as when it was laid down, but time alone can say how long it will last. Ordinary water-bound macadam in this road only lasts a year.

Roads grouted with Rocmac and with Glutrin have also been laid in an experimental manner, also with various results, but the latter experiments, made about twelve months ago, when the materials in both cases were mixed on boards in the form of concrete, have been much more satisfactory, and promise to make a more lasting surface, and one which affords at the same time a most excellent foothold for horses. The great advantage of these two materials is that they may be laid in wet weather even better than in fine weather, and consequently the work is not interrupted for any outside causes, as is the case with tar roads sometimes.

Beyond the fact that Rocmac and Glutrin grouted roads can be constructed in winter, they afford a much better foothold for horses. A coat of tar dressing in the summer will prevent them being dusty, and add to the length of life generally.

There may be other forms of grouted roads equally good and useful, but there is still room for further progress in this direction, and the inventor, if the method be not an expensive one, might easily make a fortune. Most engineers would be glad to have a longer period, extending through the winter, in which to continue their road work, especially as sometimes it is difficult to find sufficient employment for all their good and useful men during the winter months when work is most needed.

On July 16, in London, England, the foundation stone of the new offices of the Agent-General for the Province of British Columbia, was laid by Prince Arthur of Connaught. The building is being constructed as a further means of stimulating the general development of the province.

Chas. T. Schoen, formerly of Pittsburg, Pa., the pressed steel car inventor and manufacturer, announced recently that he is planning to establish a plant for the manufacture of pressed steel cars at Leeds, England. As yet no decision has been reached as to when the plant will be established, nor what will be the name of the projected company. But Mr. Schoen has been in communication with Betts Machine Company, of Wilmington, Del., regarding equipment for the proposed British works.

The Vancouver syndicate which purchased the Monarch Collieries at Taber, Alta., about a year ago, has decided to install a complete new plant, costing in the neighborhood of $50,000; and it is expected that the company will be ready to recommence operation in the near future. The new superintendent of the mine will be Ralph Smith, ex-Liberal member of the Dominion Parliament for Nanaimo. The company has also completed arrangements to have the spur track extended to its property from the present terminal near the Rock Springs Coal Co.'s mine.

On July 14, at Washington, in a letter from Secretary Garrison to the House Foreign Affairs Committee, it was advocated to remove the restrictions upon the importation of electric power from Canada and to retain the present limit of 15,600 cubic feet per second upon the amount of water diverted for power purposes from the Niagara River, above the falls on the American side. With the letter Mr. Garrison sent a report by Brigadier General Kingman, chief of the army engineers, declaring that the enormous commerce of the lakes probably soon would demand a ship canal between Lakes Erie and Ontario on American soil. As to the situation below the falls, Secretary Garrison said there seemed to be no reason for an express limitation upon water diverted there. He endorsed in a general way the Smith and Cline bill which, he said, "closely approached the legislation needed for the protection of Niagara River, and for the best and most economic use of its water for power development not inconsistent with navigation interests."

SPECIFICATIONS RELATING TO COMPRESSED AIR IN TUNNEL WORK.

THE construction of additional subway tunnels under the East River, New York, has required the preparation of specifications covering the new contracts. These are very comprehensive and specific and embody details of requirement suggested by the latest experiences in similar work. The requirements relating to the use of compressed air and the safety of the workers under pressure are much extended, and embody important requirements beyond those found in existing laws. These, it is understood, were specially prepared by Mr. Frederick C. Noble, division engineer, and appeared in a recent issue of the Compressed Air Magazine.

There are nearly two miles of double lines of single track tunnel excavation under compressed air, most of it shield work with cast iron lining. A large portion of the work is in sand at a maximum depth of 90 ft. below mean high water.

The first requirements are as to the sufficiency and the reliability of the mechanical equipment. The contractor must install air compression, hydraulic and electrical machinery, hoists, pumps and all other necessary apparatus of the highest grade in use for the work to be performed and having a capacity sufficient to meet not only unusual conditions but emergencies, and to afford a margin for repairs at all times. Provision must be made for storing in tanks at the boiler house enough feed water for twelve hours' supply, unless connections can be made with two independent and separately sufficient sources of supply. If electricity is used for operating compressors supplying air to the tunnel headings, the supply cables shall be in separate lines and shall each connect, if possible, with two independent and separately sufficient sources of current.

The compressors shall be capable of furnishing simultaneously to each heading an air supply sufficient in volume and pressure to enable work to be done as nearly as possible in the dry, and to afford the specified degree of ventilation. At each heading where the shield is used the air supply pressure of 45 lb. per square inch above atmospheric pressure must equal at least 10,000 cu. ft. of free air per minute as measured by piston displacement, unless both tunnels are operated from the same compressor plant, when this air supply may be reduced to 8,000 cu. ft. of free air per minute. The plant, in addition, must be capable of furnishing to all parts of the work a sufficient air supply at a pressure of 100 lb. or more if required for operating drills, grouting machinery and other pneumatic tools. The air for the compressors shall be drawn from pure outside sources and protected from fouling by lubricating oil.

The compressor revolutions shall be registered by mechanical counters, and the pressure in the air receiver shall be continuously registered. Cooling apparatus shall be provided to maintain the temperature of the air in the tunnels and caissons always at a moderate degree. All buildings for the compressor plant and in the immediate vicinity shall be as nearly as practicable fireproof and all reasonable precautions shall be taken to prevent and extinguish fires. A water line shall be extended into each heading, 200 ft. of hose, and nozzle connections shall be maintained ready for constant use at each bulkhead and no lighted candles or matches will be allowed near roof timbering in compressed air.

Medical and Sanitary Rules.—The workmen's quarters shall be well lighted, heated and adequately provided with running hot and cold water, showers, lockers and facilities for resting, for drying clothing, and for providing hot coffee. Care should be taken to keep all parts of the tunnel in a thoroughly sanitary condition and free from refuse or decaying matter. There shall always be on duty a competent physician and surgeon experienced in the treatment of the physiological effects of compressed air, and he shall care for the health of the employees and supply treatment and medicines to them whenever needed.

There shall be maintained in close proximity to the shaft at each side of the river a completely equipped hospital room with an attendant constantly in charge. Each hospital room shall include in its equipment a commodious hospital lock in two compartments, where men can be subjected to the regular working pressure if attacked by caisson disease. Such locks shall contain cots, a telephone, air gauge, and arrangements for ventilating and heating. Provision shall be made for the immediate removal and hospital treatment of any employee who may be injured or become ill. No person shall be employed in compressed air until after passing a satisfactory medical examination, and any employee absent for ten or more successive days shall be re-examined before being permitted to resume work in compressed air.

All reasonable facilities shall be afforded for the investigation of the physiological effect of compressed air, including the conduct of experiments and the collection of records in connection therewith, to be undertaken by such scientific bodies of individuals as may be designated for the purpose by the commission.

Air Chambers.—Air chambers shall be formed in the tunnels by brick, concrete or steel plate bulkheads of sufficient strength to safely resist a pressure of 15 lb. per square inch. Whenever the air pressure in the heading exceeds 22 lb. per square inch above atmospheric pressure, two air chambers shall always be in use, except when headings are being started from shafts, and the pressure in the outer one shall not exceed one-half the pressure in the heading. The distance from the heading to the nearest bulkhead shall not exceed 800 ft. during the progress of the work.

Three metal airlocks are to be firmly set and anchored in each bulkhead. These shall consist of two main locks not less than 6 ft. in diameter, heated and ventilated if required, and an emergency lock not less than 5 ft. in diameter, which shall be located as high up from the bulkhead as practicable and shall be large enough to hold an entire heading shift. When not occupied, the emergency lock shall be kept open toward the heading and ready for instant use at all times. Lock doors must operate easily. A heavy glass bull's-eye must be set in each end of each lock.

Air valves must be arranged to be controlled from inside the lock. One of the main locks shall be connected to the main air line so that it may be locked from outside. Each lock shall be provided with an air gauge and a clock. An 8½-in. air gauge shall be placed in an accessible position on the outer side of each bulkhead. A recording air gauge shall be placed on each main and shall be locked and the key kept by the engineer. A lock tender shall be on duty at all times at each lock bulkhead. A watchman shall be on duty at all times in the heading and when for any reason the work is suspended.

Safety Screen.—In each heading chamber, when the same extends beyond the river bulkhead line, there shall be provided a safety screen extending from the springing line of the tube to the track. It shall be made of substantially braced steel plates with airtight joints. It shall

be moved forward as the work progresses so as never to be more than 115 ft. in the rear of the shield. In each heading chamber, when the same extends beyond the bulkhead line, the contractor shall provide about the middle of the height of the tunnel a substantial runway, at least 3 ft. wide, leading from the shield platform to a platform at the emergency lock. The runway shall be provided with a handrail and steps or ladders at frequent intervals for access from the track level. A telephone connection shall be maintained in service from each heading and each lock to the power house and to the office of the commission's engineer corps near the shaft.

The air supply through the shaft and tunnel in each heading shall be through two pipes, each at least 10 in. in diameter, with sufficient capacity to prevent excessive drop in pressure in regular working. Each supply pipe shall be provided with a pressure-regulating valve in each air chamber and with suitable valves arranged for by-passing at a convenient point between the power house and the shaft. Special devices shall be used to deaden the noise of air supplied or exhausted.

The supply of fresh air shall be sufficient to permit work without danger or discomfort, and where work is in compressed air such supply shall be sufficient at all times and places to prevent the accumulation of carbon dioxide to a greater amount than one part in one thousand by volume. A foul-air vent pipe 6 in. in diameter shall be carried back from each heading under pressure to the ordinary atmosphere and shall be provided with a suitable regulating valve so placed as not to be readily tampered with. The compressors must be so run as to maintain at all times a change of air through the regulating valves. Special means must be provided for the rapid removal of blasting fumes.

PRIZES FOR HIGHWAY STUDY.

Awards have been made in the competition announced several months ago by the Barber Asphalt Paving Company, for papers from engineering students on the subject of asphaltic materials for highway construction. The judges of the competition, E. J. Mehren, Editor of "Engineering Record," and H. P. Gillette, Editor of "Engineering and Contracting," have made awards of prizes of $100 each to the following contestants:—

Name of Student.	College.
Frederic O. X. McLoughlin	Columbia University, New York City.
Harry Schindler	Cornell University, Brooklyn, N.Y.
B. J. Fletcher	University of Georgia, Parrott, Ga.
John W. Hill	University of Illinois, Chicago, Ill.
Robert S. Johnson	Iowa State College, Ireton, Iowa.
M. V. Holmes	University of Kansas, Kansas City, Kansas.
F. P. Gilbert	Massachusetts "Tech," Beverley, Mass.
Harold J. LaLonde	University of Michigan, Sault Ste. Marie, Mich.
Benjamin Wilk	University of Minnesota, Virginia, Minn.
Alvin C. Smith	University of Nebraska, Lyons, Neb.
O. H. Gosswein	Purdue University, St. Louis, Mo.
Alfred A. Berkowitz	Scheffield Scientific School, New Britain, Conn.
W. J. Campbell	Syracuse University, Cohoes, N.Y.

The purpose of the competition was to turn the attention of engineering students to street and road construction as a promising field of work. The company offering the prizes believes that the plan was successful in this direction.

The Mobile and Ohio Railway Company is preparing to erect a bridge across the Ohio river at Cairo at a cost of $5,000,000.

MODERN CONCRETE WORK WITHOUT FORMS.*

By James E. Payne, Assoc.M.Am.Soc.C.E.

THE art of building concrete roofs, walls and floors without forms and with fewer shores and temporary supports than has been customary is still in its infancy. In the past few years there have been a large number of roofs and floors built using for forms and reinforcement some one of the many types of ribbed metals now on the market. As the cost of wood for form work is steadily increasing and the cost of steel is decreasing, we may look for rapid developments along this line.

These ribbed metals can be divided into two general classes, those that are expanded between the ribs and those that are merely stamped, cut or bent. The expanded ribbed metal sheets which we will consider first are made in widths of from 10½ to 28 inches and in lengths up to 12 feet. The ribs are spaced from about 3 to 7 inches apart and are from ¾-inch to 1½-inch in depth. The metal used is what is known to the sheet mills as soft open heart steel and has an elastic limit before working of 30,000 to 40,000 pounds per square inch.

As these ribbed expanded metals not only act as reinforcement, but take the place of the wood forms, in a cost comparison to determine which is cheaper, ribbed expanded metal or wood forms and wire mesh, the increasing cost of lumber is a big factor. This point, coupled with a stationary or falling steel market, is one reason why ribbed expanded metal slabs have grown so popular the last few years.

Another reason is the time saved in the erection and as wood forms are not needed, several floors can be placed and poured at the same time which is usually a costly method when a complete set of wood forms are used for each of several floors.

The saving in cost by using ribbed expanded metals for roof work is still greater than for floors as the complete cost of the wood framework for a roof frequently has to be charged up to the roof alone and it cannot be distributed over several floors. Roofs are built by laying these sheets on top of the purlins, lapping about 2 inches over the supports. The sheets are held down by clips fastened over every third or fourth rib and the side ribs of the sheets are fitted one over the other and punched together, making the roof a monolithic slab. Some of these sheets are stiff enough to carry 2 inches of concrete without any vibration for spans up to 4 feet, but with spans above that, one and sometimes two temporary supports are needed. These temporary supports are built by hanging a 2 x 6 or 8 across the under side of the purlins held up by wire slings wrapped around the purlins, or wedged up on the lower flange where I-beams are used. These cross pieces held up one or two planks on edge which stiffen the metal while the concrete is being poured and while it sets. This is essentially a short span light load system and 14 feet is the maximum span, with the most economical span between 6 and 8 feet. For a span of 7 feet, No. 24 or No. 26 gauge sheets with 2 inches of concrete on top with ½-inch of cement between 15 and 20 cents per square foot, exclusive of structural steel and waterproofing. As floors are usually thicker than roofs, the cost increases proportionally.

The concrete is specified to be made of a 1:2:4 mix with stone or gravel to pass a ½-inch ring with the dust

*Abstract of a paper read before the 10th annual meeting of the American Concrete Institute.

screened out, but is usually made according to the accepted standards for concrete work in that locality. When the concrete has set enough to carry itself the wires are cut and the supports dropped, leaving the under surface of the slab ready for plaster. These temporary supports seldom cost more than 1 cent per square foot, including lumber-placing and removing. The plaster used is a cement plaster mixed about 1 to 2½ with a small amount of hair and only enough lime (not more than 5 per cent. of the volume of cement and sand) to make the cement work easily under the plasterer's trowel. For factory buildings this finish is sometimes floated, but for offices, hospitals, hotels, etc., the white coat is frequently added. The trouble of making the plaster stick to a reinforced concrete slab, usually experienced, cannot occur with ribbed expanded metals because the concrete projects through the mesh to some extent and that with the mesh formation makes an excellent key for the plaster.

Usually the first question asked by a stranger to this material is, "How do you keep the concrete from running through?" This is a natural question considering the care taken to make wood forms water-tight, but the concrete used with open mesh ribbed expanded metal is dryer than that used with wood forms. The mix is sometimes known as a quaking mixture and when dumped from a barrow tends to stay where dumped and is spread with a shovel or hoe. The material that drips through the mesh is principally water and contains very little cement. In a factory building erected this summer in Youngstown, 290 feet long, the contractors sprinkled sand on the finished cement floor below the roof, and as the roof was poured a man below shoveled up the sand and carted it out. The drip from the roof was not enough to set up the sand. It seems as if the mesh curls the mortar around itself something like the way metal lath does with plaster. In a test conducted recently to determine the amount of loss through dripping it was shown that the loss amounts to from 36 ozs. to 80 ozs. from an area of 3½ sq. ft. In percentage, this ranges from 2.6 to 4.3 per cent. loss, depending on the style of mesh between the ribs.

One of the most important advantages of using these steel sheets for combined forms and reinforcing, is that there is no waiting for the removal of forms from one floor to start the construction of another, and the delay in pouring concrete, occasioned by the time taken to place and wire the reinforcement, is saved entirely, as the concrete is poured as soon as the expanded metal forms are in place.

In the Youngstown City Hall having 6 floors—an attic and roof—all the sheets were placed and floors poured in 30 days, an average of less than 4 days to a floor. This is an important matter on penalty jobs, and also in the fall, in order to get the roof on before the snow flies. Scarcely a month goes by without the newspapers reporting a failure in reinforced concrete somewhere in this country and in practically all of these cases, the too early removal of forms is a contributing cause, if not the sole reason for the collapse. This great danger is eliminated by using materials that combine the two functions of forms and reinforcement. Another use for ribbed expanded metal is in the construction of inclined slabs. They have been built having an angle of as much as 60 per cent. from the horizontal. Formerly to build a slab like that, it was necessary to have forms on both sides. By using a dry mix and running the ribs in a horizontal direction each rib acts as a baffle to prevent the concrete from sliding down the slope. The roof over the new hotel of the Union Stock Yards and Transit Co., in Chicago, is an example of this kind.

It sometimes happens that ribbed expanded metals are used for forms only—and no attention is paid to the reinforcing value. In the roof over the Washington Theatre in Detroit, the cost of erecting and removing wood forms would have been very high as the roof was 50 or 60 feet above the pit. Ribbed expanded metal was used on top of the purlins and rod reinforcement placed above the metal. The concrete was poured and the under surface left unplastered. To plaster the underside of that roof, scaffolds would have been hung from the roof beams or built up from below at the time the roof was poured or shortly afterward. The cost of the additional reinforcement of rods was much less than the cost of the other alternative which necessitated the scaffold remaining in place several weeks or possibly months waiting for the building to reach a condition which would permit the use of the scaffold by the ornamental plasterer.

For large areas the objection has sometimes been made that these materials could not be used in connection with the gravity system of distributing concrete, because of the large amount of water needed to properly work the gravity system, and consequently the large loss through the expanded section of the mesh. For example, a roof 100 feet square needs theoretically 61.7 yards of concrete for a roof 2 inches thick. With 5 per cent. loss through the mesh, we would lose 3 yards of concrete, which at $6.50 per yard amounts to $19.50. Probably a fair average of saving secured by using the gravity system over wheelbarrows and dumpboards is 75 cents per yard, or a saving in this roof of $46. These figures show the falsity of the idea entertained by some engineers that the gravity system must be discarded if ribbed expanded metals are used as forms.

The above remarks have referred entirely to flat sheets, but the use of curved sheets is almost as large. It frequently happens that a curved or arched floor is wanted, but heretofore it has been almost prohibitive because of the excessive cost of labor in making arched or semi-circular forms. By arching these sheets and resting the ends on the lower flanges of the steel beam or on the wood sides, or bottom of the beam box, the sheets take the place of curved forms and also stiffen the concrete in the arch. These arched floors are quite popular in breweries and also other warehouses where heavy loads are liable to be applied. They are also well fitted for highway bridges.

In the Buhl Country Club at Sharon, Pa., the beams were 8 feet 8 inches apart and 24 gauge curved sheets were placed resting on the lower flanges of the I-beams. The rise of the arch was 16 inches and the concrete was poured with no temporary supports. This system is well fitted for cases where the under surface is difficult of access, as the concrete arch carries the load, the steel sheets acting only as permanent forms, and also for cases where heavy loads will be carried.

Cement non-bearing partitions are erected more cheaply by plastering cement mortar on ribbed expanded metal than by a double wall of wood forms with poured concrete between. The time lost in waiting between the time of removal of the wood forms in one place and their erection in another is saved completely as the sheets are ready to be plastered as soon as erected. Almost all competing fireproof partitions are at least 4 inches thick when finished, some as much as 6 inches. Solid plastered partitions are only 2 inches thick, which means that every lineal yard of partition erected adds a square foot to the floor space. When made of cement, these 2-inch solid partitions are as fireproof, if not more so, than any other partition in common use.

In Cleveland, at the laboratories of the Associated Metal Lath Manufacturers, a 2-inch solid partition 7 feet wide by 9 feet high was built plastered on ribbed expanded metal. On November 20, 1912, it was tested, the fire burning for two hours with a temperature averaging 1,849 degrees after the first half hour. While the partition showed some deflection toward the fire, and a number of cracks on the side away from the fire, no smoke came through and when the panel was swung open, there were but two small cracks on the side exposed to the fire. Water at Cleveland city pressure was then turned on for 2½ minutes, and while sections of plaster were washed off on the fire side, the water did not go through the partition, and it was evident that a new coat of plaster was the only thing needed to render it as fire proof as ever.

Twenty-eight gauge sheets and 2 inches of solid cement plaster has proven entirely satisfactory for interior partitions up to 12 feet high and 26-gauge sheets and 2½-inch of concrete for partitions up to 17 feet. The sheets are fastened to the floor and ceiling with a runner bar or angle which has been previously placed and lined up, the sheets being wired or clamped to the angle. 2 x 4 temporary stiffeners are wired to one side of the sheets about 4 feet apart, and are then braced back to the floor. When the opposite side is scratched in, the supports are removed and that side of the partition is plastered. The baseboard chair rail and picture mold are nailed into small blocks which are wired to the steel between the ribs at intervals and used to hold the grounds.

Some of these metals are made in such a way so that a ¾-inch electric conduit fits in between the ribs and is imbedded in the plaster. The metal is cut away as much as necessary to allow the outlet box to be placed. The average cost is between $1.25 and $1.75 per square yard complete in the populous sections of the country and we find this coat is usually less than the cost of burned clay tile partitions.

Probably the least expensive silo of all the fireproof silos now on the market can be constructed of ribbed expanded metals plastered with cement. The sheets are curved at the factory and temporarily held in place by wood uprights on one side which are removed as soon as the scratch coat hardens. By punching the ends of the ribs together so that the joint is as strong as the rib, and lapping the ends enough to develop the full strength of the mesh, the steel sheets have sufficient sectional area to resist the bursting pressure developed by the ensilage. This same method is used for small water tanks, but for larger tanks, it has been found that a better job is secured by building two walls of curved ribbed expanded metal, and pouring between with concrete. In this way, enough additional reinforcing can be introduced to take up the stress over and above those taken care of by the ribbed metal.

Floor and roof slabs are designed according to accepted engineering practice, except that they are usually considered to be simply supported at the ends and are not reinforced against negative bending stresses over the supports. A test was made on October 26, 1912, under the control of the Cleveland Building Department, on two spans of six feet each. This test was expected to prove that the accepted methods of design could be applied to slabs reinforced with sheet metal of certain patterns. Slab No. 1 was 2 inches thick and designed to carry a working load of 126 pounds. When loaded to 2½ times that, or 329 pounds per square foot, the deflection was .16 of an inch, which increased to .20, 24 hours later. Slab No. 2 was 2½ inches thick and designed for a working load of 156 pounds. Its deflection at 2½ times that was .16 of an inch, and .20, 24 hours later.

In a sheet of No. 24 gauge expanded ribbed metal, the surface of steel in contact with the concrete is about five times the surface of a round bar of equal cross-sectional area. In ordinary bar and slab construction where the bond stress on the bars seldom equal 125 pounds per square inch, the bond stress in the ribbed metal would be only 25 pounds per square inch of surface. This low bond stress is taken advantage of, by shipping painted sheets instead of plain, which prevents incidental rust during transportation. The expanded section of the street is also gripped by the concrete so practically all sides of the metal in the mesh is covered and this will reduce the bond stress still lower than 25 pounds per square inch. Numerous attempts have been made to increase the efficiency of those different metals by the spacing and height of the ribs and also changing the type of mesh between the ribs. It will readily be seen that to increase the depth of the ribs is to stiffen the sheet so the temporary supports can be spaced further apart, but when the ribs are made deeper, the centre of gravity of the steel is raised, requiring an increased thickness of the concrete slab, and the saving in the cost of temporary supports is more than offset by the additional concrete required. In conclusion, it appears that the high quality of this type of construction, with its low cost coupled with the fact that the features of design are so simple and sure, would warrant the careful consideration of all engineers and architects.

Indications seem to be that the Alberta Clay Products Company of Medicine Hat, will manufacture its brick, tile, sewer pipe, and other clay products in Saskatchewan as soon as natural gas has been found and can be the means of furnishing cheap power. This company secured the material for the manufacture of its products in Saskatchewan, though its plant is now located at Medicine Hat, where the natural gas affords cheap power for its operation.

On July 8, the new docks at Hull, England, were opened by King George. These have been constructed by the North-Eastern, Hull, and Barnsley Railway companies of Hull. This port was already third largest in the United Kingdom, and now has 11 docks with a water area of 211 acres. The quays have a length of 8,162 feet. There are 154 cranes, with a maximum lifting capacity of 100 tons, 34 coaling appliances, with a total rate of shipment of 9,980 tons an hour, and 57 warehouses having a combined storage capacity of 211,150 tons.

A report from Adelaide, South Australia, gives the following account of railway construction upon that island. Tenders for the construction of the railway from Karoonda to Peebinga were received by the South Australian government a short time ago. This is the last of the four new lines which were initiated by the government for the purpose of serving the River Murray lands in South Australia. The only other one not finished in this country is that to Wailerie, an irrigation settlement on the river, but that line is nearly completed and will be opened for traffic shortly. The two lines already working are those from Brown's Well to Parings, near the Renmark irrigation settlement, and the Railway from Alawoona to Loxton. The length of the line for which tenders have now been received will be 69 miles, and its estimated cost is $263,000. The area which will be served by the four railways when completed totals 3,113,000 acres, and the lines have been planned so that no settler in this large stretch of country will be outside a convenient distance from a railway. Good progress is also being made with the new railways authorized by Parliament to be built on Eyre's peninsula which should result in the successful cultivation of many thousands of acres. Near the capital the line to Willunga, designed to serve an old-settled district, is now being worked as far as Brighton, and it is anticipated that the whole length will be open for traffic before the end of the present year.

THE USE OF TURNED SECTIONS IN TENSION TESTS OF REINFORCING BARS.*

By E. P. Withrow and L. C. Niedner.

In conducting tests on reinforcing bars at the Municipal Testing Laboratory of St. Louis, our attention has frequently been drawn to the increase in the values of yield point and ultimate strength, caused by the removal of material in machined test specimens. Our experience has shown that in any one type of deformed bar, this increase exists as a variable quantity, the percentage increase often reaching an amount many times greater than the percentage of material contained in the deformations. This phenomenon was found to occur in "constant-section" deformed bars, and even in plain bars.

Since the standard specifications of the American Society for Testing Materials for billet-steel concrete reinforcement bars permit the use of turned test specimens of deformed bars, it is thought desirable to submit certain facts for consideration. It will be noted that the greater portion of the data has been taken from tests on a certain type of "constant-section" bar. The manufacturer's claim for the "constancy of section" of this bar has been practically substantiated by this laboratory, by comparing the elastic moduli of the bar before and after the removal of the deformations. In the computation of these moduli from their respective stress-deformation ratios, the areas of the rough bar was computed from its entire weight per foot, while in the case of the machined bar, its calipered section was used. The tests referred to cover several sizes of both round and square bars, and show an agreement well within 0.5 per cent.

In the study of the phenomenon under consideration several factors were suggested as possibly contributory. The effect of grips, the reinforcing action of large ends, and the effect of non-uniformity of steel due to segregation were among them.

Still another factor, namely, rate of application of load, could not be neglected, because working conditions in most laboratories will introduce it secondarily when reduced area specimens are tested. This factor can cause a variation of indicated yield point and ultimate strength of 1 or 2 per cent. As this amount is of the same magnitude as the percentage of steel in some types of deformations, it should not be neglected.

Many testing machines have only one motor speed with three or four speeds of pulling-heads obtained by gear shifts. One of these is usually the most convenient and is used for this purpose in testing specimens of all sizes. It has been our experience that in the case of turned specimens, if the speed of pulling-head is unchanged, the rate of application of unit stress may be increased to two or three times that found in testing the rough bar. There exists, with good lubrication, a slipping of the grips in the pulling-heads as the load increases. This is equal to the product of the wedge ratio and the approach of the jaw surfaces as they take hold of the bar, and is, in general, a function of the total load. If the bar does not slip in the grips, the rate of elongation is, therefore, the rate of separation of heads minus a function of the total load.

From the data given by Campbell in his "Structural Steel" an increase of 100 per cent. in the speed of the pulling-head could cause an increase of 1 or 2 per cent. in yield point. In this reference the term "elastic limit" has been used, although the tabulated values are yield points. As this gives the speeds of pulling-heads, it is impossible to estimate the corresponding rates of application of load. For reasons previously given, this would be different for each machine and size of bar. In Fig. 1 is shown the effect of varying rates of loading, using a ¾-in. round bar. Each point represents the average of three or four tests. The highest speed shown is below that at which inertia and error of observation could enter to any great extent.

Therefore, the average rate of application of stress has been kept constant up to the yield point in each series of tests. The differences are, therefore, somewhat smaller than those which would be reported for the same material if tested in the usual manner. Owing to the fact that this precaution was not observed in testing for the ultimate strength, the differences in ultimate strength may be too great by a small amount. This is probably not over 0.5 per cent., and is due to the change from 5,000 to 10,000 lbs. per sq. in. per minute, as may be seen from Fig. 1.

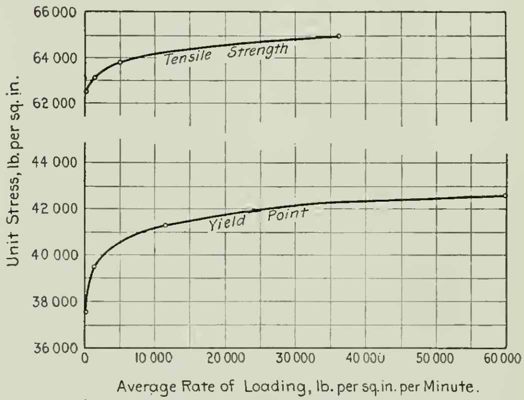

Fig. 1.—Effect of Varying Rates of Loading.

In a search for references giving comparisons of tests on machined and rolled sections, some data were found which seemed to neglect the influence of certain variables of such magnitude as would obscure the one sought for. As an example Campbell compares ¾-in. round bars with specimens made by turning ⅞-in. bars down to a ¾-in. diameter. Therefore, in the tests here described such methods were selected as would avoid the obscuring influences which destroy the value of much data of this nature.

The effect of the large ends of machined specimens could be either protection of the specimens, or reinforcing action. That the reinforcing action becomes negligible in its effect on the yield point, when the length exceeds the small diameter, has been shown by Johnson, "Materials of Construction," p. 513. As turned specimens used in the present investigation had a length about eighteen times the diameter, the only effect of large ends, if it existed, would be that of protection from the grips. The data exhibit no evidence of such protection.

To secure comparable data, several long bars were secured and from each were made various types of specimens. The different types are designated as Nos. 1, 2, 3, 4 and 5. The dimensions and method of gripping are shown in Fig. 2.

In the plain bar the yield points of types Nos. 3 and 4 agreed within about 0.5 per cent. As types Nos. 1 and 3 had received an equally severe treatment in the

* Extract of paper read before the Atlantic City convention of the American Society for Testing Materials.

grips, it was evident that the increase of the yield point of type No. 4 over type No. 1 was not due to the influence of large ends. It was seen also that type No. 3 of another bar, although badly crushed by the grips, showed a yield point 4.2 per cent. higher than that of type No. 1. It also showed an increase of 2.9 per cent. in the ultimate strength. In this bar the ultimate strength and yield point of types Nos. 1 and 2 were practically the same, although the specimens of type No. 2 were decidedly flattened by the grips.

On examination of the data from other bars, the behavior of the yield point of specimens embedded in concrete was found to agree closely with that of the same steel held in wedge grips. Owing to the impossibility of cutting many of these long specimens (type No. 5)

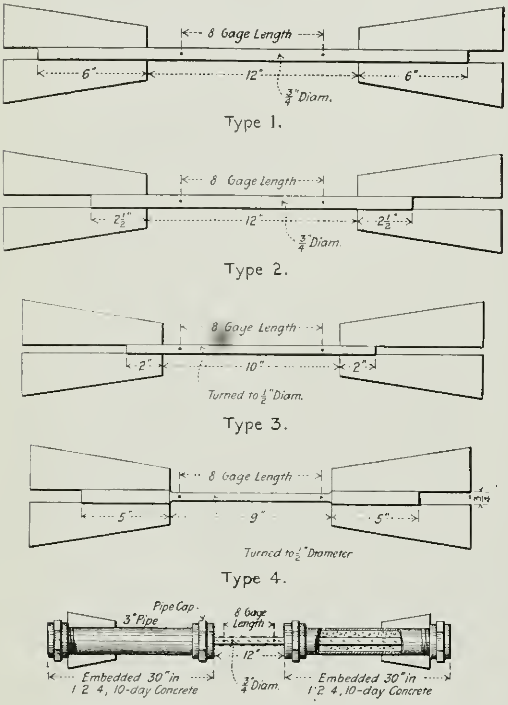

Fig. 2.—Types of Specimens.

from any one bar at our disposal, the following method of comparison was used:—

Bar No.	Percentage increase of Yield Point in concrete grips over that in wedge grips.	Number of specimens in concrete.	Number of specimens in wedge grips.
7	+ 1.5	3	7
4	— 1.1	2	4
6	— 0.5	3	6
Average	—.03		

In the investigation of the influence of grips, this method seems to effect the elimination of practically all other variables. Lack of time prevented a more extended study with type No. 5 of the effect of gripping. The ultimate strengths of specimens of type No. 5 cannot be compared with those of type No. 1, because the elongation and slip in the concrete grips after the yield point was passed made the rate of application of load uncertain. This was in evidence to such an extent that the intention of keeping it near that of type No. 1 was abandoned, and the bars were broken at a high speed. The comparison of ultimate strengths offers little interest at this point, because the soft grade of steel used showed fracture near the central portion in nearly all cases.

The appearance of a 1-in. plain, square bar, which was being examined microscopically, suggested non-uniformity of metal as one of the causes contributing to the raising of the elastic limit by machining specimens. There was a decided segregation of pearlite in the centre as well as a very marked change in the arrangement of grains in lines parallel to the axis of the bar. The macrograph of the entirely etched, longitudinal section showed the distribution and the axial arrangement of structure referred to.

The non-uniformity of steel probably offers the principal reason for the fact that most bars, plain and deformed, are known to show some increase when machined to a smaller diameter, and that this increase is known to be irregular in bars having the same kind of deformations. An examination of the photomicrographs of the specimens showed that in most cases there exists a difference in the structure of the central and marginal portions of the bars. The greatest uniformity was evident in bar No. 2. The turned sections of this bar showed the least increase of yield point and ultimate strength of any bar, about 2 per cent. and 1 per cent., respectively.

The effect of non-uniformity of structure was evidenced by bars Nos. 3 and 4. The yield points of the turned section of both of these bars showed practically the same increase—6.5 per cent. and 6.7 per cent., respectively—while the ultimate strengths are higher by 1.4 per cent. and 8.2 per cent., respectively. A marked segregation of pearlite in the centre of bar No. 4 probably explained this difference in ultimate strength.

That segregation exists over a large central portion of this bar was clearly shown. This was verified by chemical analysis on material from a 3/8-in. hole drilled axially, which analyzed 0.24 per cent. of carbon, as against 0.17 per cent. of carbon in a sample turned from the margin after the removal of mill scale and 1-32 in. of the metal. This observed difference in ultimate strength is not far from that which would be expected to accompany the difference in carbon content. Particular attention was paid to carbon because of the ease with which small variations in its distribution are detected by means of the microscope.

There has been no attempt to determine the magnitude of the effects on the physical properties caused by segregation of various elements. It has been shown, however, that large and variable differences may exist, and that these differences, probably due to non-uniformity of steel, may, even in a constant-section bar, be greater than the reduction of section due to the removal of inactive deformations.

Besides the effects of non-uniformity of chemical composition, non-uniformity of grain size and arrangement could have a marked effect on the physical properties. As the heat and mechanical treatment determine both the grain size and arrangement, and also, in a large measure, the yield point, an observed variation in one might be expected to accompany a difference in the other. Some of the photomicrographs, especially those of the longitudinal sections, show that the granular arrangement of the marginal and central portions differ greatly. This difference does not require the presence of decided segregation, as was seen in bar No. 3, where segregation was not evident, but where a more decided axial

arrangement of grains in the central portion than in its margin was found. The observation of a much greater increase in the yield point than in the ultimate strength of this bar when turned sections are used, seems to point to the reason why this increase in turned sections is rarely the same in both yield point and ultimate strength.

TRACK CONSTRUCTION AND MAINTENANCE.*

By Martin Schreiber,
Engineer, Maintenance of Way, Public Service Railway.

EVERY railway company should have approved plans and specifications for all the different elements that make up track construction as well as proper organization. Beginning with the proper rail, we find this subject has been well covered by the American Electric Railway Engineering Association, for both high T and girder rail. An important work at the last convention at Atlantic City was the final development of standard girder rail for tangent and curved track in paved streets. The Lorain Steel Company has already prepared rolls for the new 7-in. rail recommended by the association and which will be known as Section 122 No. 467. Our modern present rails all conform in a way to the new design, as to their tendency to offset the gauge line to the centre of the web, thereby causing the rail to be better balanced when under influence of wheel loads. The principles for increasing the thickness of the web and depth of groove are apparent. The new standards are only four in number and it is the writer's firm opinion that we still will see a further reduction in the type of rail used on account of the tendency to eliminate the 9-in. rail.

As far as the composition of the rail is concerned, it is now recognized that the use of open-hearth steel is the best practice. The new standard specifications of the American Electric Railway Engineering Association, which have also been ratified by the American Society for Testing Materials, provide for two schedules for carbon content. Many engineers are now strongly endorsing the higher schedule for carbon, but it seems that when welded joints are used it is better practice to use .60% to .75% carbon content to prevent binding near the joint.

The subject of proper rail joints is one of the most difficult which we have to solve. Indeed, it has been the burning question of the past, but in the writer's judgment the joint question has been eliminated to a large degree by the success which we have obtained with the modern welded joints. Besides the straight welds, very good success has been obtained with certain combination welded and riveted joints, and now we have seen a new joint coming from Europe which consists of an ordinary plate electrically welded at the edges.

Sometimes electric railway engineers follow too closely the custom of the steam roads in the matter of rail fastenings. For example, some are now advocating the screw spike, instead of the cut spike. A little consideration, however, will show that the conditions of the electric railway are entirely different from those of the steam road. There is a vast difference between a 50-ton car operating on a street railway track, which is not only spiked down but also has a solid encasement of paving, and where you have a 200-ton locomotive operating over an exposed track.

*Abstract of address presented at regular monthly meeting of the New England Street Railway Club at Boston, Mass., on May 28, 1914.

Most electric railways now recognize the economy of using treated ties and other timber. For permanent track construction the 6-in. by 8-in. by 8-ft. yellow pine tie, treated with 10 lb. creosote oil per cu. ft., seems to cover the requirements very well, and ties so treated will probably last 25 years. If you consider the pressure treatment too expensive, at least a superficial treatment of some high-grade oil should be used.

The steel tie is a good competitor of the wood tie, except that it is more expensive. We must also recognize the cushion effect of the wood tie and the advantage of shifting and aligning the rail. A number of concrete ties have been introduced, but so far experience has not demonstrated their practicability.

A few years ago many street railway companies laid their tracks with concrete foundation. Now some of them are going back to broken stone, because they find broken stone ballast lasts about as well, is just as satisfactory and a good deal cheaper than concrete. Broken stone provides excellent drainage, is easier on rolling stock, as it is less rigid than the concrete foundation, and may be installed under traffic. Besides, any shifting and aligning of tracks in the future is less expensive where broken stone has been used. Although certain kinds of soil make it necessary to provide some sort of beam support to the track through the foundation, in a large majority of cases the sub-grade which has been properly rolled and has spread upon it good sharp stone ballast that is rolled and tamped under traffic, will provide a foundation which will be satisfactory for electric railway operation.

Municipal engineers now generally recognize the wisdom in the omission of any monolith paving next to the rail, such as concrete or asphalt. If a perfectly smooth pavement is required, it is better to install wood block in preference to any manufactured block, brick or others. But, for life of service and ultimate economy, the granite block seems to stand alone.

It has not been so long ago that it was considered by even high officials in the electric railway industry that any kind of equipment was good enough for track construction. It was not uncommon to see practically no accommodation for storage yards for shipping and receiving of materials, and old and dilapidated cars were reconstructed for work cars. Track work carried out under these conditions is bound to be a business failure, and it is far better to contract the track work out.

A canvas which the writer recently made has led him to believe that very few companies know just what track work is costing them. Seldom the cost for power, interest on equipment and overhead expenses are taken into consideration, and these items should be, if you compare what the work is costing with what actual moneys a contractor would require to produce it.

Assuming that you have proper specifications and organization, along with right facilities to execute track construction, in order to get the best product for the expenditure you are making, careful inspection is a necessity. Many roads to-day are doing the work and only give the material a "once over," and are hiding behind the illusion that they are saving money. All track materials should be carefully inspected, not only the rail but joints, tie plates, track bolts, tie rods, track spikes, cement and paving materials.

From experience, the writer does not see any grounds for contention that the solid manganese is not superior to manganese inserts, if it is properly applied. Undoubtedly it does not pay to buy solid manganese at a possible 30%

increase in price over the manganese inserts, if traffic does not demand it. Besides, a great deal of solid manganese which has been cited as not altogether coming up to expectations (as we have in Chicago) was the crop of the first experiments. Now we have the pieces made up in sections, instead of the tendency toward an all-unit casting, so that if a part fails it is not always required to throw away the entire piece. In the city of Newark, at Broad and Market Streets, we have one of the busiest electric railway crossings in the country. Approximately 5,000 30-ton cars pass over this intersection every 24 hours. Previously insert crossings were good at this location for 16 to 20 months. The first solid manganese crossing which was installed stood approximately three and one-half years. I leave it to you if there is any economy in the solid manganese crossing at a cost of approximately 30% over the insert crossing. The writer has found that a very economical construction for steam road crossing is to use the old bolted type with solid manganese running and bearing rails. This crossing has an advantage of being cheap, easy to repair under operation, and still the most vulnerable point is of the best material that is known, inasmuch as the running and bearing rails in steam track are rolled manganese and here in the old type breaks generally occur.

Another important consideration in connection with special work design, which I would like to call your attention to, is the way the engineer is called on now to work on account of the varying equipment design. First, you have the city and interurban flanges; second, old and new cars with wheel bases from 4 to 6 ft., and third, steel wheels. An ideal curve design would be one which would be traversed only by cars with the same size wheel flange and the same wheel base. The proper groove of the curve is a function of the contour of the flange, length of the wheel base and the radii of curves. Theoretically every time you change the radius of a curve and the size of the wheel flange, or the length of the wheel base, the design of the groove in the curve should be altered to suit. Again, most of our special work to-day is designed for flange bearing, and it is not possible to properly design special work for two depths of flanges, still we are constantly called on to provide special work to take both city and interurban cars that have two types of flanges. It is easily seen that with special work designed for ¾-in. flange, the ⅞-in. flange cuts out the floor of your frogs, switches and mates. On the other hand, if you design the special work for ⅞-in. flange and operate ¾-in. depth flange on it, the wheel treads are pounding and destroying the points in frogs, switches and mates.

COMPARATIVE STRENGTHS OF BLASTING EXPLOSIVES.

IN the course of its investigations of blasting explosives, the U.S. Bureau of Mines made tests to determine the potential energy, the disruptive effect and the propulsive effect of some of the explosives in common use. The potential energy was measured by means of the bomb calorimeter in water. The disruptive effect was measured, using the Mettegang recorder, detonating fuse, Trauzl lead blocks and small lead blocks. The propulsive effect was measured in the Bichel pressure gauge and by means of the ballistic pendulum. The tabulated results are given herewith, together with the approximate composition of typical examples of the various explosives. The percentages figured are rated against the effect of 40% straight nitroglycerine dynamite taken at 100%.

The figures are fairly consistent with general practice, and it is believed that the classification will serve as a useful guide for comparing the practical value of explosives. It is worthy of note that the potential energy of 40% strength ammonia dynamite and of 40% strength gelatine dynamite, that is, the theoretical maximum work that these explosives can accomplish, is higher than that of 40% straight nitroglycerine dynamite, but that the disruptive and propulsive effects, which represent the useful work done as shown by actual tests, are less. Accordingly, straight nitroglycerine dynamite is more economical for general use in blasting operations if the conditions and character of the work are such as to permit its use; nevertheless, the ammonia dynamite and the gelatine dynamite are more efficient and economical for certain kinds of work that require explosives having a large propulsive effect and a comparatively small disruptive effect. For example, in blasting soft rock, 40% straight nitroglycerine dynamite, which has a very high percussive force, may be too quick in action, whereas the ammonia dynamite or the gelatine dynamite having practically the same heaving and pushing action and less percussive force will be more suitable. The tests also show that 60% strength low-freezing dynamite is not quite equivalent to the 40% straight nitroglycerine dynamite. It is worthy of note that black blasting powder has little disruptive effect, only about one-third that of granulated nitroglycerine powder.

LOGGING FLUME CONSTRUCTION.

In a bulletin, entitled "Flumes and Fluming," issued by the United States Department of Agriculture, the use of flumes in lumbering operations is discussed, with instructions concerning their construction, and some valuable data concerning volume, velocity, etc., of water to use in different sized flumes.

Of the two types in general use the V-shaped flume has proved more satisfactory, both in cost of construction and efficiency of operation, than the box or square, upright-sided flume.

The square flume is usually constructed along the general lines of the well-known mill flume or artificial conduit used to convey water from the mill pond to the mill for water-power or other purposes, but with this difference, that the uprights on the sides of the square or box timber flume are rarely braced across the top of the flume, but instead the top of the flume is left open to afford free passage for logs, wood, or lumber, and the sides are held in place by uprights fastened on the sills or crosspieces on which the bottom of the flume rests, and braced from the outside.

This is the oldest type of wooden flume in use, and is employed to some extent at the present time where economy in the use of water is not of any particular importance. However, the square flume requires more water to operate successfully with the same class of material, and, generally speaking, requires more lumber for construction than does the V-shaped flume. Furthermore, the material being handled is more apt to "jam" (especially the short material) in the square-box type. Owing to the form of its construction there are more joints in this type that are liable to open up and cause "leakage," in case the flume is allowed to stand without water running in it for any length of time, and, except where it is desired to combine in one flume the two objects of carrying a large amount of water to be used for some purpose other than fluming below and at the same time to use the flume for the transportation of lumber or timber, it is generally more advisable to use the type of flume which requires the least amount of water and the least average amount of repair. Up to the present that is the V-shaped wooden flume, but it is, perhaps, not a flight of fancy to predict that it is only a question of time when strong and light "sectional" metal flumes, semicircular in form, that can be quickly taken apart and transported from one point to another and put together and set up again, will be in common use. Metal semicircular conduits, made in sections and easily put together, have already been used in hydroelectric and irrigation projects.

The V-shaped flume is at present the type of flume most generally used in the western portion of the United States, and it has given the most general satisfaction for the transportation of manufactured lumber or timber in its different forms of logs, railroad cross-ties, cordwood, etc.

Some of the salient points in which the V-shaped flume excels are:—

(1) It can be successfully operated with a less volume of water than any other type, since, owing to the V form of construction, the water is always held confined or "compact," and, therefore, has the greatest carrying power for the amount used.

(2) There is less likelihood of jams forming, since the narrowness of the flume prevents the material from getting partially crosswise and forming a "brace," through the ends "wedging" or pressing against the sides of the flume. This is a feature especially desirable when handling short material. The narrow formation of the V-shaped flume keeps the timber running "straight," and according as the volume of water in the flume is reduced the formation of the V keeps the water confined in the smallest possible triangle down which the sides of the flume compel the material to travel.

(3) In fluming logs or round timbers the rounded portion of the log settles well down into the V. The water thus confined between the bottom of the stick and the sides of the V constantly tends to lift the log, and this keeps the stick from settling down or rubbing hard against the sides of the flume. In a square flume, on the other hand, the same amount of water could run on both sides of the log and not beneath and would so lose the tendency to "lift" through lack of proper confinement.

Thus if a log or stick of timber is large and heavy, it may sometimes nearly fill the V-shaped flume and occasionally touch both sides. But whenever this occurs the log has the pressure of the full volume of water which the flume can carry backed up behind it to force it along, and the V formation keeps the stick running "straight ahead," so that there is very little opportunity for the water to spread out or run around or get by the stick without taking it along with it. Its transportation is further aided by the uplift of the partially confined water, running around and under it, that is trying to find an outlet or relief from the pressure of the water behind, which must either aid in forcing the stick along or run over the top of the flume.

(4) In cases where it is necessary to have an unusually abrupt descent in some portions of the grade, the V-shaped flume is best adapted to serve as a "slide," or "slip," or "chute," since it is less likely to become jammed, while the material being handled is held by its own weight in proper position in the centre of the V. In a great many localities this particular feature of control of the log or stick of timber when it is "coasting" will be found very necessary in handling material from the higher mountain slopes, especially in places where it is impossible to maintain a steady and equable grade from the top to the bottom of the mountain without too great expense, and where it may be necessary to have a form of construction that will carry logs or timber safely for a long distance when the grade is so abrupt that it is impossible to maintain a sufficient volume of water in the flume to prevent the material from rubbing or sliding along on the sides and bottom. In such localities and under such conditions the V-shaped flume, when strongly constructed so as to combine both the objects of flume and chute, has been and will be found altogether the most desirable.

In the construction of flume sections angles of from 70 to 110° have been tried; but the consensus of opinion favors 90°. Construction methods are dependent upon the kind of material to be handled. The sections vary in length from 6 to 20 ft. Sometimes only one thickness of board is used, but more often two thicknesses are employed, with joints broken or staggered. The details of the box construction is largely a matter of individual opinion. The aim almost always is to keep down leakage.

A triangular section of wood, sawed to fit snugly into the bottom of the V on the inside in sometimes employed for purposes of reducing the amount of water necessary and strengthening the flume itself. The value of this measure is, however, disputed on the ground of too great cost.

Size of Flume.—The kind of material to be handled is a prime factor in determining the size of a flume. If a 30-inch V-shaped flume would satisfactorily handle the material, there would be nothing gained by going to the

extra expense of constructing a flume with a V of 48 inches. On the other hand, it is always good policy to construct a flume large enough to carry sufficient water to handle the material desired with certainty and dispatch. For railroad cross-ties, cants, poles, cordwood, etc., the 30-inch flume is usually large enough, wherever there is a sufficient volume of water available to fill the flume two-thirds full, while for the handling of logs, piling, long timbers, or "brailed" sawed lumber it is usually advisable to have the flume constructed with the sides of the V from 40 to 60 inches in height, according to the volume of water available and the size of the material to be handled. This is also a feature in flume construction in which the prospective operator can save money by not constructing his flume larger or in any more expensive form than is actually needed, since every additional inch in height means the use of more lumber in construction, and is consequently an added and unnecessary cost.

Grades.—The matter of grade in flume construction is one of great importance. Flume operators have found the question of satisfactory grade to be one of the most important features of successfully fluming material, since where there is a stretch of comparatively flat grade the supply of water may be ample to nearly fill the flume, but upon arrival at a point in the flume line where the descent is very abrupt, the accelerated speed of the water reduces its volume to a small amount in the bottom of the flume, and, consequently, results in the flumed material "rubbing" or "sliding" down the descent for a long distance on the sides of the V. Such action wears out the lining very rapidly, necessitates its being frequently renewed, and produces a dangerous condition through the liability of the material to jam and pile up, and either be thrown out of the flume or break it down as a result of the increased weight.

In general, the lowest grade that is considered satisfactory for successful operation is approximately 1 per cent., or 1 foot in 100 feet, but it is better to maintain a grade of from 2 to 5 per cent. when possible. The maximum grade that can be used runs up to a very high pitch; some flumes have been successfully operated for a short distance at a grade of 30°, but such a steep grade is very undesirable, as it is usually impossible to maintain a sufficient volume of water in the flume. The most satisfactory results in fluming will be obtained at from 2 to 10 per cent. grade, and it should be held below 15 per cent. whenever possible.

Curves.—In the location of a flume line, for obvious reasons a sharp curve is inadvisable. It throws the weight of the material and water to the outside of the curve, with a tendency toward jamming. The degree of curvature should be kept as low as practicable, and should rarely be permitted to exceed 20°. Shorter "boxes" and the closer spacing of supporting bents, arms and bracing are very necessary in sharp curves.

Feeders.—Feeders constructed at various points along the line are necessary in order to maintain the requisite amount of water on different grades.

A Glasgow, Scotland, publication announces that the select committee of the House of Lords has passed the bill promoted by the corporation of Glasgow with reference to the building of a new bridge over the Clyde, at Glasgow, between Oswald Street on the north side of the river and Commerce Street on the south. The new bridge, with the necessary alterations to provide a suitable approach to it, will cost about £300,000. The bill permitting the bridge to be built will be proceeded with, subject to certain restrictions. A delay of 1½ years has been added to the five years in the original proposal.

PROPOSED RAILWAY VIADUCT, TORONTO.

By W. H. B.

Is the proposed railway viaduct along the Toronto waterfront a mistake? In 1907 the city had an investigation and report made by Wm. Barclay Parsons, of New York, an engineer of international reputation, Chief Engineer of Subways in New York, etc., and the late Cecil B. Smith, who also was a well-qualified and experienced engineer, acting with Mr. Rust, the City Engineer, on the general question of traffic facilities along the entire front of the city.

The main feature of this report was the consideration of elimination of level crossings, particularly along the central part of the city. Two schemes of doing this were worked out and considered in all their bearings:—

Scheme 1. Elevating the tracks.

Scheme 2. Placing the streets on overhead bridges.

As to elevating the tracks, four main running tracks only were considered (the viaduct scheme as adopted), and not the great network and ramification of existing surface tracks. For operating surface tracks retained it had been proposed—not by the engineers making the report—in recognition of the great danger of running trains close to, and, therefore, obstructed by, the masonry of the viaduct, that shunting on these tracks be limited to the night hours, or that the shunting engines be preceded by a man on foot carrying a flag—a rather fatuous scheme for handling the traffic on the numerous private sidings to shops and warehouses and the harbor traffic of a city of 500,000 population.

Summarizing, the report gave for Scheme 1:—

Advantages:—

Every street would be carried through to the waterfront at its existing elevation.

Disadvantages:—

First—The raising of the station would place the tracks westerly of it at such a height as to require the abolition of the John Street bridge.

Second—The existing freight yards would have to be reconstructed.

Third—The shifting and delivery facilities on the Esplanade would have to be reduced.

Fourth—Crossings of the shifting tracks on the Esplanade would still remain.

Fifth—Greater cost.

For Scheme 2:—

Advantages:—

First—No interference with existing tracks.

Second—Delivery facilities on the Esplanade could be increased.

Third—A lower cost.

Fourth—Better appearance to persons approaching from the water.

Disadvantages:—

That some streets would be cut off before reaching the water.

Scheme 2 is elimination of level crossings; Scheme 1 is not. In fact, with the inevitable growth and further ramifications of local distributing tracks as business and consequent traffic increase the expected relief by a viaduct eliminating the four main running tracks only will be found to be largely visionary. The report strongly advocates Scheme 2, the retention of steam railway tracks on the surface and the placing of street lines on overhead bridges as the only practicable elimination of level crossings at this location.

The city report as printed is accompanied by a report on the same question made to the Toronto Board

of Trade by the late R. M. Berrian, who was a well-known Boston engineer, and by J. W. Moyes. This report advocates the viaduct as against street bridges.

For some reason not clear the viaduct scheme found popular favor, was loudly acclaimed by the daily papers without thought of technical analysis of the situation, and was adopted.

Several features not considered in either report are pertinent to this inquiry.

Traverse by street cars along the passenger landings, which, though numerous, are practically all along a short section of the waterfront, during the season of navigation at least, is an urgent requirement, and a car line will in any event be wanted along the new harbor street, outside of the railways, shown in the Waterfront Development plans (1912) of the Toronto Harbor Commissioners. Tracks for such cars would have to cross the remaining surface steam railway tracks at grade. The required protection by interlocking derails and signals at such complicated level crossings would be intricate and costly, and a great hindrance to traffic.

The bridges to carry streets over railways contemplate the clearance of 22 ft. over top of rail, specified in the Dominion Railway Act of 1904. A statement of facts will be of interest in this connection. The Railway Age Gazette of Dec. 12, 1913, gives a tabulated "Resume of City Requirements for Grade Separation Work" for various States in the United States and for Canada. Clearance requirement for overhead bridges varies from 15 ft. to 22 ft., the latter the Canadian requirement, which is the highest of all. In the city of New York, where electric traction is used exclusively for railways, within the electric zone, extending beyond the city limits, the clearance requirement is 16 ft. 6 in.

The recently renewed Milwaukee Avenue and Desplaines Avenue double viaduct in Chicago traversing a trackage width of 460 ft. and crossing main tracks of the Chicago, Milwaukee and St. Paul, the Chicago and North Western and the Pennsylvania Railways, has clearance over top of rail of only 15½ ft.

In main line crossings over the Pennsylvania and other railways in Pittsburg, with all steam locomotive traction, bridges with clearance over top of rail as low as 17 ft. 2 in. have long been in use, and the same may be said of crossings in many cities in the United States.

Rolling stock and railway conditions generally are practically identical in the United States and Canada. In fact, rolling stock, which determines clearance requirement, is constantly interchanged.

With clearance of 17 ft., or even 18 ft., over top of rail, instead of 22 ft., the Toronto problem would assume an entirely different aspect, and the only plausible argument for a viaduct instead of street bridges, even by Mr. Berrian in the Board of Trade report referred to, would disappear.

A consideration that has important bearing on this inquiry is the electrification of steam railways, within the city district at least. With electric traction control of trains, short or long, is better, and the need of brakemen on top of car less, making for material reduction of overhead clearance.

In cities such as Toronto smoke abatement is one strong reason, among others, for electrification. Careful observers claim that in the city of Chicago 47 per cent. of the city smoke is caused by railways.

Notwithstanding the recent very material improvements in economy and power of the steam locomotive, during the past ten years or less, electrification of steam railways is steadily progressing throughout the world, particularly at terminals and at other places of congested traffic. In and about London and elsewhere in England vast schemes of electrification have been already accomplished and are under way. The same may be said of almost every country in Europe. As one instance, the Giovi railway, running from Genoa, a line with heavy grades and long tunnels, has demonstrated an increase due to electric traction of 100 per cent. in capacity during the past four years. To come nearer home, and considering progress of the past year or so only, mention may be made of electrification of New York, New Haven and Hartford lines out from New York, of Pennsylvania lines in and about Philadelphia and Pittsburg, of parts of the Norfolk and Western, the Chicago, Milwaukee and St. Paul, the Atchison, Topeka and Santa Fe, the Southern Pacific and other lines. The success attending the electrification of the Butte, Anaconda and Pacific, in economy and general improvement in operating, has resulted in power contracts being placed for 440 miles of the Chicago, Milwaukee and St. Paul. The Canadian Pacific Railway has planned large electrification in British Columbia.

The advance in the past seven years, since presentation of the reports referred to, in the availability of electric energy in south-western Ontario, due mainly to the activity of the Hydro-Electric Power Commission of Ontario, has been greatly beyond expectation. It is not yet four years since this commission began transmitting electricity, Oct. 11th, 1910. It was then thought the distribution would not reach 100,000 h.p. in forty years, while now it is already 90,000 h.p., with all difficulties of the beginning period practically overcome. Electrification in such contiguous cities as Buffalo, Hamilton and Toronto will in the near future have to be seriously considered, and who will say it will not prevail throughout the district from Windsor to Toronto, if not to Montreal, with the greatest available source of hydro-electric energy in the world alongside.

This electrification feature alone merits reconsideration of the whole question of Toronto transportation facilities.

A few odd figures have been taken at random from the 1913 annual reports of the C.P.R. Company, showing accounts for additional improvements to the system have been $29,000,000; for rolling stock and machinery, $30,000,000; for construction of acquired branch lines, $9,113,050; for Ogden shops at Calgary, $2,446,035; for dividends paid up to June 30, in round figures, $15,000,000.

Particulars recently published by the C.P.R. company in connection with its policy of bridge construction, gives the following interesting figures of dimension and cost for four outstanding structures, e.g., the Lethbridge viaduct, the Outlook, the Edmonton, and the Lachine bridges. The first is 5,327 feet long and 314 feet above the water level, with a weight of steel of 25,000,000 pounds; and cost $1,500,000. It was made up of 44 through plate girders 67 feet long, 33 girders 100 feet long, and one 167-foot truss span supported on 33 steel towers. It required 645 cars to transport steel used in construction. The second bridge, across the South Saskatchewan River, is 3,004 feet in length, 140 feet above water level, and has a weight of 5,737,000 pounds of steel; and cost $900,000. It has 240-foot truss spans, supported by concrete piers, with approaches consisting of three 80-foot, seven 60-foot, and nine 45-foot plate girder spans on steel towers. The third, over the North Saskatchewan, is 2,550 feet in length; is 152 feet above the water level; has 16,204,146 pounds of steel; and cost $1,400,000. The fourth bridge—the Lachine, across the St. Lawrence—has 3,657 feet of length; is 60 feet above water level; has 28,462,931 pounds of steel; and cost $2,000,000—that is, both for converting into double track, and for the original cost of the structure, which was something like $1,500,000. It has three 80-foot, nine 120-foot, four 240-foot, two 270-foot, and two 498-foot spans; and 19 piers, 3,500,000 rivets; while 3,500 cars were required to handle the material employed in the entire structure.

SOME LARGE CYLINDRICAL VALVES FOR HIGH WATER PRESSURES.

The valves or water-gates used or projected to be used by the United States Reclamation Service under great heads at reservoir outlets are described as follows by Gen. W. L. Marshall, United States Army consulting engineer to the Secretary of the Interior, in No. 27, Vol. VI. of "Professional Memoirs" of the Corps of Engineers. They are slide gates for guard valves and automatic plug, or needle, valves for closely regulating discharges. Under great heads the slide valves are difficult to operate, and when of considerable size are not practicable under pressures due such heads, especially since roller bearings applied to them have failed in practice. The use of slide valves must then be restricted to sluice gates operated under moderate or low heads, and to guard gates for regulating valves, to be operated in still water.

The regulating valves, designed and used in the Reclamation Service, form a distinct cylindrical class wherein the cylinder is closed at top, which top projects beyond the cylindrical body and forms a hydraulic piston in direct connection with the valve. The bottom of such type is also closed by a conoidal or concave surface of revolution terminating in a point at the axis of the cylindrical body prolonged. The projection of the top surface or "bull-ring" closely fits the surface of, and moves smoothly into and out from a hood or housing, just as

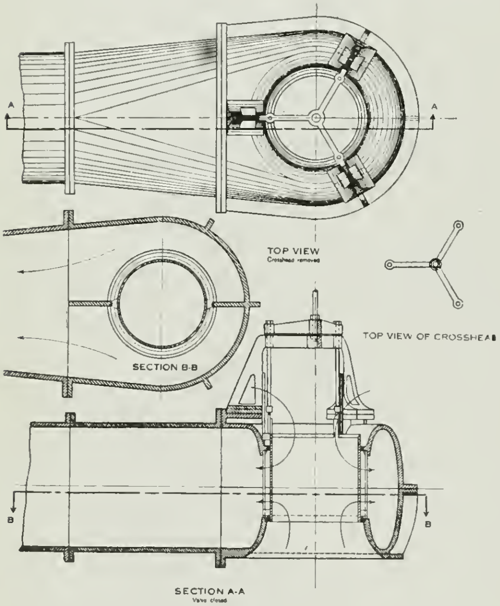

Fig. 1.

a piston of a hydraulic engine moves in its cylinder; and carries the plug or valve to and from its seat.

These automatic but controllable plug or needle valves are in many of their principal features, if not all of them, the inventions of Mr. O. H. Ensign, Chief Electrical Engineer, and of Mr. F. Teichman, Engineer in the United States Reclamation Service, and are very interesting, useful, and scientific applications of the laws of the mechanics of fluids, correct in principle and extremely ingenious. Quite a number of the Ensign valves have been in use for several years. The Teichman type has not yet been tried, but has been contracted for to be placed in the Elephant Butte Dam on the Rio Grande.

The regulating plug valves are automatic but controllable, and are used under heads up to and greater than 100 feet quite successfully. They still have some minor defects, but all such defects seem to be remediable, and doubtless will be remedied shortly.

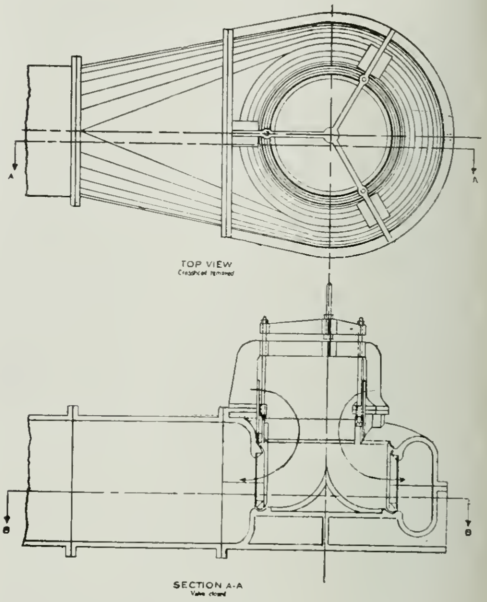

Fig. 2.

In operating these valves not only is hydrostatic pressure used and controlled, but auxiliary forces such as "suction" from artificially produced partial vacuums in the housing, and "reaction" due the change in direction of the discharge by the curved surface of the bottom of the plug. The main differences between the Ensign and Teichman types consist in the relative intensity of these forces employed and relative importance of or reliance placed in the three forces named, and in methods of control and operation. Each type has distinctive good points.

Notwithstanding such defects as have been met in plug valves (up to 10 feet diameter), they are believed to be the best regulating valves under great heads now in use, and certainly will be the best when the new models come out. There is no detailed scientific description of these valves as far as known to the writer.

In designing the cylindrical valves now in question there was not in view to devise a valve or type of gate to take the place of the regulating valves, or to be used as regulating valves at all, but to arrive at some type of gate or valve of medium cost, upon the surfaces of which fluid pressures in every direction may be balanced or in equilibrium, to be used as sluice and guard gates under considerably greater heads than practicable for slide gates; and especially adapted for use for guard gates to the Ensign or Teichman regulating valves, and which may be capable of being conveniently operated

under all heads for which slide valves are designed and used. They are not yet (experimental data wanting) considered by me as suitable for use in intermediate positions between open and closed; in other words, for regulating discharge, on account of disturbances that may be expected to be set up by partial vacuums due tortuous course of water through them under high velocities, and the probable hammering due the formation, destruction, reformation, etc., of such vacuums about the edges of the cylinders if not very securely held by close-fitting guides. They can, however, be opened and closed in front of the regulating valves in high-current velocities,

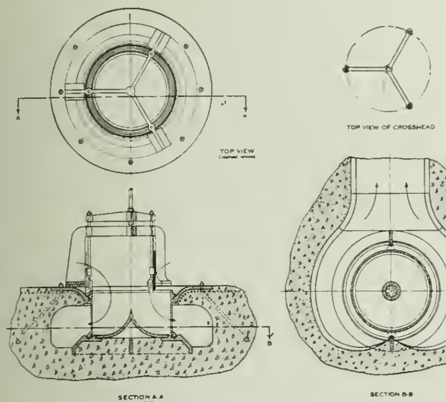

Fig. 3.

if it be found necessary on account of wedging or failure of such valves, under circumstances where slide valves or gates are impossible of operation, and also for emergency discharge gates and sluices, when close regulation is not necessary, or when for any cause the corresponding regulating valve is awaiting repairs. They may all be made water-tight when closed by very simple devices already in use with cylindrical valves.

The single discharge types, and the double-acting valves shown in concrete setting are designed for small heads mainly, but in all types, except that one shown as attached to a pipe elbow (see Fig. 5), the discharge is through the hollow cylinder, and there is no housing or hood required in any of them as in the Fontaine low cylindrical valves used at Panama and for forty years or more elsewhere in this country or abroad. The drawings show types only, and all minor things, like packing, etc., are omitted to avoid confusion. It is unnecessary to show devices well understood to be common to all close-fitting valves.

None of these valves is in use; in fact, they are novelties published just now for what they may be worth in considering projects requiring guard and sluice gates of large capacity under considerable heads. They will doubtless be used, if found useful and advantageous, otherwise they will remain as part of the record of attempts at solving a serious problem in hydraulic engineering that must be solved in some way. The writer believes that the slide gates for large sluices, and for guard gates, under high pressures must go, and that some form of plain, positively operated cylinder or balanced gate will be substituted therefor for closing outlets greater, say, than 20 square feet under high heads, but any of the known cylindrical valves may be made automatic if the expense justifies.

Of the valves proposed herein one form only is of any considerable interest, that is, the "double entry" valves (Figs. 1 and 3), wherein a section of a hollow right cylinder with circular bases is inserted in an annular housing, and closes or opens the inner sides of the inclosing hollow ring. When the cylinder (supposed submerged in water) is raised from its seat a distance equal to one-half or more of its diameter, the liquid discharges into the hollow ring and out through the discharge pipe not only through the interior of the hollow cylinder, but also through the hole at the bottom of the ring heretofore closed by the surface and the base of the cylinder, giving a discharge equal to that of two orifices of capacity equal to the inner section of the cylinder. This form is interesting in two ways:—

1. It may give the greatest possible discharge with the least possible valve movement, and with minimum weight of moving parts and with least frictional resistance. 2. Under very high heads the disturbance at the bases of the cylinder and in the ring might be found dangerous to the material and the surface of the caning might be rapidly eroded by gritty water under the increased velocities, if the full discharge under such head were allowed to pass the valve. In such case the velocities in the valve and casing can be cut down to any extent by reducing the size of the discharge pipe so as to cut down the discharge through the valve itself when wide open to well below the capacity of the valve under that head.

Thus, if the valve were barely capable of safely and smoothly discharging to it full or duplex capacity at 100-ft. head, and it be in question to use it at, say, 400-ft. head, under which head the velocity would be

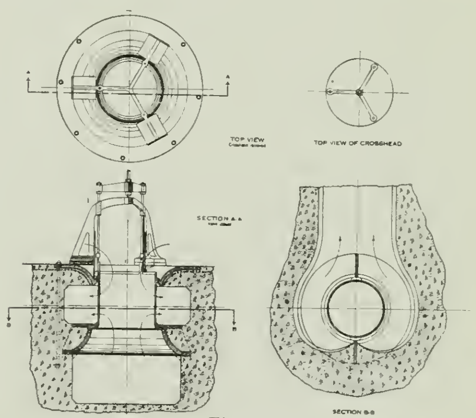

Fig. 4.

doubled and the wearing energy quadrupled, it would be necessary for safe and smooth action to reduce the capacity of the discharge pipe to one-half the capacity of the valves under the full head of 400 feet. This would result in bringing down the velocities, pressures, etc., in the valve and casing when fully opened to the same values as at 100-ft. head, with precisely the same discharge, the velocity in discharge pipe being doubled and the capacity of the pipe at same time reduced one-half.

In similar manner the valve may be adjusted to its greatest safe discharge capacity, at any head, by adjusting the capacity of the discharge pipe or conduit.

The valve is, therefore, practicable through a wide variation in maximum heads due its position in the reser-

voir, by varying the discharge pipe to give equal discharges at such varying maximum heads, or positions. Other types, of course, may be treated likewise, but under similar conditions of adjustment, etc., the form in question will always give approximately twice the discharge of any other type of cylindrical valve of same diameter.

Referring to the drawings, Fig. 1 shows a balanced valve for high or low heads, giving maximum discharge with minimum material and with least movement possible in proportion to discharge. The moving part is a section of a right cylinder, open at both ends, and actuated positively by hand or otherwise. When valve is lifted through a distance equal to or greater than the radius of the interior of the cylinder (if submerged) the liquid in which it is immersed may discharge: 1. Through

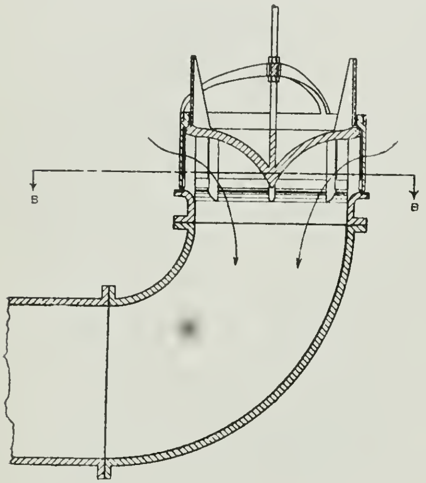

Fig. 5.

the unobstructed interior of the cylinder. 2. Through the orifice at its base, giving thus a discharge equal to that obtained through two cylindrical valves of same size of orifice.

If r be radius of interior of valve and of valve seat and R be radius of discharge pipe, then $2\pi r^2 = \pi R^2$ or $R = r\sqrt{2} = 1.414\, r$.

For instance, if the moving clinder be 5 feet in diameter, the discharge pipe must be at least 7.07 feet in diameter.

The drawing shows essential parts only, but is readily understood. The valve may be made of many forms and of various materials. Inasmuch as the pressures in the valve produce stresses of tension only, the barrel or cylinder may be of ordinary thickness of boiler plate, with flanges if necessary for valve seats. If its weight be counterpoised the valve may be very easily moved by any positive acting force.

To increase efficiency of valve and prevent possible violent shocks under high heads suitable deflecting valves may be constructed in valve casings.

Fig. 2 shows a design for a hoodless cylinder valve discharging through one end and under the other end of an open cylinder, which constitutes the movable part of the valve.

Fig. 3 illustrates a balanced valve of the same type as that shown in Fig. 1, only showing the application of the valve to a setting in concrete.

Fig. 4 is similar to Fig. 2, except that it also shows the valve in a concrete setting. Fig. 5 shows another application of the hoodless cylinder valve, this time to a setting on a pipe below.

All these valves are proposals of Gen. Marshall for the Reclamation Service. In connection with their presentation, he submits the following cautionary notes respecting large valves:—

(1) Care must be taken that the valve is balanced in direction of its axis, to insure ease in operation.

(2) Valve seats may better be separately constructed rings, carefully machined to fit, and attached to valve castings. They may be of other material than the exit conduits.

(3) The guides, side bars, etc., should accurately fit and be sufficient in number and strength to prevent balloting or vibration of the cylinder when wholly or partly raised.

(4) The bails for manœuvring the valve and as guides to tail or lifting rod should not obstruct the approach of the liquid to the cylinder, which obstruction may increase the force required to manœuvre the valve.

(5) The surfaces of approach and exit to and from the valve may be such as to facilitate and increase the discharge, but such refinements should not be practised where the gain will not justify the cost.

ACCIDENTS IN MINES IN QUEBEC.

During the year 1913, there were 8,611 persons employed in the mines, quarries, clay-pits and concentrating mills of the Province of Quebec. This number is not the actual number, which was somewhat higher, but it is a reduction to a basis of 300 days work per man per year, from the actual number of days work performed, which totalled 2,583,673. The total sum paid in wages during the year amounted to $5,401,702, or an average of $626 per person per year. This may perhaps appear low, but it must be considered that all the mines and quarries are situated in the settled parts of the province, where unskilled labor commands a much lower rate than in the average northern mining camp, and also that a certain proportion of the employed are signal-boys in the asbestos open pits, girls in the mica trimming shops, and in the asbestos sorting sheds.

Throughout the year, sixteen deaths occurred through accidents in mines, quarries, clay pits, in the province. Taking the basis of 8,611 persons employed, this gives a general proportion of 1.86 per 1,000 men employed. In the mines proper, asbestos, copper, graphite, mica, etc., the proportion was much higher; of 3,444 men, 11 were killed, or a proportion of 3.19 per 1,000 men employed. In the quarries proper, clay pits, brick-yards, etc., there were 5,167 persons employed, 5 of whom were killed, or a proportion of 0.97 per 1,000 employed.

BUFFALO RAILWAY TERMINALS.

Railway terminal work in Buffalo, N.Y., calling for an expenditure of $15,000,000 to $17,000,000, will be placed under construction in the next year or two. Plans for a new station and other improvements for the Lehigh Valley, to cost about $5,000,000, have been approved by the Buffalo Terminal Commission. The Lehigh facilities will be shared by the Grand Trunk, Erie, Nickel Plate and Wabash. The New York Central lines are developing a scheme for a new terminal, which according to present plans will cost close to $10,000,000. In addition work is now progressing on the new Lackawanna station which will cost about $2,500,000.

On July 11, the Port Dover Brick and Fire Works were destroyed by fire, entailing a loss of $20,000. It is proposed to rebuild the plant next year.

COMPRESSION MACHINE FOR TESTING STRUCTURAL MATERIALS.

With the increasing recognition of the necessity for laboratory tests of concrete has come a demand for a simple machine for testing the compressive strength of specimens as large as 8 and 10 in. in diameter. Engineers and builders are beginning to appreciate the fact that a great deal of money can be saved on a large concrete job, amounting often to thousands of dollars, by proper selection and proportioning of the aggregates. To compare the qualities and proportioning of different materials, it is necessary to make fairly large concrete specimens with the cement and aggregate to be used on the work. Advance tests are also essential from the standpoint of safety, and to determine the allowable working compressive strength of the concrete in a reinforced-concrete structure.

In addition to these tests of specimens made in the laboratory, it is now required on important construction that blocks of concrete shall be made up in the field at stated intervals, and tested for compressive strength at ages of, say, 7, 14 and 28 days.

Compression machines of from 100 to 150 tons capacity for testing concrete specimens would be in much greater demand were it not for their high cost and their bulkiness. There are two types of compression machines on the market: Screw machines and hydraulic machines. For very large work the screw machines are preferred to the hydraulic machines; but for small work, the former have the disadvantages of high cost, heavy weight, large floor area required, and mechanical power necessary to operate.

The hydraulic machines now on the market lack some of the objectionable features of the screw type, being less in cost and in weight, requiring less floor area, and being generally operated by hand. However, they are still out of the reach of the smaller laboratories and of construction jobs where concrete specimens of 6 or 8 in. in diameter are made up for testing. The small hydraulic machines on the market at the present time within the reach of laboratories and construction jobs from the standpoint of cost and size, are not of sufficient capacity to test specimens of mortar or concrete larger than 3 in. or less in diameter. To obtain a good average sample of concrete, specimens should be cast at least 6 in. and preferably 8 in. in diameter. A machine to test specimens 8 in. in diameter must have a capacity of at least 100 tons. A capacity of 125 to 150 tons is still more preferable as affording a slight excess capacity and also providing for cases where it is desirable to test an old piece of concrete such as is sometimes cut from a wall. Such a piece, even after sawing the faces true in a power saw, is apt to be irregular in shape and may run a trifle over 8 in. in one dimension.

With a view to obtaining, particularly for tests of mortar and concrete, a reliable, accurate, and efficient machine of a capacity up to 125 tons, at a low cost, and requiring comparatively small floor space, a design was developed by W. H. Weston, under the supervision of Mr. W. O. Lichtner, consulting engineer, Newton Highlands, Mass., and described by the latter at the recent convention of the American Society for Testing Materials. His description is as follows:

This machine consists of an ordinary hydraulic jack like those used in ship-yard work, set in a frame consisting of a heavy base and top. The top of the frame is provided with a head block having a ball-and-socket joint with about ½-in. play in the joint, so as to adjust itself to the specimen and give it a square bearing.

To cover the range required by small specimens of mortar and large blocks of concrete, two gauges are necessary. These gauges are calibrated to read the total pressure on the ram. The small gauge registers up to 20,000 lb. by 100-lb. intervals, and the large gauge registers up to 250,000 by 1,000-lb. intervals, with possibility of interpolation for finer readings. Specimens of small sectional area will break under a comparatively small load on the ram, so it was desirable to be able to take readings by 100-lb. intervals when reading on the small gauge. When the pressure on the ram exceeds 20,000 lb. the stop-cock on the small gauge is turned off, which prevents any further pressure coming on this gauge. This arrangement has been found to work very satisfactorily. Both gauges are equipped with a "maximum hand" which consists of a wire held on the main stem of the gauge hand by a spring in the form of a bent wire. This leaves the wire loose enough to be pushed around the dial of the gauge, but not so loose as to be jarred out of position when the specimen breaks. The top end of the wire is bent outward so as to be caught by the gauge hand as it moves around the dial when the pressure is applied. When the pressure is released, the gauge hand returns to zero and leaves the maximum hand to indicate the pressure which was reached when the specimen broke. The gauges have been carefully calibrated and register accurately at all points.

In order to protect the large gauge from the sudden release of pressure occurring when the specimen breaks, it was found necessary to design a check valve to be inserted in the pressure line to the gauge. This check valve consists of a small valve seated by a spring. When the pressure is applied, it forces the valve against the spring, allowing the water to pass into the gauge. When a sudden release in pressure takes place, the spring seats the valve and the water in the gauge gradually runs back to the pump by means of a very minute by-pass, which is in reality only a small scratch on the seat of the valve.

The jack is equipped with a single-stroke compound pump. The large plunger is used in raising the ram to a height sufficient to tighten the specimen in the machine, and then this plunger is thrown out of service, which allows the small plunger to operate. The large plunger raises the ram about 0.08 in. per stroke, while the small plunger raises the ram about 0.02 in. per stroke. The load should be applied to the test specimen uniformly. This cannot be accomplished with quite the same uniformity in a hydraulic machine that can be obtained in a screw machine on account of the upward stroke of the pump handle. It has been found, however, that with care the pump can be so operated as to apply the load very evenly and without a jerk, and that by making a quick return stroke of the handle the pressure may be considered as being increased continuously. In applying the load, the ram should be raised at the rate of 0.026 ft. per minute, which can be done by operating the pump handle so as to make a stroke and return in 3½ seconds. A clock arrangement is being devised to strike every 3½ seconds, so that the man operating the machine can accurately regulate the pumping. When the load on the ram reaches the vicinity of 125,000 lb. or over, a pipe extension about 3 ft. long is put on the end of the 3-ft. pump handle. This gives the operator the necessary leverage to operate the pump without the assistance of another man.

A guard should be placed around the working parts of the machine to protect them and also the operator of

the machine from injury when the specimens break. Concrete specimens having a height twice the diameter often break very suddenly, throwing small pieces of the specimen around in all directions.

The frame of the machine measures 20 by 32 by 60 in. high, outside dimensions, and the total weight is about 1½ tons.

The machine described has been in operation now for some time and has been found to give accurate and reliable results. The results have been checked several times by a series of check tests on a large expensive screw machine.

THE PREVENTION OF THE SUBCRUST MOVEMENT IN ROADS.

THE behavior of roads subjected to heavy traffic has been under the observation of road engineers everywhere, and in several instances certain experiments have been initiated to determine, as far as possible, the lateral and longitudinal movement of material forming the subcrust of highways. One of the investigators, Mr. E. S. Sinnott, M. Inst. C.E., county surveyor of Gloucestershire, Eng., read a paper before the recent Cheltenham convention of the Institution of Municipal and County Engineers, concerning his work. It is largely descriptive of observations made as a preliminary to more precise investigation under way, the former comprising the opening and inspection of various sections of grass verge adjoining the principal roads.

Speaking generally, these indicate that lateral movement, in some instances to a considerable extent, has been taking place, and such movement seems to call for special consideration.

The following examples will serve as illustrations: (i.) On main road (Gloucester to Bristol) at Whitfield, near Falfield. At this point the grass verges were opened on both sides of the road, and on the west side there was found, at a depth of about 4 in., a bed of broken limestone having a width of 3 ft. from the metalled surface, varying in thickness from 7 in. nearest the road to 4 in. at the 3 ft. distance. On the east side a somewhat similar state of affairs was found to exist, the width in this case being 2 ft. 6 in. from the verge. The subsoil is a hard, red clay. (ii.) On main road (Bath to Malmesbury) near Chipping Sodbury. In this instance the lateral thrust is shown in the movement of a line of channelling formed of three stones on edge put in to protect the foot of a bank: originally laid with a horizontal face of 13 in. in width, the stones having been forced into a vertical position, having moved through an angle of 90 deg. In several instances the upper stones have been forced completely over, having rotated through an angle of 180 deg., and have fallen backwards into the highway, their movement away from the road being arrested by the bank they were put in to protect. The subsoil is clay.

(iii.) On the main road (Gloucester to Bath) between Hardwicke and Stonehouse. In this case metalling and pitching have been found from 3 ft. to 5 ft. from the metalled surface, and about 18 in. in thickness. The subsoil consists of clay and sand.

(iv.) On the main road (Cirencester to Cheltenham) at Baunton Hill. The opening at this place showed that the original pitching and oolite macadam had been forced for a distance of 4 ft. from the edge of the metalled surface, the outer end showing an upward movement. The subsoil is clay.

The results above described indicate generally the position of affairs upon roads where traffic is heavy, although in a small minority of cases investigated little or no movement could be detected. It appears evident, however, that where lateral spread does occur it cannot fail to be ultimately destructive, as without substantial and immovable support the top coating cannot be kept up to its work, particularly after some wear has taken place, and it becomes a question how far new surfaces of an expensive character are justified before the subcrust movement referred to has been arrested.

With a view to obtaining more accurate information, the writer has lately placed a number of iron bolts below the surface of certain roads, and has fixed their position exactly by steel tape measurement, so that any movement can be definitely ascertained on a future occasion.

He has also inserted measuring instruments at various places, which consists of two rods arranged to slide one over the other, having iron plates at their outward extremities, which will enable any movement, either lateral or longitudinal, to be recorded.

As a means of preventing the action above described, the writer has recently designed and put into use a rigid framing, the essential feature of which is that longitudinal and cross members placed at a suitable depth below the surface preclude any movement of the subcrust, and at the same time provide a means of constructing an impervious arch of tarred macadam to carry the traffic, great additional strength being provided by the longitudinal members for the support of the heaviest road vehicles.

For various reasons, the writer thought it best to construct the frames in reinforced concrete, although timber or other material could, if preferred, be used.

The longitudinals are 12 in. by 3½ in. (average thickness) by 12 ft. long, and are slightly tapered from top to bottom. The ends of the longitudinals are securely housed at the extremities of the cross-ties.

The reinforcement consists of expanded metal 3 in. mesh ¼ in. by 3-10 in., weighing 11½ lbs. per superficial yard, cut into strips 9 in. wide—in the case of the cross-ties this is supplemented in a minor degree with wrought iron round bars of small section at the ends of the same.

A further modification consists of making the longitudinals slightly curved on the inside, in order to withstand lateral thrust more effectively; also, where difficulties due to traffic may be anticipated, in placing the cross-ties in position they can be made in two parts and connected in the centre with a bolt or bolts.

In the experimental frames which have been put down, the width between the longitudinals has been fixed at 8 ft., but there is no particular reason for adopting this dimension, other than that it appears suitable for dealing with the traffic conditions of rural roads in Gloucestershire, where most of the heavy weights are carried in the central portion of the highways.

If considered advisable, a greater width than 8 ft. may be adopted between longitudinals, or where traffic conditions justify it, the central pair can be supplemented by longitudinals on either side, connected thereto by cross-ties similar to those previously described.

The frames have been placed, the top edges of the longitudinals being 6 in. below the finished road surface, which, from the information at present at the writer's disposal, appears the most suitable position for arresting the lateral movement, also at this depth there would be little or no interference with pipes, and with 6 in. cover over the top side of the longitudinals there appears to be sufficient cushion to avoid any damage thereto.

Editorial

EXPERIMENTS WITH ROAD MATERIALS.

An English contemporary has the following to say about research experiments in connection with highway engineering: "Is it not time some one entered a protest against the waste of money in a lot of laboratory experiments on road material? The results of these tests are about as valuable as a knowledge of the canals of Mars. The sum and substance of road work is summed up in one word—'conditions.' Two roads constructed similarly of like materials, but upon the two opposite sides of a hill, will wear differently, and no amount of laboratory experiments will alter the fact. Again, a material which will serve admirably in an open country will not wear similarly if used through a woody, damp district. Further, there are materials admirable in certain positions used on the flat which are useless and dangerous if used on a gradient.

"This flinging of laboratory experimental results is a fad of faddists wanting to stereotype practice and to issue red-tape orders from a central office as to what is to be done in every corner of the land. Standardization and red tape are refuges for the destitute in common sense and the conceited empiric who believes that the result of an experiment upon granite, syenite, slag or other material is a solution of the problem where and when they should be used. No laboratory experiments will give relative values of various methods of road surfacing unless all the varying conditions of climate, soil, gradients, aspect, surroundings, character of traffic, etc., are known. The factors in the problem are too numerous to be solved by a laboratory experiment. You cannot get even some preliminary indication of probable results in the laboratory. The question of standardization is a wider one, but in most cases the result is to stereotype practice and to prevent men using their brains. It assists the degeneracy of a profession. There is no incentive to progress. What is, is, and is good enough."

What is, is not good enough; hence the field of experimental research. To ascertain, by experiment, the materials best suited for the conditions which prevail on either side of the hill, or for the conditions to be found in open country, in woody and damp districts, on the flat or on a gradient, entails the expenditure of some money, of course. But the saving to the country as a result of such experiments, and the comfort and other benefits that also accrue, cannot be reckoned in dollars and cents. The difference in cost of maintenance (and even of construction) between the scientific methods that are being so keenly investigated and the rule-of-thumb practices that have too long prevailed will be as evident, a few years hence, as a result of experimental research, as it has in so many other phases of municipal development.

"PROPOSED RAILWAY VIADUCT, TORONTO."

In view of the many arguments favoring the electrification of steam railways within city limits, as well as other points which it raises for consideration in connection with the proposed railway viaduct along the waterfront of the City of Toronto, we publish on another page a discussion submitted by a well-known consulting engineer and railway manager. Apart from the electrification feature, the question of clearance is one that merits further attention, as so much expenditure hinges upon it in an undertaking of this kind. Doubtless those not conversant with Canadian railway specifications will be surprised to learn that the requirement of 22 feet over top of rail, as in force in this country, is higher than any similar requirement in the United States or Great Britain.

CONSIDERATION OF TENDERS.

Tariffs are imposed on nearly all lines of importation into Canada, designed to equalize conditions between Canadian firms and foreign firms. When a foreign firm answers a formal call for tenders, and underbids a Canadian firm, despite the duty burdens imposed upon the foreign firm, the Canadian firm has no right to expect favoritism merely upon the made-in-Canada argument. Should the Canadian firm be able to make better deliveries or should the quality of its product be superior, then it is entitled to prior consideration even though its tender be higher, but not too high in proportion to the greater service it is prepared to render.

To a far less extent is any one section of the Dominion warranted in favoring local firms at higher figures in preference to other Canadian firms more distantly situated. The city of Vancouver recently bought a number of valves. Three tenders were finally considered. A United States firm bid \$8,405; a Walkerville, Ontario, firm bid \$8,485; a British Columbia firm bid \$9,700. The waterworks engineer and superintendent recommended the acceptance of the Walkerville tender. The waterworks committee of council favored the lowest tenderer, but the city council—by the mayor's vote—awarded the contract to the local firm.

This is dangerous practice, but in line, so far as engineering ethics are concerned, with other recent actions of the same council. It is reported that there is a general campaign in British Columbia in favor of using home-made goods in preference to goods made in other provinces or countries. This is said to be urged in the matter of requiring contractors for the Second Narrows Bridge across Burrard Inlet, which will cost approximately two million dollars, to specify that British Columbia-manufactured steel be used in the construction. The adoption of such a policy would have a very depressing effect upon British Columbia's credit in the money markets. Petty, narrow-visioned economics of this sort will surely not be allowed to prevail in the province that is ordinarily the most unselfish in Canada.

Before the United States Senate has appeared Senator Bryan's good roads bill, under the terms of which the federal government would issue 3 per cent. bonds to the amount of \$500,000,000 in instalments of \$100,000,000 each for 5 years, for road development. Before States could participate in the funds they would be required to issue an equal amount of 4 per cent. bonds, which, when deposited in the treasury department, would be exchanged for cash. The 1 per cent. difference would make up a sinking fund to aid the States in retiring the bonds. Creation of federal highway commissions to supervise the expenditure of highway funds is a feature.

PRODUCTION OF STRUCTURAL MATERIALS FROM QUEBEC MINES DURING 1913.

THE structural materials appear for a preponderating part of the total value of the mineral production of the Province of Quebec. In 1913, their value amounted to $8,187,917, which represents 62 per cent. of the total production. Under this heading are grouped cement, limestone, brick, granite, lime, building sand, clay products (tiles, drains, pottery, etc.) in the order of their importance. The following information is from the report for 1913 of the Mines Branch, Department of Colonization, Mines and Fisheries:—

Cement.—The cement manufactured in the Province of Quebec is exclusively Portland cement. The manufacture of cement is now an exact science, and it is almost impossible to find a natural mixture of clay and limestone which will give the results expected from a Portland cement. The natural cement industry in Canada has been entirely replaced by the manufacture of Portland cement, in which the raw materials are mixed in fixed proportions, according to a strict chemical control.

The composition of Portland cement is, therefore, definite, and, although the mixture of raw materials may vary within narrow limits, it should normally contain 75 per cent. of lime carbonate, 13 per cent. silica (soluble), 5 per cent. alumina, 1½ per cent. iron oxide (Fe_2O_3), and the remainder allowed for impurities, magnesium carbonate, alkalis and inert substances. The raw materials used in the Province are Trenton limestone exclusively, for the lime constituent, and Utica shale, or Leda marine clay, for the argillaceous component. These substances are very abundant. All along the north shore of the St. Lawrence River deposits of both limestones and clays are common.

In 1913, the cement mills of Quebec shipped 2,881,480 barrels, valued at $3,361,292. In fact, the value of the cement production was over 40 per cent. of the total value of the structural materials. Ten years ago, in 1904, the recorded production of cement of our province was 40,000 barrels, valued at $66,000.

Limestone.—The limestone industry is well developed in the vicinity of Montreal, where quarries have been opened at Mile End, at Outremont, Côte St. Louis, Longue Pointe, Villeray, Sault-au-Récollet, on beds of the Chazy and the Trenton limestones, both of which are well developed in the Island of Montreal.

At St. Vincent de Paul, St. François de Sales, where a great deal of the limestone is produced, the quarries are in the Trenton. The same formation is also worked at St. Marc des Carrières, Deschambault and Lachevrotière, in Portneuf county, as well as at Beauport and Château Richer, immediately below Quebec. Trenton limestone is also quarried in Hull, opposite Ottawa.

From returns received from producers, the limestone extracted in 1913 reached a value of $1,704,207. This, however, does not represent the whole production, for it is almost impossible to keep track of all the small operators who work spasmodically. From the 162 names of limestone producers to whom we sent return forms to be filled in, only 84 answers were received, many answering only after the second or third request. Of these 84, there were 44 who reported a production, and 40 whose quarries had been idle during the year.

Granite.—The Laurentian area, which extends to the north of the Ottawa and St. Lawrence Rivers, affords an unlimited supply of granites of various colors and textures, but, owing to the limited market, very few quarries have been opened. The main operators in the Laurentian granite are the Laurentian Granite Company, whose quarry is situated at Staynerville, in the county of Argenteuil; M. P. and J. T. Davis, who are working a quarry at Rivière à Pierre, north of Quebec, the stone being used altogether in the construction of the Quebec bridge.

Another source of granite is found in the various igneous intrusions which penetrate the rocks of Ordovician age in the Eastern townships, and large quarries on such occurrences are worked in the township of Stanstead; in the township of Whitton; on Mount Johnson, near Iberville Junction. The production of granite reached $496,588 in 1913, as compared with $358,749 in 1912.

Other Structural Materials.—There are no new developments in the other materials of construction. Brick and lime show very small increases as compared with the previous year, which may be accounted for by the fact that concrete construction is on the increase, as shown by the large increase in the production of cement. The sand which figures in the table of production only represents a very small proportion of the sand actually used in building operations, as we only keep record of the sand which is worked under mining licenses. Most of this sand is dredged or pumped from the beds of rivers.

PROGRESS ON THE C.N.P. RAILWAY.

A recent statement made by D. O. Lewis, divisional engineer of the C.N.P. company in British Columbia, announces that the work being done between Parsons Bridge and mileage 100 will be completed by the last of August. Mileage 100 is a point about 4 miles from Cowichan Lake and about 5½ miles from the Nitinat River. This means that before the end of next month the grade for over 100 miles will be ready for the sleepers and rails. The steel bridges, which are to be put at mileage 54, 68, 73 and 75, will be constructed as the rails are laid. The grade from mileage 100 to mileage 121, a point in close proximity to Alberni Canal, will probably be completed at the end of the year.

From mileage 121 to mileage 136½ the road is practically finished. Mileage 136½ is within 6½ miles of Alberni, so that, when the line from mileage 100 to 121 is finished, the road will be in condition for the rails as far as Alberni.

The wooden bridges beyond mileage 101 will not be built until all the grading is done and the rails are laid so as to avoid danger of their destruction by fire.

The line which will run from Patricia Bay down the Saanich Peninsula, round Swan Lake and Portage Inlet to Parsons Bridge, has been almost completed as far as the grading is concerned.

At Patricia Bay, where the rails are to be landed, a contract for the erection of the approach and pier has been awarded to S. Doe, of Victoria. The work is to be completed in 70 days. The steel for the small bridges will probably come from Vancouver; that of the larger structures, from Eastern Canada. The first cargo of steel will arrive at Patricia Bay between October 10 and 15; and another shipment is expected by the middle of November. These two cargoes will be sufficient for the road to mileage 100.

Plans are being prepared and considered in Denmark and Sweden for a channel tunnel between the two countries. The greatest depth at which the tunnel will run will be about 100 feet, and it is estimated that the undertaking can be completed in 5 years at a cost of about $25,000,000. The tunnel will be worked by electricity, and will be driven through the stratum of grey chalk underlying the northern European continent.

MOVABLE CRESTS FOR DAMS.

THE accompanying drawings show some types of automatic and hand-controlled flashboards, intended for use by the U.S. Reclamation Service. They were proposed by Gen. William L. Marshall, consulting engineer to the Secretary of the Interior, were described in an article in the May number of the "Professional Memoirs" of the Corps of Engineers, U.S. Army. The author calls attention to the fact that the two types shown at the top of the drawing are new but were patented by him some years ago, the straight or plane gate type (upper left-hand figure) having been in use since 1907 on one of the feeders of the Illinois and Mississippi Canal. Altered to suit local conditions, it is placed horizontally in the bottom of the feeder as an emergency stop gate, to rise and retain the canal level in case of a break in the banks. The particular gate was designed by Christopher Holth, mechanical engineer, and constructed by L. L. Wheeler, assistant engineer. The canal bank broke in 1910 and the gate automatically rose and closed the feeder, retaining the level in the feeder canal. It then repaid its cost.

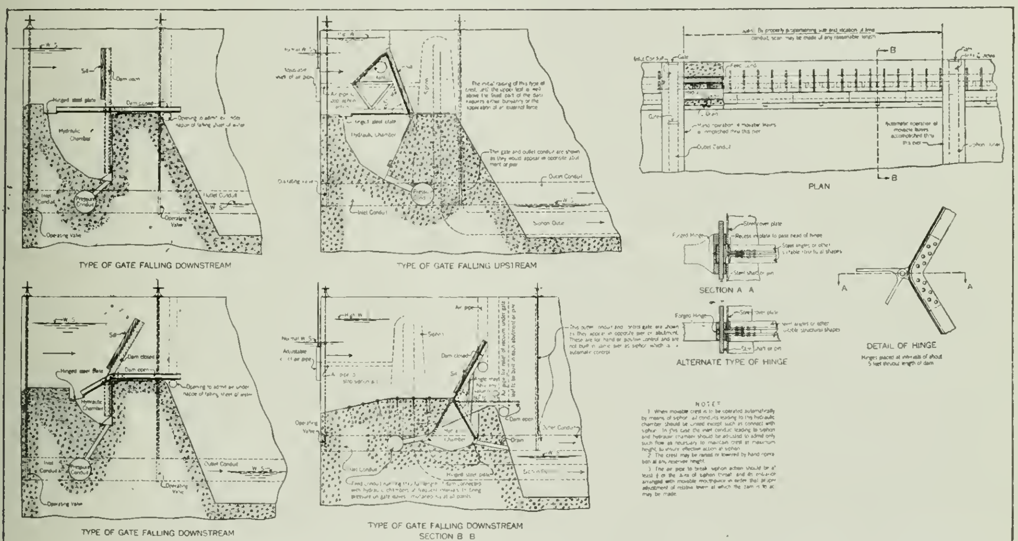

Fig. 1.—Types of Movable Dam Crests.

The second type, at the top of the drawing (without the wooden drift shield and siphon), has also been in use since 1907 as upper gates on fourteen locks on the Illinois and Mississippi Canal, but the lower leaves or aprons of those gates were designed of sufficient size only to depress the gates automatically when the locks are filled to within 10 in. or less of the surfaces of the upper pools. Those gates have worked successfully since 1907, although there were defects in workmanship that were corrected, and at least one uncorrected defect in design that is of no practical importance so long as the canal levels are maintained. These gates were also designed under General Marshall's patents by Christopher Holth, but the completed designs were not submitted to him for correction. This type requires flotation or auxiliary power to raise it until its nose is above water, when the current may act. It may be readily modified to be applicable to spans up to 100 ft., but is peculiarly adapted for use as an upper gate to a canal lock of 40 ft. or less span and not exceeding 10 to 12 ft. depth.

Later Types.—The two types at the bottom of the plate are believed to be novel, and have now been published for what they may be worth. They may be used by the United States freed from patent claims. Any one familiar with bear-trap dams will understand at a glance their working. The only features worth special remark are:—

1. The care taken to so arrange the hydraulic chambers as to cause mud and sediment to be swept by the motion of the gate into or near numerous water supply and exit pipes or "scruppers," and sufficient leakage to keep mud from accumulating. This leakage may be reduced to any extent by well-proved means.

2. The arrangement of piping for above purposes, and to secure uniform distribution of water pressures along entire length of gates by making main conduits of much greater capacity than that of all distributing pipes or conduits combined.

3. The siphon for automatic control of the gates during floods, in connection with, or rather, in addition to, hand control. These siphons "bleed" the supply mains before water in them may reach under pressure the small distributing pipes leading into hydraulic chambers, and have discharge capacities nearly equal to, but less than, the main conduits, so that (if the hand-operating devices be closed) whenever during a flood the water level above a dam reaches the level of the siphon throat or top, the siphon at once so "bleeds" the supply main that the preponderance of water pressure is at once changed from one side to the other of the axis of rotation of the gate, and it will fall and remain flat until the level in the reservoir falls below the air inlet to siphon, whereupon the siphon action is broken, the full pressure is again exerted

throughout the surface of the gate, the preponderance of pressure is again shifted from one side to the other of the axis of rotation, and the gate rises.

The type with siphon control falling down stream admits trussing or bracing, etc., so that it is possible to make it very light and at the same time strong and stiff against warping and of any reasonable length. It may be advantageously used up to 10 to 12 ft. lift on high spillways and dams. The width of that part below the axis of rotation in any of these movable crests should be not less than five-eighths the width of upper section, exclusive of width of flap leaf; the relative proportions of parts of gates should be computed to meet the special conditions in each case.

Steel plates are hinged to edges of lower sections and move along inclined planes in order that there shall be elasticity in the system even under considerable wear at axis and inaccurate work. The gates will not be subject to wedging and obstruction by gravel, chips, etc., and these narrow leaves remove most of the objections that have been made to drum weirs, etc., the leaves of which must be nearly in contact with the curved surfaces of hydraulic chambers, and are often wedged. These plates may be in sections of desirable lengths, the joints between lengths may be stopped against leakage by strips of pure rubber packing, allowing any section to rise or descend enough to pass over any chance pebble or chip without serious leakage, or straining the gate, and the plates as a whole to adjust themselves to wear or inaccurate workmanship, location of axis or informing the plane surfaces of the hydraulic chamber.

4. The air passages to remove vacuums that form under the gate, due to rapid flow of water over it when down, are not novel except in the particular disposition of them. Vacuums more or less complete under overfalls increase materially the pressures on the upstream faces of gates and dams; cause tremblings and vibrations in dams, and in old bear-trap forms sometimes determine whether they can be worked at all in certain positions or phases of their motion.

The question of prevention of partial vacuums, then, is of some importance in all dams, whether movable or fixed, and especially so in bear traps, where little or no attention has been given the subject.

Regulation of Levels of Reservoir With Spillway Crests and Sluiceway Gates.—Some criticisms of automatic movable sluice gates have been based upon the opinion that their movements are so rapid that there would be thrown into the stream below the reservoir large amounts of water en masse, thus creating waste of such magnitude that damage to animal life, or to property, might result.

This objection is well founded, but, when it is considered that the movable crests, or spillway gates proposed are in fact hydraulic engines, capable, if properly constructed, of as smooth, gradual and certain movement and control (and by similar methods) as any other hydraulic press or engine, the point is of small importance.

It is necessary for this purpose in a series of sluiceways controlled by automatic gates to provide one and only one sluiceway of the series, with a hydraulic gate to be operated carefully by hand, in order to make the increase in discharge as gradual as it would be over a fixed or movable horizontal weir of suitable length, by filling in by gradual increase in discharge the differences in total discharge caused by the sudden periodic gate movements.

For instance, suppose there is an available site 350 ft. in length for a spillway to be used in connection with a large reservoir, and that the maximum flood to be wasted is about 25,000 sec.-ft. and it be desired to store all water practicable in the reservoir, with a fluctuation in its water level of about 2 ft.

The effective depth of the sluiceways, if 50 ft. wide each, must be 9 ft. at maximum flood level, and there must be six of such sluiceways of that width to discharge the maximum floods of 25,000 sec.-ft.

The sluice gates or movable crests may be made of 7-ft. lift each, and the water levels in the reservoir must be so controlled as to rise not more than 2 ft. above their crests when raised.

Each 50-ft. sluiceway 7 ft. deep will discharge approximately 3,000 sec.-ft. When the water rises to the limit assumed there will be 9 ft. depth in the sluices and the discharge of each will then approximate 4,500 sec.-ft. The discharges may be less than above given, but they are assumed for the purposes of a demonstration; accuracy is not now in question.

One of the sluice-gates is to be of most careful construction, and fitted in all its parts for hand control and operation, and five of them are supposed to be operated automatically by siphon, all gates being of a type falling down stream from the reservoir. These latter have the siphon throats and their air-entrance breaks adjusted in level so that the gates will fall in succession, upon increments of, say, about 3 in. in reservoir levels, beginning with the first gate falling when that level reaches 7 in. above the crest when raised, and the last or sixth gate falling when the water level of the reservoir is about 3 in. below the maximum safe limit named above. Now, when the water level in the reservoir rises until it is nearing 7 in. above the crests of the gates—at which level the first gate is arranged to fall—the operator would begin to lower the hand-operated gate at a rate that preserves the level of the reservoir water until that gate be fully depressed.

Whenever the first automatic gate goes down, the hand-operated gate should at once be raised, and the same gradual movement of the hand-operated gate be resumed between the falling of the first and second, etc., and succeeding automatic gates, if such care be necessary. It is, then, practicable to make the discharge from a reservoir by the use of these gates, or indeed of any of the "bear-trap" family, as gradual and regular as by any other device, even if that device be a fixed weir, but the controlled sluiceways have the material advantage over the fixed weir of allowing the storage of 7 ft. (in this case) depth of water over the entire surface of the reservoir, which cannot be done by a fixed weir of same length of crest with as little waste and as little fluctuation in water level in the reservoir, and the sluices moreover, serve admirably for drift chutes.

In some very large reservoirs now in existence, or under construction, this additional storage of 7 ft. in the reservoir might run to a hundred thousand acre-feet or even much more, a matter of very great importance in our arid region, where water is so precious for irrigation and domestic use.

EXPLOSIVE PRODUCTION.

The United States Bureau of Mines has compiled some figures on the production of explosives in the United States in 1912. It appears that there were manufactured, 230,233,369 lbs. of black powder; 24,630,270 lbs. of permissible explosives; and 234,460,402 lbs. of high explosives, such as dynamite, nitroglycerine, etc. Of the high explosives, 89,703,081 lbs. were consumed in mining other than coal and 4,668,399 lbs. of permissible explosives in the same industry.

ELECTRIFICATION OF STEAM RAILWAYS.

IN *The Canadian Engineer* for July 9th, 1914, appeared a discussion of the steam railway electrification problem, by Mr. J. A. Shaw, of the Canadian Pacific Railway Company. The following, extracted from a paper read by Prof. D. D. Ewing before the Indiana Engineering Society, will be found of particular interest, as the statements advanced by both authorities leave little to be desired in the matter of general information respecting the systems that have received practical recognition. Prof. Ewing states that power companies are interested in electrification because they have electrical energy for sale. The railway companies can build and operate their own power plants, but in many cases they find it cheaper to buy energy than to generate it, the low ratio of average demand to maximum demand making a railway load alone rather unprofitable for a power station.

As far as the power station and transmission lines are concerned, nearly all systems of electric traction are similar, consisting generally of three-phase power generation and high voltage and three-phase transmission. It is in the motive power equipment and the distribution systems that the differences come. Four systems are finding practical application to-day.

Direct-Current System.—In this system direct-current series motors are used on the locomotives or motor cars and voltages ranging from 600 to 2,400 volts are used on the trolley or third rail. The trolley or third rail and its feeders receive direct-current energy from substations located at intervals along the right-of-way. In the substations, transformers and rotary converters change the high-voltage three-phase currents of the transmission system to direct current at the proper trolley voltage. This is the well-known system used on street railways, modified to meet the demands of steam line traffic, and up to the present time has found wider application in this country than all of the other systems put together. Of interest in connection with this system is the recent announcement that the Chicago, Milwaukee and Puget Sound Railway has decided to use it in its electrification over the Rocky Mountains.

Single-Phase System.—Either series or modified repulsion type, single-phase motors are used on the locomotives or motor cars. The trolley receives its single-phase current supply from transformers, located at intervals along the line, which transform the high voltage of the transmission system to a value suitable for the trolley. Trolley voltages range from 3,300 to 25,000 volts, 11,000 volts being common in this country. A balanced three-phase load is approximately secured by dividing the trolley line into sections and feeding the different sections from different phases. Transformers on the locomotives or motor cars step the trolley voltage down to a value suitable for the motors. The motors are rather complicated and have high maintenance charges. On account of the high trolley voltages used, the first cost and line losses of the distribution system are low. The most prominent example of this system, in this country, is that of the New York, New Haven and Hartford Railway.

Three-Phase System.—In this system three-phase induction motors are used on the locomotives, and two trolley wires are required, the track forming the third leg of the three-phase circuit. Trolley voltages up to 11,000 volts have been used. Transformers on the locomotives step the trolley voltage down to a value suitable for the motors.

The two trolley wires required complicate the overhead work, but the motors are simple and rugged. The system is readily adapted itself to regenerative control ot trains on down grades. The motor is inherently a constant speed motor, and will carry its load up grade approximately as fast as it will carry it down grade or on the level. With some modifications in the design of the motor, its speed can be varied in steps without seriously affecting its efficiency.

The Great Northern Cascade Tunnel electrification is the only example of this system in this country, although locomotives having an aggregate rating of about 200,000 h.p. are in use in Europe.

Split-Phase System.—The locomotives are equipped with polyphase motors and single-phase current is supplied from the trolley. A phase converter on the locomotive converts the single-phase energy to the polyphase energy required by the motors. The distribution system is the same as with the single-phase system, and the motive power equipment is the same as with the three-phase system, with the exception of the phase converter. In a measure the good points of both systems are combined. The system is a new one, and is possibly the most spectacular development in electric traction made during the year just passed.

Advantages and Disadvantages of Electric Traction.—The following are a few of the more important advantages and disadvantages of electric traction for railway trains. Briefly, the advantages are:—

The safety of operation is increased because signals are not obscured by smoke and steam, and the locomotive-driver can give his entire attention to driving, and his seat can be located so that he can see both sides of the track at all times.

Regenerative control is possible with all systems of electric traction. With regenerative control the air-brakes are used only in stopping or in case of emergency. Car wheels and brake shoes are not heated by long-continued applications of the brakes on down grades, and the number of wrecks due to cracked wheels is lessened. The energy that would otherwise be used up in heating the brake shoes and wheels is pumped back into the line and helps pull some other train up hill. While regenerative control is possible with all systems, it has not been used on all systems in the past on account of the resulting complication in the control apparatus and motor windings of series type motors.

The dispatcher can stop a train at any time by ordering the power supply shut off from the section in which the train is running, and the control mechanism may be readily arranged so that the brakes are applied automatically if the power is shut off from the trolley.

In mountain grade work, higher speeds may be maintained over the grades than is possible with steam locomotives. Going upgrade, the speed of the steam locomotive is limited because its power output is limited by the boiler capacity. The electric locomotive is not limited in this way, and for short intervals it can carry large overloads.

Powerful motors can be mounted on comparatively light locomotives. While the weight of a locomotive fixes the drawbar pull at starting, its horsepower capacity fixes the pull when running at a given speed. This means that electrically operated trains can be accelerated at much higher rates than steam trains and can be operated at higher speeds over grades.

Electric locomotives require inspection once in from 1,200 to 2,500 miles of operation. To keep steam locomotives in similar condition they must be inspected and cleaned at the end of every run. On those roads which are operating electric locomotives, the daily mileage of

the locomotives is from 25 to 50 per cent. greater than the steam locomotives which they replaced, and their reliability is indicated by the fact that the delays chargeable to motive power are less than 50 per cent. as compared with steam motive power.

Experience has shown that the fuel cost with electric operation is from 40 to 75 per cent. of that with steam operation. There are no standby losses. Prof. Goss has estimated that one-fifth of the coal burned under locomotive boilers is burned while the locomotives are standing on sidings, or in starting fires.

The first cost of electrification is high as compared with the first cost of steam motive power. The cost of steam motive power for the average steam road is about $2,000 per mile of single track, while the cost of electric motive power runs from $7,000 to $12,000 per mile of single track. The cost of terminal electrifications may be even higher.

Power-house accident might put a whole railway system out of commission. The dependence of the electric locomotive on the power-house tends to make it inflexible in some respects.

Steam locomotives have passed through the development stages and are practically a standard product. They have developed to their present perfection through a period covering nearly a century. They are reliable and remarkably efficient, considering the conditions under which they operate, and their characteristics and limitations are well understood by a majority of the operating men. On the other hand, electric traction as applied to railway trains is scarcely two decades old. Progress in the electric arts has been so rapid during the past quarter of a century that apparatus which to-day represents best modern practice is likely to be on the scrap-heap tomorrow, not because it is worn out, but because it is obsolete.

Long-continued overloads overheat and burn out the electrical equipment. Such overloads are common in railway service and do not seriously injure a steam locomotive. If the overload on a steam locomotive is too great, it simply stops work, and no serious injury results.

As the rails are used as part of the main power circuit, the signal circuits for electric block signals and for interlocking plants are more complicated and expensive to maintain.

While no trainmen within the motor cars or locomotives have been killed or seriously injured, there have been a few fatalities among the men employed outside.

The losses, in a poorly-designed transmission and distribution may amount to as much as the power actually used to operate the trains.

In general it may be said that no one system of electric traction is best adapted to all classes of service. The direct current system seems best adapated to terminal work where a large number of trains are operated, and where, on account of the large number of stops per mile, rapid accelerations are necessary. On account of the denseness of the traffic the substations may economically be placed close together, and, as the distances are short, transmission losses are low. As far as fulfilling the general requirements of railway service is concerned, the series direct-current motor is the best motor available. But its use is limited because it cannot be operated at high voltages; low voltages on the trolley mean high line losses. Likewise, the alternating-current systems, with their high trolley voltages and low line losses, and motors which lack the powerful starting torque of the direct-current series motor, seem best adapted to long trunk-line service where the stops are few and the accelerating period is short as compared with the total time of the run.

Coast to Coast

Winnipeg, Man.—Excellent progress is reported upon the work of erection of the new Parliament buildings and court house at Winnipeg.

Brantford, Ont.—It is claimed that the C.P.R. will transform into an electrically operated road the new L.E. and N. Railway being constructed between Brantford and Lake Erie.

Owen Sound, Ont.—On August 1, plans for Owen Sound's drydock were filed with the Ottawa department of public works. The structure, which will be 775 feet long, will be the largest drydock on the Great Lakes.

Medicine Hat, Alta.—Several carloads of building materials have been delivered to the site of the Saskatchewan Bridge and Iron Company's factory; and the work of construction has started on the laying of brick and the erecting of the iron work.

Ottawa, Ont.—It is announced that the contract for the construction of the Morrisburg and Ottawa Electric Railway has been let; but further details concerning the contract will still be published. It is expected that the work on the line will commence very soon.

Revelstoke, B.C.—The automobile road which is being constructed to the summit in the Revelstoke national park is reaching completion. The work is starting at the upper end of the completed portion of the road, and 10 miles will be completed this summer at an estimated cost of $27,000.

Ottawa, Ont.—A flow of water of the highest quality was struck recently at Ottawa, while excavation was proceeding for the furnace room of the new horticultural building in the city's exhibition grounds; and it is believed that by the opening of the exhibition, a supply can be piped to all parts of the grounds.

Toronto, Ont.—The new registry office which is to be constructed in Toronto, is estimated to cost $400,000, and to be completed in 18 months. It is planned to be a 2-story structure with a basement, which is to contain a bindery in addition to regular equipment; and it will be as nearly fire-proof as possible.

West Vancouver, B.C.—The urgency of providing a water supply to West Vancouver is receiving the attention of the ratepayers and council of the municipality; and a report is to be made by the municipal engineer in the near future.

Quebec, Que.—About two weeks ago was commenced the work of setting in position the four shoes, upon which will rest the superstructure of the Quebec bridge, and which have been made by the St. Lawrence Bridge Company. Three cars were required to ship each shoe, and each has a weight of 204 tons and took 2 months to manufacture.

Brantford, Ont.—The hydro-electric branch line between Brant substation and Port Dover is to be commenced immediately. A new aluminum steel-covered cable has been completed by the commission between Brant substation and Dundas; and further protection is to be given to the city by the construction of a fourth series of cables from Niagara Falls to Dundas, according to a recent announcement made by the commission.

Fredericton, N.B.—Repairs are in progress on the road-bed of the Canada Eastern division of the I.C.R. New ties are being laid between Fredericton and Loggieville, and new sleepers are to be placed along the same portion of the line this month, as well as about 40 miles of 85-pound rails on different section of the same length of line. On the portion between Blackville and Derby Junction, 85-pound rails have already been installed.

Victoria, B.C.—Further delay in the progress of arrangements for the construction of the Johnson Street bridge structure has arisen owing to the request of the British Columbia Electric Railway Company to have modifications made in the plans for the bridge in order to widen it to 47 feet and to provide for the passage over the bridge of freight cars; and to have the bridge made stronger beneath so that heavy cars may be conveyed across it with safety.

Indian Bay, Man.—A recent inspection of the Falcon River diversion works at Indian Bay made under the auspices of the Greater Winnipeg Water District Commission shows that very rapid progress is being made. A distance of 1,500 yards has been built in the four weeks since the commencement of operations; while still more rapid work will now be done, since three engines, instead of two as previously will now be used for the hauling of sand and gravel.

Moose Jaw, Sask.—It is now expected that the necessary financial arrangements for the city's programme of sewer, watermain, sidewalk, and paving construction will soon be completed. And since no injunction has been served on the city by the Bitulithic and Contracting Company of Winnipeg to restrain the National Paving and Construction Company of Regina from proceeding with the paving for which it was awarded a contract in June, it is likely that the entire programme of works will be set in operation at once.

Victoria, B.C.—The contractors, Sir John Jackson, Limited, have erected another dolphin off Macaulay Point to replace their fifth dolphin which was carried away recently when a tug with a scow became entangled with the piles. It is expected that some time will elapse before this fifth breakwater dolphin, which marked the extreme end of the seawall, can be again placed in position. In the meantime the newly erected temporary dolphin will facilitate the dumping of rubble on the final 750-foot section of the breakwater.

Red Deer, Alta.—An announcement has been made which states that the Alberta Central Railway, a subsidiary line of the C.P.R. system, which extends for 60 miles from Red Deer to the Rocky Mountain House, will be taken over by the latter railway company at the conclusion of the present month, when a service will be placed in operation. All construction work on the line has been completed and all that at present delays the opening of the new branch is the lack of the consent of the board of railway commissioners, who have not yet made an inspection.

Barton Township, Wentworth County, Ont.—Some of the improvement work at present being carried out in Barton township includes concrete sidewalk construction approximating $16,000 and being undertaken by Chas. Brayley; while a staff of engineers is engaged upon plans for a comprehensive sewer and water scheme for the township, which, in the event of favorable consideration by both the township and city of Hamilton councils, will be constructed at a cost of $500,000. These plans, if possible, are to be completed and ready for submitting the first week of August.

Montreal, Que.—News comes from Montreal that the commission which was appointed to study the problem of the lowering of the water levels in the St. Lawrence River expects to hand in its report in time for action to be taken at the coming session of Parliament. The commission began its investigations last summer, and it is at present making examinations at Cap Rouge. It has been said that a system of weirs will be the possible recommendation to prevent the water from becoming shallower, these having been found satisfactory in other rivers.

Winnipeg, Man.—At the next session of the Greater Winnipeg Water District board, a deputation of Winnipeg business men will urge that still greater efforts be made to secure for Winnipeg a better supply of water considerably in advance of the contemplated time. It is believed that, with greater speed, the work can be completed within 3 years, rather than within 5 years' time. Business men of the city state that the water supply from the wells, though comparatively pure, is very hard and thus detrimental to the equipment of their establishments, causing them annually an enormous expenditure for the replacing of machinery.

Brandon, Man.—The city of Brandon is making every endeavor to hasten the completion of the construction of the G.T.P. Railway line into Brandon. To this end, a new matter which is to be brought before the Board of Railway Commissioners is with regard to a double subsidy which the railway company will receive in case the construction exceeds $15,000 per mile. A single subsidy of $32,000 per mile was provided in case that the construction work cost $15,000 or under; but if it exceeds $15,000 per mile, provision has now been made for a double subsidy, amounting to $64,000 per mile. Another new phase is that the company will be given an additional grant of 35 per cent. of the cost of the bridge, which will be required to be constructed to admit of the entry of the line into the city.

London, Ont.—The form of construction which will comprise the major portion of the work on the London breakwater provides for a 3-foot by 2-foot concrete base toe line and a 26-foot natural slope front of embankment, faced with reinforced concrete 11 inches thick at base and 7 inches thick on top of slope, where provision is made for a substantial concrete cap and a 5-foot sidewalk with guard tubular iron railing. Short lengths of vertical retaining walls will be necessary at the Oxford and Blackfriars bridge ends of the breakwater. The proposition is to provide for a top area of embankment, giving provision for a driveway, and utilizing existing conditions without disturbing trees or making excessive filling necessary in fixing face line of embankment. The estimated expenditure, as authorized, is $25,000.

London, Ont.—A report made following a recent inspection of the work being done on the London and Port Stanley Railway, shows that the new steel has been laid from St. Thomas to Port Stanley; and that new rails are being laid north of St. Thomas, this work on the whole line from London to the lake being practically completed. No statement of cost has yet been given on the roadbed, the 23 miles of steel rails, the 70,000 ties and the ballasting. A number of new sidings are to be constructed; and at present, the foundations of a new freight shed are being laid, which building it is expected to have completed by fall. The officials of the railway say that the road will be in operation within a few months, though so far no rolling stock has been purchased. However, they plan to lose no time in expending the $750,000 which has been expropriated for the electrification of the line.

Edmonton, Alta.—In addition to an offer of cheap power which has just been made to the city of Edmonton by New York and San Francisco engineers, it is understood that a second proposition is to be made by a syndicate, for which Sir John Jackson, of Montreal and London, Eng., is engineer. The site for the water power plant is just 50 miles from the city on the Saskatchewan River, above the Rocky Rapids. For two years or more, the company has been investigating and studying the location, and many plans have been prepared, showing where 3 immense storage dams can be built, capable of holding several hundred million cubic feet of water each. The scheme contemplates the development of 40,000 horsepower, while investigation has shown that further power can be secured when the load increases. The approximate expenditure, which the company estimates will be spent in harnessing the Saskatchewan River, is $6,000,000.

St. John, N.B.—Four hundred men, 5 tugboats, 3 dredges, 2 locomotives and trams and 4 reclamation plants are engaged upon the scheme of reclamation and development which is in progress on the western side of the St. John Harbor, where berths are being constructed to accommodate some of the large ocean steamships of the C.P.R. Company this coming winter, and where the contract is held by the Maritime Dredging and Construction Company, sublet to Cape and Company and to Mr. D. C. Clark. Three hundred workmen, 1 powerful suction dredge, 3 high-power elevator dredges, an ocean tug, 5 locomotives and ballast trains, 2 steam shovels, and other accessories, are being constantly employed by the Norton Griffiths Company in pushing forward the harbor and industrial development at East St. John. The firm has almost completed an immense breakwater of stone; has reclaimed over 12 acres of land for a ship repair plant; has excavated about one-third of the site for a dry dock; and has made considerable progress in dredging berths inside the breakwater for ocean commerce and in widening and deepening the entrance channel. Next spring the company will begin the construction of concrete and steel cylinder quays for ocean berths, and a pier at the entrance to the dry dock. The contract, which expires in 1917, covers the supplying of 23 steamship berths and involves an expenditure of over $30,000,000. It is expected that this particular point will be utilized by the G.T.P.R. Company.

Moose Jaw, Sask.—Recently, what was thought might prove to be a serious break occurred at the infiltration gallery at the headworks of the Moose Jaw water system at Caron, Sask. The break occurred while the water department was engaged at cleaning out one-half of the Rosedale reservoir, which has not been cleaned since put into commission in December, 1912. The break is a large one and only a few feet west of the pumping station, so that it does not allow of the water being brought in through the infiltration gallery. A large flume has had to be built out to the side of the natural reservoir and a steam pump installed. In this way the water now being used in the city is being pumped twice. In the first place, it is pumped from the reservoirs into the flume by the steam pump, and afterwards from the well into the pressure main to the reservoir. The cleaning of the reservoir has proven, apart from this, to be a difficult task, no provision having been made for the like at the time of its construction. One-half of the big reservoir, which has a capacity of 1,000,000 gallons, was left full, while the other half was emptied and Moose Jaw supplied with water direct from the pressure main from Caron. During the 18 months that the reservoir has been in use, there has been deposited in the bottom of it almost 4 feet of silt. This has been pumped into a surface reservoir which had to be constructed on a street north of the reservoir. The work has been in charge of Commissioner Mackie of Moose Jaw; and no further serious trouble is anticipated by him from the break at the headworks, provided none is caused by the steam pump before the break has been repaired.

PERSONAL.

J. B. NICHOLSON, B.A. Sc., is engineer for the Township of Barton, Ontario.

H. E. M. KENSIT, has tendered his resignation as city commissioner for the city of Prince Albert, Sask.

W. V. HUNT, electrical engineer in the employ of the British Columbia Electric Railway Company for the past several years, has resigned to engage in private practice in Vancouver, B.C.

OBITUARY.

The death has been reported from Porcupine, Ont., of Mr. B. C. Wolfram, manager of the West Dome mine.

It is reported that Mr. Louis Margolin, formerly with Clarke and Lyfrod, forest engineers, of Vancouver, met death recently in the Sierras, Nevada, by drowning. Mr. Margolin, who was 34 years of age, was a well-known timber estimator in British Columbia.

NEW CANADIAN MEMBERS A.W.W.A.

Among recent additions to the membership of the American Water Works Association are noted the following names:—

James Barr, M. E., Department of Water Works, city of Toronto.

R. C. Harris, Commissioner of Works, city of Toronto.

Robt. B. Owens, B.A., B.E., Governmet Buildings, Edmonton.

Joseph Race, City Bacteriologist and Chemist, Ottawa.

R. A. Ross, Consulting Engineer, Montreal.

Jas. T. Wickham, City Engineer's Office, Eastern Division, Montreal.

JOINT ROAD CONGRESS IN 1915.

The matter of holding a joint convention or congress in which the American Highway Association and the American Road Builders' Association are the chief factors, is under consideration in connection with the Panama Pacific Exposition in 1915. The meeting will probably be held at Oakland or San Francisco.

COMING MEETINGS.

WESTERN CANADA IRRIGATION ASSOCIATION.—Eighth Annual Meeting to be held at Penticton, B.C., on August 17, 18 and 19. Secretary, Norman S. Rankin, P.O. Box 1317, Calgary, Alta.

AMERICAN PEAT SOCIETY.—Eight Annual Meeting will be held in Duluth, Minn., on August 20th, 21st and 22nd, 1914. Secretary-Treasurer, Julius Bordollo, 17 Battery Place, New York, N.Y.

CANADIAN FORESTRY ASSOCIATION.—Annual Convention to be held in Halifax, N.S., September 1st to 4th, 1914. Secretary, James Lawler, Journal Building, Ottawa.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown, Indianapolis, Ind., Secretary.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—11th Annual Convention; 5th American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau St., New York, N.Y.

STORAGE ON THE UPPER ST. MAURICE RIVER

PROPOSED MASONRY DAM AND STORAGE WORKS NEAR LA LOUTRE FALLS FOR THE REGULATION OF RIVER FLOW—TO BE ERECTED UNDER EXTREME CONDITIONS OF TRANSPORTATION AND CLIMATE.

A DIFFICULT storage undertaking, but one that will have an important bearing upon power development and the lumbering industry in northern Quebec, is under construction. The consideration of flow regulation of this river was adopted by the Provincial Legislature in 1912, and an act was passed granting additional powers to the Quebec Streams Commission for the execution of the works provided for. Since that time, the engineers of the commission have gathered all available data concerning precipitation, run-off and evaporation on the watershed, as well as the stream flow of the river and its tributaries. This information was, generally speaking, too meagre to be of much value, necessitating the establishment of gauging stations all along the river, as well as other careful data compilation.

Records of daily observation at Shawinigan from 1900 to 1912 had shown that the minimum flow of the river was 6,000 cu. ft. per sec., representing 0.37 cu. ft. per sec. for every square mile of drainage basin. The proportion of the flood to the minimum flow on the St. Maurice is, generally speaking, 30 to 1. The commission, after careful study, ascertained that, by a storage dam above the La Loutre rapids a volume of water estimated at 160 billion cu. ft. could be stored. The flow thereof could be made as follows:

For 150 days	....	12,345 cu. ft. per sec.
" 200 "	....	9,317 " "
" 250 "	....	7,407 " "
" 300 "	....	6,172 " "

The present storage reservoirs on the Manouan River, a tributary of the St. Maurice, give a total storage of 590 square-mile-feet, or 16,448,256,000 cubic feet, equal to a flow of:

For 150 days	....	1,269 cu. ft. per sec.
" 200 "	....	952 " "
" 250 "	....	761 " "
" 300 "	....	635 " "

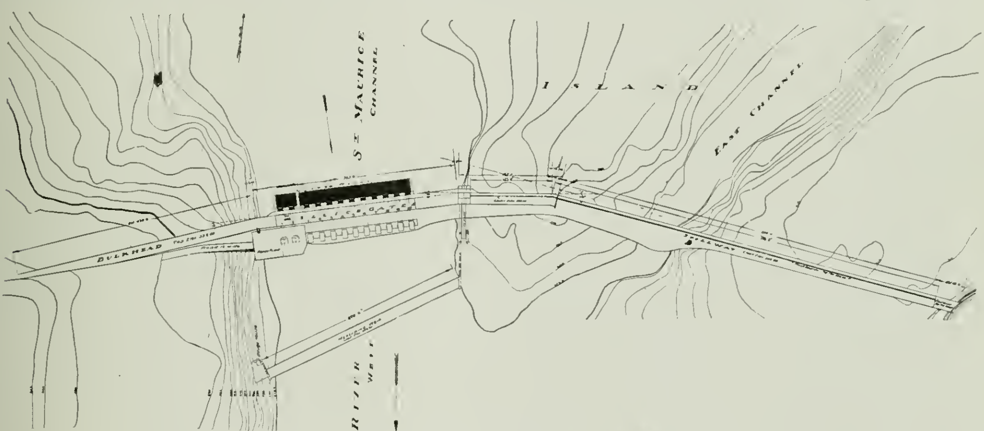

Fig. 1.—Plan of the Proposed Dam on the St. Maurice River.

But a close analysis of the records giving the flow at Shawinigan shows that, for the year 1906, the lowest year for the period from 1900 to 1912, it was as follows:

Under 12,000 c. f. s.	—230 days	—Average	8,000 c. f. s.
" 15,000 c. f. s.	255 "	"	8,558 c. f. s.
" 18,000 c. f. s.	270 "	"	9,030 c. f. s

The records for 1911 show practically the same conditions. To regulate the flow to 12,000 cubic feet per second would have required an average of 4,000 cubic feet per second for 230 days. The storage of the two reservoirs will give, for the same period, 8,051 and 828 cubic feet per second respectively, leaving in the reservoirs 4,879 cubic feet per second, or 55% of the water stored.

The regulating of the flow to 15,000 cubic feet per second would, in the same year, have required an average of 6,442 cubic feet per second during 255 days. The two storage reservoirs could give for that length of time 7,262 and 746 cubic feet per second respectively, leaving 1,566 cubic feet per second, or 19½% stored water not needed.

The regulating of the flow to 18,000 c. f. s. would have required an average of 9,000 c. f. s. for 270 days. During that period the reservoirs would only give 6,859 and 705 c. f. s. respectively, say, a deficiency of 1,437 c. f. s. The river could not be regulated to that high figure in a year when the rainfall is very low.

The river could, however, be regulated at 15,000 c. f. s. at Shawinigan, leaving an over-supply of the stored water in a very low year. But the commission deem it advisable to provide for the loss in the volume of water from the storage reservoirs, especially in winter, while coming down the distance of 220 miles to Shawinigan. And the fact also is not overlooked that water may be needed for floating logs at a time when it would not be wanted for power purposes.

For these reasons the commission adopted a flow of 12,000 c. f. s. to compute the increased value of the water powers concerned. A scheme was accordingly worked out, as outlined below, for storage above La Loutre falls.

It should be remembered that at present 206,300 h.p. are being developed on the river; viz., Shawinigan 163,000; Grand'Mère, 19,500; La Tuque, 3,500. In addition, the Shawinigan Power Company is adding two units of a capacity of 37,000 h.p., while the plant of the Laurentide Company at Grand'Mère is being added to, increasing the capacity of the plant to 120,000 h.p.

The present and future value (after regulation) of the water powers of the St. Maurice River are indicated in Table I.

The site of the proposed dam across the St. Maurice, 2⅓ miles above the falls of La Loutre, is 120 miles from Escalona, 37 miles in a straight line north of Parent, a divisional point on the Transcontinental Railway, and 240 miles from the St. Lawrence, following the course of the river.

In its preliminary laying out, bench marks were established on all important lakes and at all falls. Two different level lines were run with the same instrument, one checking the other by means of the height of the instrument. A party under Mr. W. Thibaudeau, assistant engineer, starting from Escalona on the Transcontinental, proceeding to the site of the dam and from there by way of Manouan, back to the Transcontinental, completed the circuit of 180 miles. The allowable error was not to exceed 0.05 d where d was the distance in miles. The results obtained were found considerably less in error than that amount. These levels checked figures previously obtained respecting the elevation of various lakes forming part of the drainage basin whose waters it is proposed to store. Some 35 bench marks were established at the falls and on the various lakes during 1913.

Another party proceeded to the site of the dam to investigate the nature of the ground. Its borings were made with the use of a McKiernan-Terry core-drill mounted on a raft 20 ft. x 20 ft. and moored by cables and pulleys to a steel cable across the river. Each boring was located by triangulation and was carried down to a depth of 12 ft. to 15 ft. They were made at 20 points in the western and 8 points in the eastern channel of the river, the total length of rock examined being 323 linear ft.

Gaugings were recorded at La Loutre to supplement those available at Shawinigan, 220 miles distant. The flow of the river was measured by determining the velocity and the cross-section, the velocity being measured by a Gurley current meter. The average velocity was determined at 3 points; viz., 0.2, 0.6 and 0.8 of the depth as per the method commonly used. The maximum flow was observed to be 14,500 cu. ft. per sec. and the minimum

Table I.—Statement of the Water-powers on the St. Maurice River.

NAMES.	Distance from St. Lawrence, (miles).	Head in feet.	Approximate area of drainage basin above (sq. miles).	Actual minimum flow, 0.37 cu. ft. per sec. per sq. mile.	Present value 80% efficiency. flow 3,500 cu. ft. per sec. While the proportion between flood water and low water at Shawinigan was 27 to 1, at La Loutre it was found to be 4.6 to 1.

Excavation revealed the existence of from 6 ft. to 8 ft. of sand on the west side of the site, quite suitable for concrete. Test pits 8 ft. square were dug at various points, revealing a mixture of sand and stones overlying rock within a depth of from 6 in. to 16 ft. of the surface. Several of the pits had to be abandoned owing to the excessive seepage.

vestigated with the result that "Stoney" sluices, or those of a similar type, were considered the most suitable. Five different dam sections, of dimensions larger than usual, were investigated in regard to their stability under extremely severe assumptions of forces acting on the dam, these sections being, plain gravity section with vertical, also sloping, upstream face, hollow dam with deck at an angle of 45°, the same type with upper part of deck at 30° and lower part at 60° to the horizontal, and rock-fill dam with concrete shell. About 700 ft. of the dam is to

Fig. 2.—Western and Eastern Channels at the Site of the Dam.

The plans for the dam were prepared by Mr. J. W. Thurso, hydraulic engineer. Mr. Edw. Wegmann, of New York, was retained as consulting engineer. The dam, shown herewith in plan and elevation, will be about 1,720 ft. in length and will follow a broken line formed by four straight lines intersecting at obtuse angles. The crest of the dam will be at an elevation of 1,335 ft. above sea level, while that of the overflow weir will be 10 ft. lower. The plan comprises a sluiceway for logs and floating rubbish, 10 gates, each 7½ ft. by 12 ft., capable of discharging 18,000 cu. ft. of water per sec., a rein-

form the overflow weir, its top being, as stated, 10 ft. below the crest of the remaining part of the dam. The maximum height will be 80 ft. above the foundation. The rock is Laurentian gneiss lying near the surface, rough from erosion, but entirely free from seams and fissures. It is an extremely hard stone, well adapted for the foundation and masonry of the dam.

It is proposed to unwater the river bed at the site of the proposed dam to permit of the necessary cleaning of the bed rock surface, the cutting of channels or checks for bending, etc. This will require the construction of

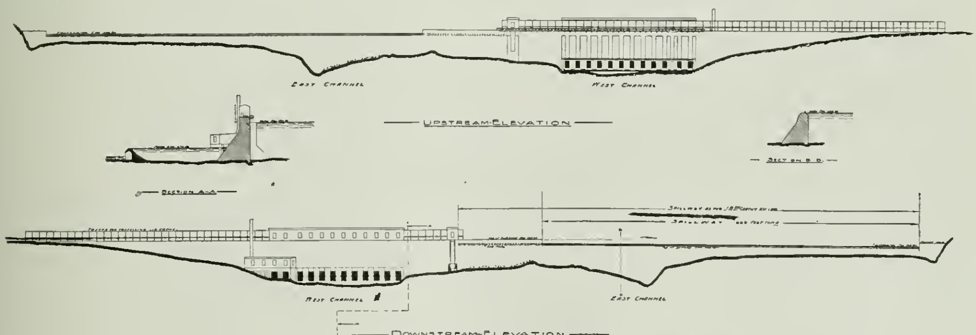

Fig. 3.—Elevations and Sections of the Proposed Dam.

forced concrete measuring weir 375 ft. in length with abutments and wing walls. In addition, the development will include a power house, two gate houses, a gauge-house, a 12-ft. roadway and a telephone line from Manouan. These will be described in a later article.

Five different types of dams were investigated in regard to their adaptability for the proposed work, these types being plain gravity dam with buttresses acting as ice breakers, hollow ram with both reinforced and arched deck, retaining wall type with loaded upstream footing, and timber dam. Different types of gates were also in-

cofferdams and the installation of pumping appliances. The surfaces of the rock foundations are to be sufficiently roughened to bond well with the masonry and cut to rough benches or steps.

The concrete for the body of the dam will be of 1:2½:5 mix, Portland cement, natural sand and broken stone respectively. Stones, varying in size up to 4 cu. yds., will be embedded in the concrete after thorough cleaning, placed 6 to 8 inches apart to allow thorough concreting between them. Reinforcement used is to be of square twisted bars, of extra soft open-hearth steel.

The site, though well adapted for a strong, watertight masonry dam, has the disadvantages of severity of

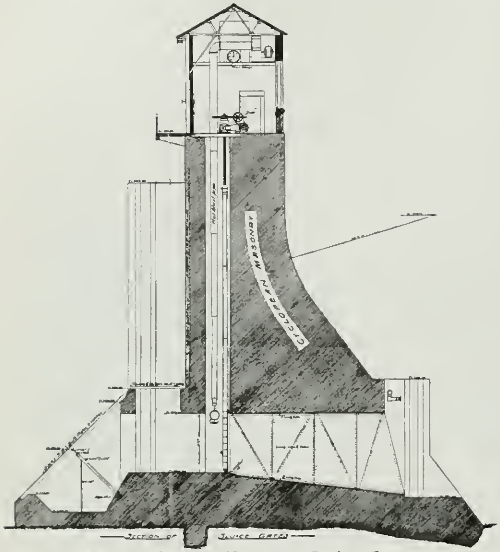

Fig. 4.—Section Through Sluice Gates.

winter weather, requiring extra strength to resist ice pressure, and inaccessibility, which will add materially to the cost of construction.

The plans have been prepared, and the work will be executed under the direction of the Quebec Streams Commission, of which Olivier Lefebvre, C.E., is chief engineer, and Ernest Bélanger, C.E., and Wm. I. Bishop, C.E., are commissioners. John W. Thurso is designing engineer of the dam, and Edward Wegmann and J. M. McCarthy consulting engineers.

In his report, Mr. Wegmann commented as follows on the design of masonry dams in general, and upon the application to the St. Maurice storage project:

Theory of Masonry Dams.—The construction of masonry dams dates from the latter part of the sixteenth century, when a number of high masonry reservoir walls were built in the southern part of Spain to store water for irrigation. The oldest of these structures is the famous Almanza dam, 68 feet high, which, according to some old records, was in existence prior to 1586. In the beginning of the nineteenth century a number of masonry dams, 30 to 75 feet high, were built in France in connection with the construction of canals. None of the early masonry dams were built according to correct principles. It has been shown that some of these reservoir walls would be stronger if they could be turned around, so that their upstream faces would be downstream.

The French engineer, M. de Sazilly, was the first to point out, in 1853, the correct principles upon which the design of the profile of a dam should be based. He was followed in the study of this subject by Delocre, Bouvier, Pelletreau, Lévy, etc., in France, and by Prof. Rankine, in England. According to these engineers there are three ways in which a masonry dam can fail; viz., by overturning; by sliding or shearing apart, or by the masonry or the foundation being crushed by the pressure it has to sustain. To insure safety, an ample factor of safety must

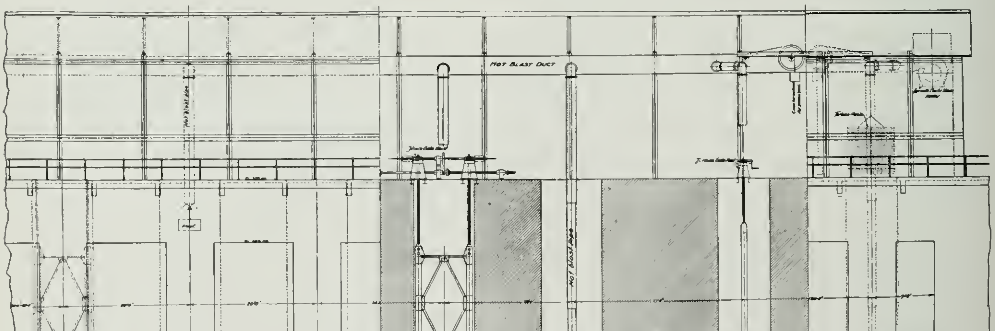

Fig. 5.—Part Longitudinal Section of the Dam.

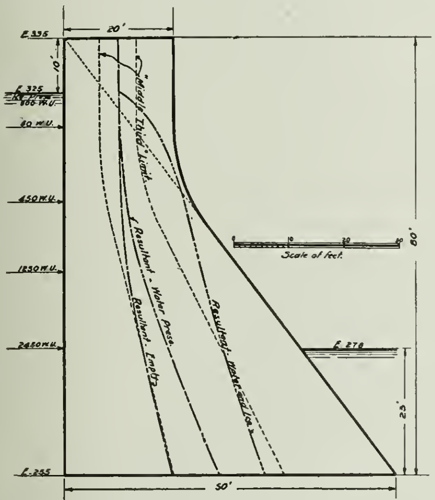
be provided against each of these possible manners of failure.

A number of high masonry dams have been built in France and Algeria according to the principles proposed by the engineers mentioned above. The greatest of these works is the celebrated Furence dam, built in 1862-66 near St. Etienne, France. It is about 170 feet high, and was for many years the greatest work of its kind.



NOTE: 50 W.U. = 50 Water Units = 50×62.5 lbs.

Fig. 6.—Profile Which Accompanied the Consulting Engineer's Report.

Prior to 1884 there was only one high masonry dam in America, viz., the Boyd's Corner dam, 78 feet high, which was built in 1866-72 to form a storage reservoir for the city of New York. From 1888 to the present time a number of high masonry dams have been built in various parts of the world. The greatest of these works with their principal dimensions are given in Table II.

Up to about twelve years ago, the profiles for all masonry dams, with one exception, were determined by considering the water as acting only on the upstream faces of the dams. The failures of three dams built on poor, porous rock, viz.: the Bouzey dam in France in 1895; the Austin dam in Texas in 1900, and the dam at Austin, Pennsylvania, in 1911, drew the attention of engineers to the fact that water might percolate under the base of a dam and exert a strong upward pressure, which would diminish the strength of the dam materially. This led designers to include such an upward force in determining the profile of a masonry dam. The intensity of the uplift depends evidently on the permeability of the rock. It may vary from practically nothing in good sound rock to almost the full head of the reservoir in porous rock, full of seams. The pressure of the water against the upstream face of a dam is easily calculated, but the amount of a possible upward force under the base or in the masonry itself must be decided, of necessity, by the judgment of the designer.

In addition to the action of the water against the upstream face, and possibly, under the base of a dam, we must consider in northern latitudes the thrust which ice may exert against a dam in forming and in expanding during a rise of temperature. When confined, as between two bridge piers, thick ice exerts a great force in expanding. A small masonry dam at Minneapolis, Minnesota, was partly revolved in 1899 by a sheet of ice, 4 feet thick and 300 feet long, lying between the dam and the retaining wall of a canal. The dam was 18 feet high, 5.25 feet wide at the top, and 12 feet at the base. The top of the wall was forced nearly a foot out of line, but, when the ice was cut, the wall returned nearly to its original position. If the ice is only about 12 to 15 inches thick and forms a long sheet, it will buckle and form "reefs" and possibly may not cause a great pressure against a dam. In the present state of knowledge we cannot determine accurately the pressure which ice may exert against a dam, and the allowance to be made for this force in designing the profile of a dam is a matter of judgment which must be based upon the local conditions. The following reservoir walls have been built for the city of New York without making any allowance for ice pressure or any possible upward pressure under the base, and stand successfully without the slightest indication of any weakness, viz.: The Sodom dam, 98 feet high, built in 1888-93; the Titicus dam, 135 feet high, built in 1890-95; and the new Croton dam, 297 feet high, built in 1892 to 1907.

On the other hand, engineers have deemed it advisable of late, to take ice pressure and possible uplift under the dam into account in designing the profile, as will be seen in the following table:

Recent Masonry Dams.

Dam.	Built.	Height, ft.	Ice pressure, lbs. per lin. foot.	Uplift.
Wachusett, Mass. ..	1900-06	228	47.000	
Cross River, N.Y...	1905-09	170	24.000	
Croton Falls, N.Y...	1906-11	173	30.000	
Olive Bridge, N.Y...	1907-13	252	47.000	
Kensico, N.Y.	In construction.			

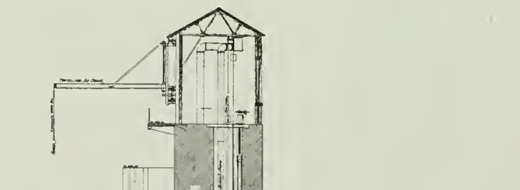


Fig. 7.—Cross-section of Portion of Power House, Showing Turbine Inlet.

In all of the above dams, the upward pressure under the base of the dam was taken as ⅔ of the full head in the reservoir at the upstream side, diminishing to zero at the downstream side.

As to recommendations for the design of the dam across the St. Maurice River, there are two types of construction that might be adopted. The dam might be built

as a solid masonry dam, or as a hollow dam of reinforced concrete. It is recommended that it be built as a solid dam of cyclopean masonry, consisting of large blocks of stone laid in and surrounded by Portland cement concrete.

As regards the profile to be adopted, this depends upon the weight of the masonry, about which we have thus far no accurate data. The specific gravity of the stone should be accurately determined, and then the percentage of large stone in the cyclopean masonry must be estimated to find the probable average weight of the masonry. In the part of the New Croton dam which was built of cyclopean masonry, there were 40 per cent. of large stone in the foundation and 20 per cent. near the top, the average being 23 per cent. of large stone for the whole wall. In the St. Maurice River dam, which will be only 80 feet high, the percentage of large stone will be less, probably not over 20 per cent.

It is recommended that an ice pressure of 50,000 lbs. per linear foot, acting at the level of the crest of the overflow weir, be assumed.

With the solid formation of rock upon which the dam is to be built there will not be much upward pressure,

* The Puentes Dam was ruptured in April, 30, 1802.

** The Habra Dam failed in December, 1881.

providing, of course, that the masonry is well laid in Portland cement mortar, the concrete being generally mixed in the proportion of 1 :2 :4.

The design of the profile submitted is based on the dam's being subjected only to the hydrostatic pressure of the water, acting on its upstream face, and also, to the ice pressure mentioned above. With these forces acting upon the dam, the profile is considered safe although, theoretically, the line of pressure would fall outside of the middle third limit for part of the height of the dam. A similar condition exists in some of the dams built for the city of New York, but these structures stand, nevertheless, successfully. In these dams the margin of safety is greater near the bottom than at the top, which is a good condition.

Having determined the profile in this manner, the effect of the greatest conceivable upward pressure acting on the dam has been calculated. Even in this case the lines of pressure would be kept within the profile of the dam. Some tension would be caused in the masonry, but such an extreme case of upward pressure can never occur and even if it did, the dam would still stand, owing to the cohesion of the masonry.

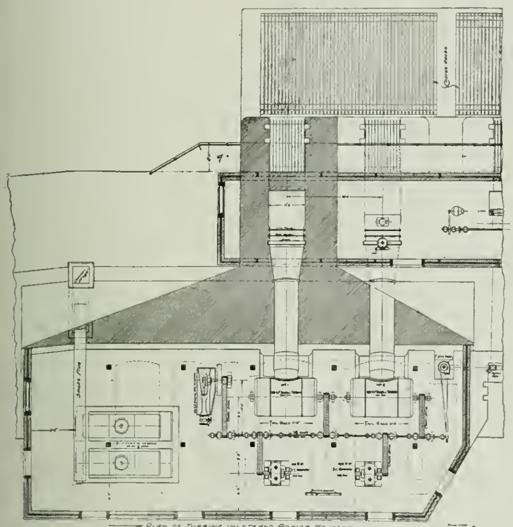

Fig. 8.—Plan of Proposed Power House.

The width given to the top of a dam must be sufficient to enable the wall to resist shocks from waves and floating bodies and also ice pressure. On account of the thickness of the ice that will form in the proposed reservoir, it is recommended that the dam be made 20 feet wide at the crest. Theoretically this would not be enough to enable the upper part of the dam to resist the combined thrust of the ice and water by its weight alone. The cohesion of the masonry would have to be counted on to insure the stability of the upper part of the dam. From practical examples a width of 20 feet at the crest is felt to be sufficient.

At the top of the overflow weir, however, some reinforcement with steel bars will be required, as this part of the dam has not the weight of masonry, 20 feet wide and 10 feet thick, above the assumed ice line to add to its strength.

THE DEVELOPMENT OF ELECTRIC TRACTION.

By John R. Hewett in "General Electric Review."

THE steam railroad is just about a century old and the electric railway about a quarter as old, and when we think of the astounding developments that have taken place in this comparatively short space of time, we can hardly refrain from asking ourselves why this development has come about. The answer to this question would seem to be that the civilization of the world is absolutely dependent upon rapid communication between man and man—the communication of thoughts and of material matter. The invention of the steam engine and locomotive pointed the way, and then, with the introduction of the electric telegraph and the submarine cable, the different peoples of the world became so much more closely connected in thought that the general extension of a more rapid means of physical communication seemed imperative. The stage coach on land and the sailing ships on the seas had to be replaced by quicker methods of communication. It was about the beginning of the nineteenth century that people began to recognize that the country which developed the best means of rapid communication with other countries would be the leader in the commerce of the world—those that had most ships would control the seas and the markets of the world; and, similarly, that it was only those countries that developed an efficient system of land transportation that could develop their natural resources, and, consequently, become manufacturing countries.

The recognition of these great economic truths came about just at a time when the whole world had been well nigh torn asunder and rent by a series of wasteful and disastrous wars. In looking back at the history of this period, the development seems miraculous. All sections of the civilized world would seem to have taken on a new form of life, and commerce became to be recognized as a better trade than war. The development of better means of communication aided the rapid spread of civilization, and the spread of civilization stimulated industrial developments of all kinds. Thus was started an action and a reaction which has been continued up to the present time, with the result that to-day a man living in New York knows more about the capitals of China and Japan than his grandfather knew about many towns scarcely a hundred miles from his own door, and that each of us individually to-day are virtually in connection with the whole rest of the world. It is easier to make a trip around the entire globe to-day, in comfort and in luxury, than it was to travel from one end of New York State to the other, at the cost of hardships and dangers, a hundred years ago.

These developments have absolutely changed our modes of living, and during the transition stage one thing of vital importance has happened, viz., we have let these means of communication become our masters as well as our servants. When we stop to consider the enormous populations congested into our large cities, and the distances from which their daily food supplies have to be transporated, it is apparent that our means of communication are the masters of the situation. Should they for any reason fail to fulfill their functions in the community for even a brief time, it would spell death by starvation to hundreds and thousands of human beings.

So in this brief period of one century we have built up a set of conditions that has so complicated our modes of living and increased our dependence on the labors of others, living at a great distance from us, that now our transportation facilities have become just as much one of the necessities of life as are food and clothing. The

character of our transportation systems has thus become a matter of national importance.

It was long after this civilizing movement had set in and became well established that the electric railway made its appearance. In fact, it is just about twenty-five years ago that Sprague, Van Depoele, Daft and Bentley-Knight, amongst other energetic pioneers in the industry in this country, began to show the possibilities of this new mode of traction. In this short space of time electric traction has not only become well established, but has grown to be one of the most important industries in the country. In the last twenty-five years electric traction has, practically speaking, superseded all modes of transportation for city, suburban and interurban service, including elevated railways and subways. A whole paper could be written with profit to show the advances that have been brought about in our social status by the electric railway. There are few who realize how much the public, and especially those interested in real estate, have benefited by the enterprise of those who have been responsible for the building of our electric railway systems, but we have not time to go into this phase of the subject here.

It seems to-day that the field for electric traction is as broad as the traction field—that is to say, that it has been developed to a stage where there are no longer any technical limitations to its adoption on every railroad in the country. The traffic could be handled electrically and the considerations which govern the choice between steam and electric traction are financial and economic, not technical. Within the last decade we have seen many notable examples of the electrification of steam railroads, and, judging by the general interest that has been awakened in railroad circles and the recognition of the splendid service being performed by those electric installations already made and the economies secured by their adoption, we shall see many more examples of steam railroads adopting electric traction during the next decade.

All modes of traction depend primarily upon energy, and whether steam or electric traction ultimately becomes universal depends upon the relative economic values of the form of energy used. It should be noted here that of all the forms of energy available, only two are generally considered for traction purposes, viz., the chemical energy stored in coal and electric energy. Dr. Steinmetz in a paper before the Franklin Institute has recently pointed out the reason for this, viz., because they are the only two forms of energy that can be economically transported or transmitted over long distances. The two following paragraphs are taken from Dr. Steinmetz's recent paper:—

"Electrical energy can be transported, or, as we usually call it, transmitted—economically over practically any distance. Mechanical energy can be transmitted over a limited distance only, by belt or rope-drive, by compressed air, etc.; heat energy may be carried from a central steam-heating plant for some hundred feet with moderate efficiency, but there are only two forms of energy which can be transmitted over practically any distance, that is, which in the distance of transmission are limited only by the economical consideration of a source of energy nearer at hand—electrical energy, and the chemical energy of fuel. These two forms of energy thus are the only competitors whenever energy is required at a place distant from any of Nature's stores of energy. Thus, when in the study of a problem of electric power transmission we consider whether it is more economical to transmit power electrically from the water power or the coal mine, or generate the power by a steam plant at the place of demand, both really are transmission problems, and the question is whether it is more economical to carry energy electrically over the transmission line, or to carry it chemically, as coal by the railroad train or boat, from the source of energy supply to the place of energy demand, where the energy is converted into the form required, as into mechanical energy by the electric motor or by steam boiler and engine or turbine.

"Electrical energy and chemical energy both share the simplicity and economy of transmission or transportation, but electric energy is vastly superior in the ease, simplicity, and efficiency of conversion into any other form of energy, while the conversion of the chemical energy of fuel into other forms of energy is difficult, requiring complicated plants and skilled attendants, and is so limited in efficiency as to make the chemical energy of fuel unavailable for all but very restricted uses: heating and the big, high-power steam plant. To appreciate the complexity of the conversion of the chemical energy of fuel, compared with the simplicity of electrical energy conversion, imagine the domestic fan motor with coal as source of energy: a small steam engine, with boiler and furnace, attached to the fan: to start the fan, we have to make a coal fire and raise steam to drive the engine. This illustrates how utterly unavailable the chemical energy of fuel is for general energy distribution. Generally, energy distribution, therefore, may justly be said to date from the introduction of electric power."

From the foregoing it will be seen that electrical energy and the chemical energy stored in coal are the only two available sources of energy for traction purposes, and that in the case of coal we have to carry our fuel and generating apparatus, adding enormously to the weight of the moving element, and consequently to the cost of transportation, while in the case of electrical energy, there is no fuel or generating apparatus to be transported. This gives electric transportation a tremendous advantage, but at the same time it must be remembered that in the case of electric traction we have to provide the means for supplying the moving elements with a continual supply of energy, which means the construction of a trolley system or third rail for the whole length of the line.

The general extension of hydro-electric developments, which is fast covering the country with a network of high-tension transmission lines, is making a source of cheap energy available in many localities. This development will prove quite an asset to many roads who would rather buy than manufacture their own power.

In the case of electric traction, the range of energy supply is very flexible—we have the whole resources of the power house available—while steam traction, if we want excessive power for only a short distance we have to transport sufficient generating apparatus and fuel all the time we are working at light loads.

So the question of the electrification of steam railroads resolves itself to a question of whether it is cheaper to build a system for the distribution of energy for the whole length of the line than to carry the fuel and generating apparatus along with our freight and passenger trains.

This is absolutely a question of economies, and will be settled as such in each individual case after a careful analysis has been made of the individual requirements.

If the traffic were sufficiently dense, it would always pay to electrify a railroad, because the economies to be secured by electric operation would more than offset the interest to be paid on the initial expenditure, but where the traffic is scarce and the length of the line is long, that is to say, where the initial cost of electrification and the cost of operating and maintaining permanently an ex-

tensive system of energy distribution would be great, in comparison with the cost of hauling the fuel and generating apparatus along with the train, then steam traction is still the most economical.

We have many examples of steam railroads with dense traffic that have made or are contemplating the change from steam to electric traction to secure these economies, and also many special cases where electrification has come into being to secure some special economies or overcome some special conditions, such as the abatement of smoke in terminal stations, etc.

The analysis of operating conditions to determine whether it would be economical to electrify or to continue steam operation is becoming an important branch of the engineering profession. There are to-day many instances where electrification would pay, but where difficulty would be found in financing the undertaking. When some of the roads that are contemplating electrification have done so and have gained the experience from actual practice, it is likely that other roads will follow their example and that the electrification of our steam railroads will become one of the large electrical industries of the country.

When an analysis of the conditions in any particular instance has shown that electrification would be economical, we still have to determine which of the available systems of electrification is best suited to the requirements. This is purely a question of economics, and here again is the necessity for a careful analysis to determine the most economical way of distributing the expenditures to be made in the inital construction, the operation and the maintenance of the system.

For example, when the traffic is very dense, and where cars or trains of moderate size have to be run at very frequent intervals and the total energy used at any one instant is not very greatly in excess of the average load, then standard 600-volt apparatus has no equal. There is no objection to the heavy outlay in substation apparatus and feeder copper when such apparatus will be in operation at an efficient load factor for a good percentage of the twenty-four hours.

It is when the load is such that the cost of copper and of the machinery installed in the power house and substations is excessive, and the percentage of time that they will be working at anything like an efficient load factor is small, that we look about for ways and means of reducing the amount of machinery necessary and of increasing the time that it will be in actual use. As a matter of fact, these conditions are just what exist on most systems where electrification is contemplated, and it is to meet such conditions and make electrification an economic possibility that the high-voltage systems, viz., the three-phase system, the single-phase alternating current system and the 1,200 and 2,400 -volt direct current systems have been evolved; in other words, higher voltage is an economic necessity to avoid excessive expenditure in copper and in machinery which would only be working at part or no load for a great percentage of the working day.

The three-phase system has found but little favor up to the present in this country, while it has been very extensively adopted in Europe; but there is one case, viz., the electrification of the Cascade Division of the Great Northern Railway, where such a system has been in successful operation for some years in this country. It would seem in the light of our present knowledge that such a system, at least for conditions as they exist in this country, is likely to be confined to mountain grade work, where the advantages of regeneration can be secured. On the other hand, as the high potential direct current system has been developed with these same features, there seems little to warrant the additional complication of the three-phase trolley.

During the last decade the relative merits of single-phase alternating current and high potential direct current systems have been freely discussed, and many examples of each system have been installed and have been operated for a sufficiently long period to enable a logical opinion to be formed as to their relative merits. It would be impossible to enter into a detailed discussion of this phase of the subject in a paper of this length, but, judging from the results of operation, as published, and the number of single-phase interurban roads that have been changed from single-phase alternating current to direct current, and from the number of direct current roads now in successful operation, and the fact that no roads adopting higher direct current potential have changed, and the present ratio of alternating and direct current work now under construction and contemplated, it would seem safe to infer that at present, at least, the higher potential direct current road has a decided advantage over all other systems for heavy traction work.

What the future has in store no one can say. The alternating current system or some modification of it may be developed along lines that will enable advantage to be taken of its good features, and its inherent limitations to be overcome. And again, new modes of power transformation may come into use, such as rectifying alternating current to direct current when the advantages of the alternating current secondary distribution could be combined with the excellent characteristics of the direct current railway motor. But if we start speculating on the future, there is no limit to the range of our imagination.

There has recently been said, both in the technical press and elsewhere, a great deal about what pople are pleased to style "The Battle of the Systems." Some people have taken the attitude that electric railway developments have been hindered because all manufacturers of electrical apparatus are not agreed upon the best system for heavy traction purposes. Such people are prone to infer that such a condition of things is hindering development and that the manufacturers are responsible for this condition. As a matter of fact, such differences of engineering judgment, when there are several different methods of attacking a problem, must, in the long run, be beneficial to the railroads rather than harmful, as without such differences of judgment, the possibilities of the art can at best be but imperfectly developed. When any art has been developed to a reasonable state of perfection and the fundamentals have been well considered and thoroughly tried, and after the process of eliminating the less suitable factors and perfecting those which have shown themselves capable of meeting the necessary demands, under actual service conditions, has been carried to the point where our knowledge, based on experience, enables us to retain the good and reject the bad, then and not until then, is the time to talk of standardization. An attempt at standardization when an art is in a more or less embryo state is likely to work a permanent harm, inasmuch as it limits our knowledge of the broader engineering possibilities that might be brought to bear upon the subject. This question is of such importance to-day that it is worthy of consideration from both sides.

This so-called "battle of the systems" to-day is, as we all know, applied to heavy traction between single-phase and high-voltage direct current. Briefly, there are two courses open: to attempt to standardize one, or to try both. First, let us imagine that we are living under such conditions that an imperial edict has been issued that single-phase is par excellence, and that henceforth every railroad in the country that wishes to be electrified

must use this system. This is not very far from what has happened in Germany. The first fruits of such a condition might possibly be that a great amount of talent would be focussed upon one subject and that developments along certain limited lines might be stimulated. Also, the customers or railroads would be relieved of any worry concerning the selection of the correct system. There would be no choice in the matter; they must take what was presented or leave it. Under such conditions, the field of research and development would be limited to such an extent that any inherent limitations in this one system of electrification would literally form a stone wall across the paths of progress. If there are inherent limitations in any system and we insist on its adoption, we are hindering rather than helping the permanent sound progress of the art. On the other hand, when there are two or more systems that are recognized as competitors, and there are, as it were, opposing camps, one side championing one system and the other side championing the second system, we are building on broader foundations. As a matter of fact, the battle of the systems is merely a bogg—the selection of the best electrical apparatus to meet the service conditions in any particular case is the settlement of engineering details—not the adoption or rejection of a system.

There are some engineering firms that have thoroughly tried out all the apparatus which has been developed up to the present time, and their judgment in these matters is tempered by experience and costly tests, and the railroad companies are getting the benefit of this experience.

The development of the higher potential direct current railroad is of peculiar interest, as the apparatus used has gone through such a logical sequence of evolution. It is just about a decade ago that we began to recognize that 500 or 550 volts was no longer the standard potential for railway work. The voltage had gradually been raised from these figures to 600 volts, until there were more roads operating on 600 volts than at any other potential. When this condition was recognized, 600 volts was talked of as the standard. The evolution from 500 to 600 volts was largely brought about by a gradual increase of the traffic on existing systems, the raising of the voltage being the simplest and cheapest method of meeting the severe demands. There have been isolated cases of roads operated at 700, 750 and 800 volts, and the step from these potentials to 1,200 volts was a comparatively small one. It should be specially noted that the increase from 500 to 600 volts made no difference whatsoever in the design, construction and operation of the equipments. When the jump to 1,200 volts was taken, it was made for purely economic reasons, and no radical changes were made in the equipment. To retain the good and well-tried features of 600-volt control, a very simple piece of apparatus called the "dynamotor" was devised which enabled the control and auxiliary circuits to be operated at 600 volts and the main motors to use the higher potential. The only change in the motors to suit the higher voltage was that they were insulated for 1,200 volts instead of 600 volts, the common arrangement being to operate two motors in series so that 600-volt windings were still used. The adoption of commutating poles on railway motors greatly facilitated the raising of the trolley potential without the introduction of complications. The marked success that attended the operation of 1,200-volt apparatus under severe service conditions encouraged further steps along the same line with the result that some roads of 1,500 volts were installed. The results were equally satisfactory. Most of the roads at present operating at higher direct current potentials are in the nature of interurban railways but some, however, approximated steam railroad conditions. In all cases the apparatus has proved itself as well suited to the severe conditions as the older 500- and 600-volt apparatus had. Under these circumstances it is not surprising that a still higher direct current potential should have been considered for a heavier class of service. In 1912, just five years after the first 1,200-volt road was put into successful operation in this country, 2,400-volt direct current was adopted as the most suitable system to meet the peculiarly severe conditions existing on the Butte, Anaconda & Pacific Railway—thus direct current apparatus has evolved from a small beginning until it has reached a stage where it meets the demands of the heaviest traction undertakings contemplated.

This is as far as we have gone at present in this direction, in actual practice, but there seem no logical reasons or limiting conditions that we know of at present which would prohibit the use of still higher direct current potentials.

Since the initial adoption of 1,200 volts, the extension of its use has been exceedingly rapid, and it may now be regarded as the standard for all new interurban railways. In some cases where marked economies can be secured 2,400 volts may be used in interurban service. One example of this is already under construction, viz., the Michigan & Chicago Railway.

The first road to adopt 1,200 volts in this country was the Pittsburgh, Harmony, Butler & New Castle Railway. This road started operation in 1907. Since this date, the extension of high potential direct current railways has been exceedingly rapid, as shown in the following table:

Date of installation.	No. of roads.	Total road mileage.
1907	1	41
1908	2	134
1909	0	0
1910	6	424.6
1911	2	201
1912	3	196.5
1913-14	17	1061
Totals	31	2058.1

Most of the roads are in the nature of interurban railways, but it should be noted that as far as we can see the vast majority of the heavy traction work now under construction or contemplation will employ direct current apparatus and this will, in most instances, be operated on "higher potentials."

We are apparently fast coming to recognize that there is such a thing as "a science of development" and that such a science among other factors must include the following fundamentals:

(1) An accurate determination of the actual operating conditions which will enable us to settle definitely what is wanted.

(2) The co-ordination of the work of a large number of differently trained men, so that the finished product may embrace the experience of each worker in his particular line, and thus become in every detail the product of experts.

(3) The confidence and co-operation of the users and makers of apparatus both before and after its manufacture, this co-operation to continue in some form or other during the useful life of the machine.

(4) The standardization of apparatus when such will be profitable to all concerned.

(1) There are, perhaps, many who do not realize the costliness of determining what is wanted to suit a par-

ticular set of service conditions. An accurate determination of the precise requirements will often necessitate months of exhaustive investigation, often including costly tests. This is particularly true in large undertakings. If we compare the work done in this direction to-day with the older haphazard methods of designing machinery first and seeing whether it would do the work afterwards, it is apparent that the art has benefited enormously by the work of the large corporation along these lines. Some phases of the research and development work undertaken to-day are so costly and require such a large staff of expert workers that no small engineering undertaking could shoulder the burden, as assumed by the large corporation.

(2) The proper co-ordination of the work of a host of men who are contributing to the design, manufacture and testing of electric railway apparatus is no small part of the Science of Development. The extent of this work is enormous, including as it does, preliminary proposition, final proposition, designing, drafting, actual manufacture and work incident to following apparatus through the factory, assembling, testing, installing, and preliminary operation. The final cost of the apparatus depends largely upon whether this co-ordination of work is done in a scientific or unscientific manner.

(3) A whole paper might be read with profit on the subject of the confidence and co-operation between the user and the maker. Upon the encouragement and extension of what we might call "the modern business idea," the rapidity with which we are going to develop in the future must largely depend. The successful development of electric apparatus for traction purposes depends on "how it is made" and "how it is used." The manufacturer is dependent upon the user just as the user is dependent upon the manufacturer. An ounce of mutual confidence and co-operation will do more towards the development of the art than a ton of fault finding and mutual distrust. In the broadest sense, the aims and objects of both parties are identical. The user wants the best obtainable for his service and the maker wishes to produce the best and most efficient apparatus, as upon this his reputation and future business depends. The work of all parties concerned is in reality the part of one great plan.

(4) The correct time at which the standardization of electric apparatus should be attempted is a science in itself, e.g., it would undoubtedly be profitable to all concerned if all trolley systems would co-operate with the manufacturers in using standard apparatus, especially standard railway motors and standard control equipment, where such standards will fulfill the requirements. There will, however, always be special conditions arising that will demand special apparatus, and the things that dictate these special requirements are many and varied, e.g.: Who could have foreseen that the fashion of ladies' skirts could affect the design of railway motors? But such has been the case—the hobble skirt gave birth to the low-step car—and the low-step car required a new design of motor.

The standardization of all apparatus that is used in large quantities and has reached a high state of perfection would be a great asset to the industry.

On the other hand, until we have more experience with the different systems of electrification, it would seem unwise to lay down too definite standards for heavy traction work, although it might be profitable to standardize such things as trolley voltages that would vitally affect the future development of the art as much as the present.

In conclusion, it is well to emphasize one point, namely, that modern engineering involves, above all things, the study of economics. Yesterday we were finding out how to do things—to-day we are striving to find out how to do them more cheaply than yesterday. To combat the increased cost of living and of labor, etc., and the generally more complicated social and commercial conditions under which we are living, the work of the scientist and the engineer is to teach the world at large how to do for one dollar that which they could not do for two dollars yesterday.

AN IMPROVED TUNNELING MACHINE.

IN Fig. 1 is shown the side view of an improved pneumatic machine designed for driving an 8-ft. tunnel in rock. The machine is the invention of Mr. O. O. App, and is manufactured by the Terry, Tench & Proctor Tunneling Machine Company, New York.

The present design is a modification of a previous machine, the first of its type, introduced in 1908. This was practically operated in a rock tunnel in New York City, where it developed a capacity for cutting at the rate of from 1 ft. 4 in. to 3 ft. 4 in. per hour. While the improved machine is constructed on the same general principles as its predecessor, it embodies important modifications in detail. Through six years of experiments and tests in actual service conducted by the inventor, every detail has been carefully worked out and perfected to the point where it is now ready to be placed on the market.

As every engineer familiar with previous developments of this character knows, failures of tunneling machines in the past have been due chiefly to lack of capacity to stand up in all kinds of rock. One of the main problems has been to find a material for the vulnerable parts that would meet the drastic service requirements.

In the machine here illustrated, the chief difficulties have been to make it take care of itself automatically and to have the cutting tools and tool holders of the proper shape and quality to stand 1,000 rapid-fire blows a minute, each of sufficient power to chip ½ in. or more of rock.

An ingenious design of drill, worked out by the inventor, has successfully overcome the first of the above two troubles; the other has been solved by the use of vanadium steel for the cutting tools and the moving parts and other parts subject to wear of the drills. This has been clearly demonstrated by the results of actual service tests of the machine operating in the hard rock formation along the Harlem Ship Canal, in cutting the channel through which the greatest difficulty was experienced in the construction of the canal.

An unusual combination of hardness and toughness is essential to meet the duty placed upon the steel in this class of service. Probably no severer test could be given these properties of a steel than in this kind of a machine. It is because it combines these characteristics in an exceptional degree that vanadium steel has been used. Formerly, cutting tools 2 in. square and 12 in. long of high-grade carbon steel were used; whereas they now use tools 1⅜ in. square and 4½ in. long. Breakages have been practically eliminated and wear on the tools reduced. The inventor, to whom credit for the development of the device in all its details is due, claims that the type of steel used has made possible the achievement of a practical, efficient machine that will cut rock tunnel commercially.

The general construction of the machine is shown in the accompanying illustrations.

Sixteen 3-in. hammer drills are mounted on a massive cast steel revolving head with four arms or shafts. Each drill cylinder passes through an arm of the head and is

firmly held in a swivel holder, thus permitting changing the hammers to the proper angle with the face of the rock.

Compressed air is supplied to the drills at 80 to 100 pounds pressure through the main horizontal shaft on which the head is mounted. This shaft is rotated by a worm wheel 3 ft. 4 in. in diameter, operated by a 25-h.p. air engine geared 200 to 1.

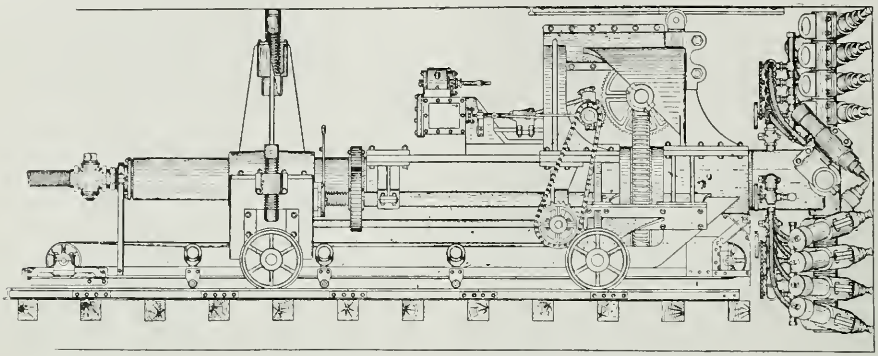

Fig. 1.—Side View of 8-ft. Tunneling Machine.

The shaft and engine are carried in a main horizontal frame with front and rear vertical transverse diaphragms, mounted on wheels.

In the upper part of each diaphragm are screw jacks which are operated to engage the roof of the tunnel and hold the machine firmly in position.

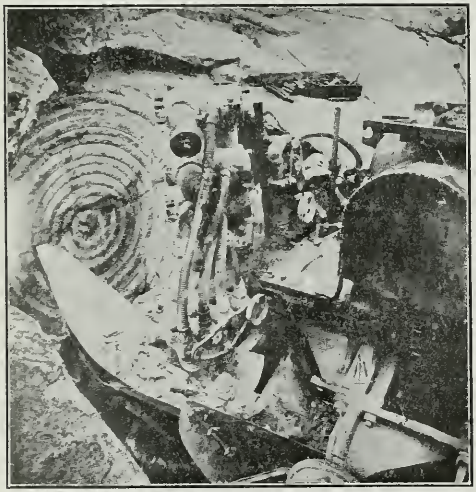

Fig. 2.—Showing Face of Bore Made by Tunneling Machine.

The machine is advanced by a pair of horizontal, longitudinal screw jacks 4 in. in diameter and of 36-in. feed. These connect the front and rear diaphragms and move them back and forth relative to each other, being operated by the central shaft by means of spur gears.

When the machine is in operation, the screw jacks move the front portion of the machine forward ½ in. for each complete revolution of the head. This action thus permits each cutting tool to carry positively a ½ in. chip of rock; and the machine thus removes a ½ in. layer of rock from the entire face of the tunnel for each revolution of the head.

The muck is removed by a belt conveyer, suspended from the forward diaphragm and carried by a pair of rear wheels. This is operated by a 2-h.p. electric motor, and delivers into dump cars on a track following the machine.

One of the most interesting details is the improved type of drills, which are so designed that they are automatically governed by the character of the rock. The cutting tools have a slight longitudinal movement in the drill cylinders and are provided with ports which control the exhaust. They do not reciprocate; but are held in one position or another and receive the impact from the hammer, which weighs 25 pounds and strikes from 1,000

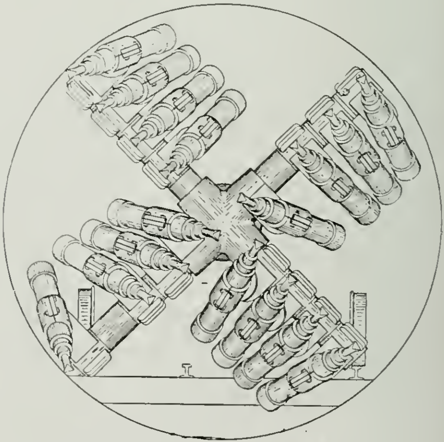

Fig. 3.—Front View of 8-ft. Machine.

to 1,200 blows per minute. When the pressure against the cutting steel is sufficient to overcome the constant pressure in the rock drill, it moves slightly backwards and opens the exhaust port, putting the hammer in operation against the head of the cutting steel. This action continues as long as the machine is in operation, and the cutting steel is forced against the rock with a pressure

of about 100 pounds. If the resistance against the point of the cutting steel becomes less than 100 pounds, through soft rock, open fissures or other reasons, the interior pressure forces it forward, closing the exhaust port and stopping the action of the hammer piston. If the machine is still continued in operation, the cutting steel acts as a gouge, milling off the tunnel face until the resistance is great enough to force it slightly back in its seat, when the hammer action is resumed, thus maintaining uniform regular action and automatically stopping the hammers when they are not needed.

The tool holders are so designed that the entire set of sixteen drills can be changed in 15 minutes. The cutters are so arranged as to remove all of the rock in the face of the heading and provide clearance for the machine.

The muck is removed by the conveyer before any accumulation can interfere with the operation of the cutters in the lower part of the tunnel.

All parts of the machine are accessible while it is in operation in the tunnel.

This machine can be controlled and operated by one man and is expected in ordinary rock to have a capacity of from 25 to 50 lineal feet of 8-ft. tunnel in 24 hours.

The advantages of an efficient tunneling machine are readily appreciated. Such a machine offers possibilities for large economies in the cost of construction work. The present demand for a device of this kind to drive subway, aqueduct, hydro-electric, irrigation and pneumatic tube tunnels furnishes a wide field of usefulness.

KOOTENAY CENTRAL RAILWAY NEARING COMPLETION.

While on a tour of inspection through British Columbia last week, Mr. J. G. Sullivan, chief engineer of the western lines of the Canadian Pacific Railway, stated that about 20 miles of track beyond Spillimacheen was completed on the Kootenay central line south from Golden. It is expected that the entire line, from Golden to the junction point with the Crow's Nest line near Ft. Steel, will be open for traffic this season.

The new line, which will afford direct railway communication from the Crow's Nest to the main line of the C.P.R. through the Columbia valley is 160 miles in length. Sections from both ends have been finished for some time, the service being placed in operation from Golden to Spillimacheen, a distance of about 40 miles, several months ago. The Kootenay Central opens up a large tract of fertile land through the Columbia valley.

Discussing the work being carried on by the C.P.R., Mr. Sullivan said that the company was laying 600 miles of new track in the west this year. Another 80 miles of double-track line would be ready for operation in British Columbia by October next.

Ballasting is now proceeding on the 34-mile stretch of double track east of Kamloops, and on a nine-mile section west of Kamloops. Tracklaying is now proceeding on the 28-mile portion between Revelstoke and Taft.

The attitude of unconcern and doubt at first prevalent in connection with the Beaver Lake gold fields near Saskatoon, Sask., is rapidly changing into one of interest and importance as the result of the discovery of much definite and encouraging detail. Over 1,000 miners and prospectors are said to be already on the ground, and the mineralized area is stated to be quite extensive and very rich.

COST OF SUBWAY CONSTRUCTION.

Diagrams for facilitating preliminary estimates of cost of subway construction have been prepared by Mr. Frank H. Carter, Designing Engineer, Boston, and have appeared in "Engineering and Contracting," to whom we are indebted for the following concerning them and their use:

The art of subway construction has advanced so rapidly towards certain standards since its inception by the city of Boston about 20 years ago as to warrant a survey of present types and their costs.

The practice to-day may be said to have narrowed to two standard sections for two track subways, the single tube with arch roof or with flat roof. The former has certain advantages in the matter of ventilation over the

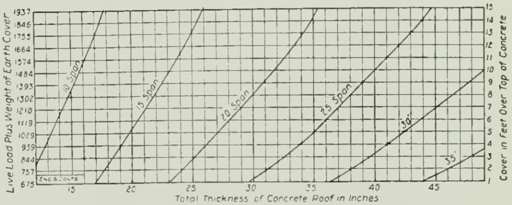

Fig. 1.

flat roof and at the outset was supposed to be cheaper per lineal foot.

Both cross-sections are now generally designed to safely withstand the stresses consequent upon the removal of part of the earth backing on one side of the structure arising from the construction of cellars for adjacent buildings or the construction of sewers. Were it not for this provision, the arch section would undoubtedly be cheaper than the flat roof.

The flat or nearly flat invert has been developed with due consideration of the opinions of the engineers of Maintenance of Way with respect to depth of ballast.

Clearance lines have been adopted from a study of the possible use of the subways for the transfer freight cars, with a centre to centre distance between tracks of 12 ft.

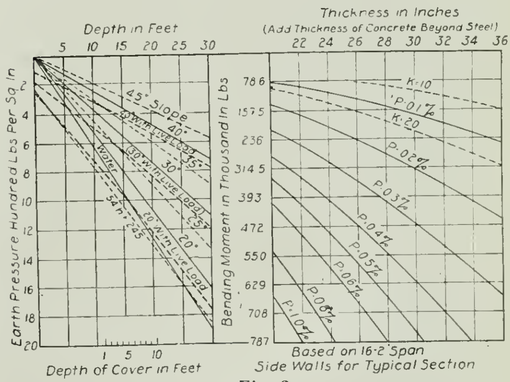

Fig. 2.

The allowable unit of stress in concrete and steel for parts of structure, subject to loads with impact, has been 600 lbs. per square inch for concrete in compression and 12,000 lbs. per square inch for steel in tension; for sides

and invert of the structure, subject to quiescent earth pressure, unit stress of 800 lbs. per square inch for concrete in compression and 16,000 lbs. per square inch for steel in tension.

Live and dead loads somewhat as follows were specified for the Cambridge Main Street Subway, being varied slightly from time to time to suit the situation.

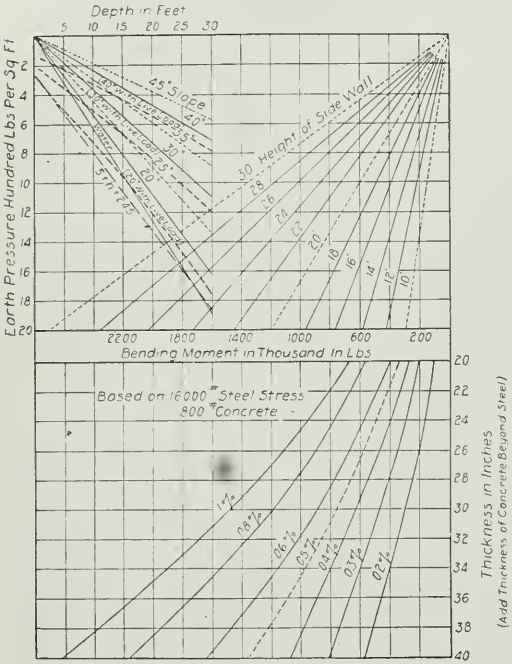

Fig. 3.

All parts of the structure under streets where the depth of cover from street surface to top of roof is 2 ft. or less, except floor or roof system girders, or beams or slabs of 30-ft. span as modified hereinafter, shall be designed for an assumed live load, including impact, of 500 lbs. per square foot or a load of 30,000 lbs. on each of two wheels, spaced 10 ft. on centres, where the latter cause greater strains. Where the depth of cover exceeds 15 ft. this loading shall be taken as 250 lbs. distributed, or 15,000 lbs. on each of two wheels. Where the depth of cover is between 2 ft. and 15 ft., the loads shall vary with the depth and shall be determined from the formula:

$$L = \frac{(28-d)}{13} \times L^\circ \text{ in which}$$

L = the load to be used.
d = the depth of cover.
L° = the corresponding load in case the cover is 15 ft. or more.

The distribution of concentrated loads through the earth (and concrete in the case of a reinforced concrete roof) in addition to the reduction for depth of cover, shall be assumed a trapezoid in a vertical plane at right angles to the direction of the span, 2 ft. wide on top and sides sloping outwards ½ to 1. Live loads for floor or roof system girders carrying over 100 and less than 200 sq. ft. of roof may be reduced 10 per cent. before applying other corrections; over 200 and less than 300 sq. ft., 20 per cent.; over 300 and less than 400 sq. ft., 30 per cent.; over 400 and less than 500 sq. ft., 40 per cent.; over 500 sq. ft., 50 per cent. Where the span of a beam or slab is over 30 feet, excepting as provided for the floor or roof system girders as above, uniform live loads may be reduced before applying other corrections 10 lbs. per square foot for each foot of span more than 30.

In general, two-track subway construction to-day will cost from $250 to $300 per lineal foot, depending upon the character of the material through which it is built as well as the depth of rail below the surface of the ground. Earth excavation for subway construction including the removal or support of street railway tracks during construction and street surfacing and the complete restoration of both, also the sheeting and bracing of trenches and underground water pumping will cost from $2.50 to $5 per cubic yard with an average perhaps of $4 per cubic yard. Concrete will cost from $8 to $12, including labor and materials but exclusive of the cost of steel reinforcement or its placing. Steel reinforcement will, of course, vary with the market but may be estimated at 2 cents per pound with an allowance of ¾ cent per pound for cutting, bending and placing, or at the rate of $15 per ton of 2,000 lbs. The item of cutting, bending and placing steel may be reduced to $8 per ton under proper management.

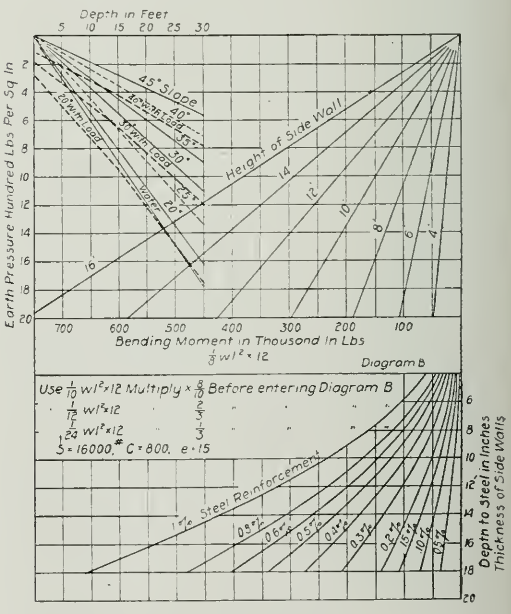

Fig. 4.

Thickness of Concrete.—The thickness of the side walls of the arch section should be decided only after study of the stresses in the arch proper and the consequent economical thickness of the arch ring. This observation applies as well to the invert of the arch section because of the racking stresses at the lower corners of the section due to the assumptions in regard to deep trench excavations on one side of the structure. In other words,

the thickness of side walls and invert depends upon the arch thickness to a certain extent. This does not apply in the case of the flat section, the thickness of whose side walls is not closely related to the thickness of the roof. It is in this case, however, desirable to maintain the thickness of side walls and invert at the corner very nearly the same because of the racking stresses due to the assumption of a deep trench on one side of the structure.

Fig. 1 gves the allowable total thickness of roof for the specified loads and allowable unit stresses of 12,000 lbs. per square inch on the steel in tension and 600 lbs. per inch on the concrete in tension.

Fig. 2 gives the thickness of side wall for the typical section under the earth pressures specified and for the unit stresses of 16,000 lbs. per square inch tension in the steel and 800 lbs. per square inch compression in the concrete.

Fig. 3 gives the thickness of side walls for section greater than the standard in height.

Fig. 4 gives the thickness of side walls of sections less than the standard height.

Fig. 5 gives the thickness of side walls for section composed of steel beams placed vertically.

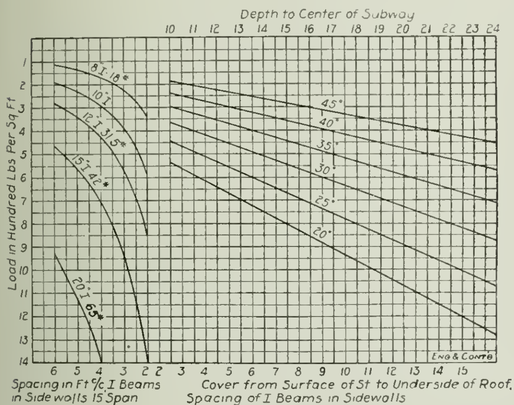

Fig. 5.

Fig. 6 gives the allowable thickness of side walls of typical sections of subway with no steel reinforcement assuming a tension of 60 and 120 lbs. per square inch in the concrete for *K* of 10 and 20 respectively.

The costs of subways per lineal foot given below in the table are from actual designs of sections, as shown in Figs. 7 and 8, for the arch and flat roof respectively. The cost of arch or flat section is practically the same pei lineal foot of subway for a depth of rail of 26.5 ft. below the surface. It is probable that the arch section is the more stable, better ventilated and perhaps more attractive in appearance, though obviously the latter feature is scarcely worthy of consideration.

For other widths of subway, the cost is almost directly proportional to the width of section, for instance, for a 25-ft. section our diagram reads $285 as the cost per lineal foot of structure. For a one-track subway, therefore, we should have (13 ft. span) $150 as the cost per lineal foot and for a six-track structure $900 per lineal foot of structure.

It is observed that this cost is about $11.40 per square foot and a variation of roughly 27 cents for each foot in depth. Indeed, Mr. Howard A. Carson states that subway stations of simple construction may be roughly estimated at $12 per square foot for a depth of rail below the surface of 20 ft., allowing 20 cents per square foot for each additional foot of depth below 20.

The removal and care of underground structures, such as sewer, gas and water pipes, must of course vary considerably from the very expensive work required, for instance, along the lower reach of Market Street, Philadelphia, down to some of the simplest work costing little or nothing.

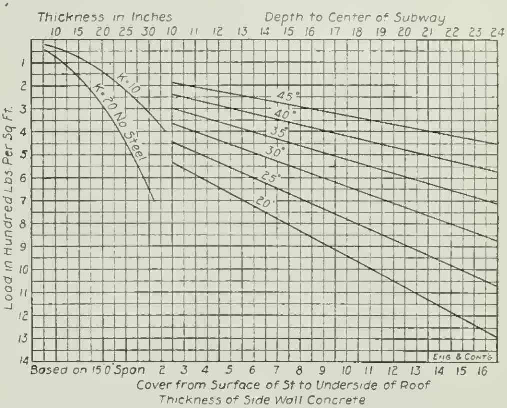

Fig. 6.

As an average at least $12 to $15 per lineal foot should be added to the cost given in the diagram as the cost for caring for underground structures.

With regard to underpinning of buildings along the line of construction, it is extremely difficult to give reliable or satisfactory figures. As a guide, however, the following three instances are cited, the authority of which is unknown. It costs to underpin along subway construction a building four stories in height 21 feet deep $122 per lineal foot of frontage. Another building of four

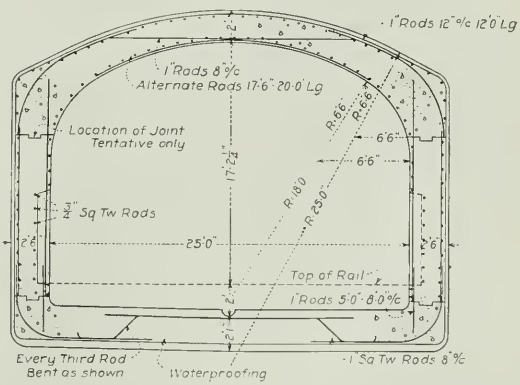

Fig. 7.

stories 11.6 ft. deep cost $120 per lineal foot of building frontage. Still another building of seven stories 20 ft. depth of underpinning cost $153 per lineal foot of building frontage. It is reputed that the foregoing costs are

from work done by the city of Boston. It is estimated that underpinning for a six-story brick building might cost $150 per lineal foot of building, while that for a two-story brick building might cost $90 per lineal foot of building with a graduated scale of prices for buildings of different heights.

Standard Arch Section.

21 ft. to rail—

28.8 cu. yds. excavation at $4.00	$116.00
8.19 cu. yds. concrete at $10.00	81.90
790 lbs. steel at $0.02¾	21.70
	$219.60

This equals $252 per lin. ft. with 15% added for contingencies and engineering.

27 ft. to rail—

35.6 cu. yds. excavation at $4.00	$143.00
8.19 cu. yds. concrete at $10.00	81.90
8.50 lbs. steel at $0.02¾	23.35
	$248.25

This equals $285 per lin. ft. with 15% added for contingencies and engineering.

21 ft. to rail—

27.4 cu. yds. excavation at $4.00	$109.50
7.73 cu. yds. concrete at $10.00	77.30
990 lbs. steel at $0.02¾	27.20
	$214.00

This equals $246 per lin. ft. with 15% added for contingencies and engineering.

Flat Roof Section.

27 ft. to rail—

34.0 cu. yds. excavation at $4.00	$136.00
8.36 cu. yds. concrete at $10.00	83.60
1,075 lbs. steel at $0.02¾	29.60
	$249.20

This equals $287 per lin. ft. with 15% added for contingencies and engineering.

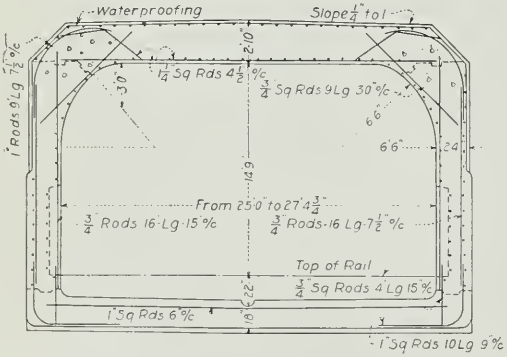

Fig. 8.

For underground structure add $12 to $15 per lineal foot and for waterproofing the outside with concrete protection to the waterproofing add $19 per lineal foot.

An example will illustrate the use of the curves for approximating the preliminary design of a sewer closely enough for the estimation of its cost.

It is required to design the roof and side walls for a rectangular sewer with a cover of 6 ft., span of 15 ft. and height of side walls of 10 ft.

First, from Fig. 1 we find for a cover of 6 ft. and a span of 15 ft. that the roof should be 20.6 ins. in thickness for 1.07 per cent. steel stressed 12,000 lbs. per square inch and concrete stressed 600 lbs. per square inch. Then, from Fig. 4 for a slope of material of 30° with super load, and for a distance below the surface of "*centre of depth*" of side wall, which consists of the sum of the following: Six feet cover plus 20.6 ins., the thickness of the roof plus 5 ft., which is one-half the height of the sewer walls or a total depth of centre of the side wall of $6 + 1.7 + 5 = 12.7$ ft., we enter the diagram at the upper left-hand

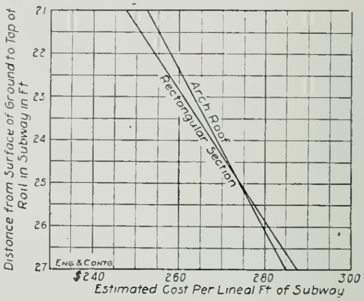

Fig. 9.

corner at 12.7, running down the 12.7 line to the diagonal "curve" marked 30° with load we read 570 lbs. per square foot pressure, we then trace along horizontally to the diagonal in the upper right-hand part of the figure marked 10 ft. height of side wall, we read 85,000 in. lbs. bending moment. Now, running down the 85,000 lbs. vertical line to the curve in the lower part of the figure to a wall 10 ins. thick to steel or 12 ins. thick total, we read 0.5 per cent. steel as the required percentage of steel for the given conditions.

Figs. 2, 3, 4, 5 and 6 are to be read similarly and are of considerable assistance in forming approximate estimates of cost or in checking designs of sections for construction.

THE ST. PAUL ELECTRIFICATION.

The St. Paul railway across Montana is the biggest thing of this kind that has yet been undertaken. The "Boston News Bureau" gives the following data. The electrification will comprise 440 miles of line. With normal traffic about 60 electric locomotives will be needed as against 82 steam locomotives. Electric power will be supplied by the Montana Power Company at 0.536c. per kw. It is estimated that 5,000 to 6,000 tons of copper will be required, or at the rate of 11½ to 13½ tons per mile. The work has already been commenced. The entire job should be finished by January 1st, 1918. It will cost about $8,000,000.

The engineering faculty of the University of Western Australia was established in 1913, and is conducting degree courses in civil, mining and electrical and mechanical engineering.

A recent report made to the Edmonton industrial association is to the effect that a virgin gold field has been discovered in the unexplored Liard River district of northern British Columbia, about 1,500 miles northwest of Edmonton, in a district which is declared to be extremely difficult of access, owing to the unfriendly attitude of the Indians inhabiting it.

SOME TRACK CONSTRUCTION STANDARDS FOR 1914.

THAT there is apparently no standard practice in track construction for street and radial railways is plainly evident from the widely differing standards of different public utility corporations. Transit companies go ahead, from year to year, improving their own standards by every possible means, but the indications of general standardization are not many. Examples of track construction standards for a number of cities are given below. For them we are indebted to "Electric Traction," and have selected those which will be of particular interest to electric railway men.

Columbus, Ohio.—Fig. 1 shows longitudinal and cross-sections of the track construction being used by the Columbus Railway, Power and Light Company, of Columbus, Ohio, at the present time. This is laid with Lorain section No. 434, 7-in. girder groove rails, 116 lb. to the yard, which are carried on Carnegie steel ties, section M-25, with the broad face turned up and spaced at 4-ft. 6-in. centres. The concrete base is carried up over the

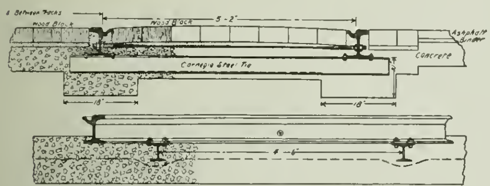

Fig. 1.—Columbus Railway, Power and Light Company.

base of the rails to form the foundation for the pavement. The concrete is carried to a depth of 12 in. below the base of the rail to form a girder 18-in. wide and is also brought down low enough between the rails to protect the ties. On top of the concrete a comparatively dry cement mortar is used in which to set the wood block paving. This variety of paving has been found to be very satisfactory and will be made use of by the company in its new work wherever possible. When 3½-in. blocks are used the steel tie rods are laid flat underneath the blocks. When 4-in. blocks are used, however, the tie rods are placed edgewise and the bottom corners of the adjacent blocks are chipped off in order to make the blocks come together.

The joint construction in Columbus has had a very interesting development. On one of the old types of track with 9-in. 94-lb. grooved-rail Lorain section No. 313 the joint was constructed by placing a piece of old rail having the same width base underneath the joint and buried in the concrete. Continuous rail joints were open up to include the base of the under rail which was turned bottom side up and the whole structure was bolted and bonded together and anchored in concrete.

The next joint development was used in connection with track employing the same weight and section of rail and was made by using a section of Carnegie steel tie of sufficient width to allow the fastening of the rail with Carnegie clips placing three clips on each side of the rail at each joint. This joint was bonded with compressed terminal bonds.

The present joint construction is the well-known Clark joint with some slight variation. In place of rivets eight drive-fit bolts are used with plates 30 in. long. A section of the Carnegie tie used as cross ties is cut off 36 in. long and placed underneath the joint parallel to the rail. These bottom bars are then welded to the rail, taking the place of the bottom thermit weld of the Clark joint and forming the bond.

Cincinnati, Ohio.—The standard track construction of the Cincinnati Traction Company is especially interesting for the thorough manner in which the sub-grade is drained and for the substitution of knee braces for the usual tie-rods.

As the gauge in Cincinnati is 5 ft. 2½ in., it is necessary to excavate for the sub-grade to a width of 9 ft. 2½ in., the depth being 21 in. Along the centre line of the track is dug a ditch 12 x 12 in. In about the centre of this is run a line of 4-in. farm tile surrounded by washed pebbles which come to within 2 in. of the top of the ditch. This space is filled with loam. In the track excavation proper is laid a 1:3:7 concrete mixture, standard oak ties being embedded in same with 6 in. underneath and about 2 in. on top. On top of this is a sand cushion for the paving. The company uses a 9-in., 140-lb. Trilby rail, Lorain section No. 402, with cast weld joints. Ties are spaced on 24-in. centres at joints where they are spaced on 28-in. centres.

Cast weld joints are used in tangents, with continuous joints at all breaks in grade and also in all curve work whether plain work or special work.

The company has found the knee brace preferable to the tie rod, as the great trouble with the tie rod was in the laying of the paving, and it was frequently found that a certain vibration was caused by the tie rod, resulting in the paving being pushed out of surface. The use of the knee brace has eliminated this trouble.

This type of construction has been in use in Cincinnati for practically seven years. The only change which has been made in the company's practice has been in the rail section itself, the rest of the work being substantially as adopted at that time. The results obtained from this construction have been very satisfactory as not a dollar has been spent on the foundation or drainage; the only expense the company has been subjected to has been an occasional slip of a joint, which has been, up to the first of this year, about ¾ of 1% of the total number of joints poured.

Lexington, Ky.—The standard construction of the Kentucky Traction and Terminal Company is to excavate a sufficient depth to allow 6 in. of crusted stone under the ties. After first thoroughly rolling the sub-grade and boarding, if necessary, any soft spots, should such be encountered, a course of crushed rock, broken to pass through a 2½-in. ring, is placed on the sub-grade. This is rolled with a 10-ton roller, and then the ties, 6 in. x 8 in. x 8 ft. and spaced on 2-ft. centres, are laid. Ties are all treated with Carbolineum. Eighty-pound A. S. C. E. open-hearth rail is used. The track is then tamped under traffic to a true surface and line. This tamping is repeated until it is evident that the ties are thoroughly bedded. The broken stone is then brought to a point 2 in. above the base of the ties, and the space between that point and the base of the rail is filled with a 1:3:5 concrete mixture. Over this a sand cushion is spread, on which to lay the paving.

A special cut granite block is laid longitudinally along the gauge side of the rail. This granite block is laid in a bed of a dry mixture of one of cement and two of sand. The brick on the outside of the rail and in the devil's strip are laid ¼ in. below the top of the rail so as to prevent breaking the skin of the brick with worn treads. All paving is laid level as this company's experience has been that it gives better riding conditions for vehicular traffic.

After the brick paving has been thoroughly rolled with a 5-ton roller, it is grouted with a mixture of one of Portland cement and two of sand. This grout is allowed to set for three days before vehicular traffic is allowed on the paving. The grout is applied in two applications, the first one being very thin so as to run into all crevices and voids. The second application, about the consistency of a rich cream, is carefully swept into all crevices, and is made before the first has had a chance to take an initial set.

The practice of this company is not to plaster the outside of the rail between the head and the base but to lay the brick snugly against the rail and allow the grout to fill this space.

An electrically welded joint, purchased from and applied with an Indianapolis Frog and Switch Company's outfit, is being used this year. Before allowing traffic on the track all joints are dressed off with a reciprocating rail grinder, so as to make the riding service absolutely true at the joints.

work trains, smaller material is delivered by a 3-ton Packard auto truck. For drilling holes for bonding, tie rods, etc., four Duntley electric track drills are used, and two Duntley electric grinders are employed for polishing rails in connection with bonding work.

Brooklyn, N.Y.—The chief feature of the standard type of surface track to be used in reconstruction of various sections of the Brooklyn Rapid Transit system during the present season, is that the ties are laid directly on the natural soil, which is a loamy sand, with good natural drainage. This company's experience has been that a ballast or concrete foundation is not necessary.

The natural soil is well compacted at the level of the sub-grade, which is 13 in. below the top of the rail. Long leaf yellow pine, 6-in. x 8-in. x 8-ft. ties, of prime inspection, are laid on this sub-grade on 2-ft. centres. A 1:3:6 gravel concrete (1½-in. washed gravel, graded) is poured between the ties and to 1 in. above them. On top of this is a 1-in. sand cushion for the 5-in. granite blocks. The rails, which are 7-in., 105-lb., grooved girder, in 60-

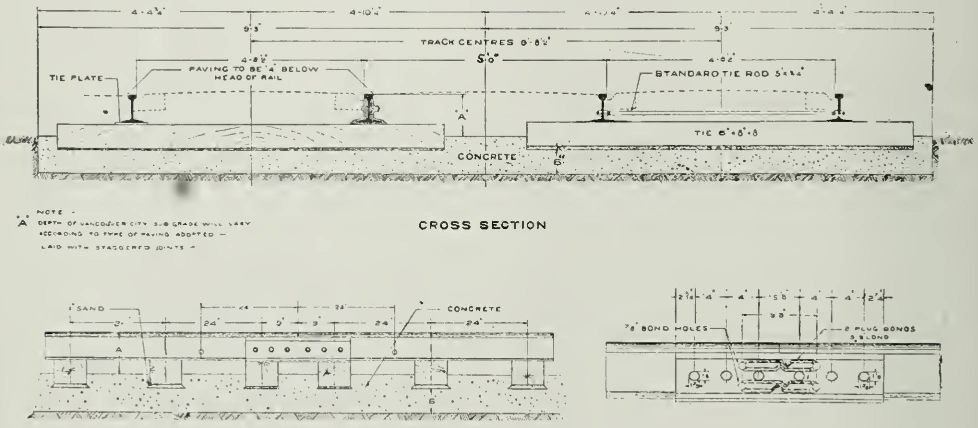

Fig. 2.—British Columbia Electric Railway Company Standard, Showing Sections and Detail of Drilling and Bonding.

Vancouver, B.C.—In its standard construction in Vancouver, B.C., the British Columbia Electric Railway Company uses 91-lb. high T-rail on its main lines and 70-lb. high T-rail on branch lines. For double track, the concrete slab foundation is made 18 ft. 6 in. in width and 6 in. in depth, partially embedding the ties. There is, however, a sand cushion under the ties varying in thickness from 1 to 2 in. The ties are rough fir (sawn) of standard size. Tie plates are used, being Australian gum ⅜ x 8 x 10 in. Other interesting details of construction are as follows: Spikes, railroad, 9/16 x 5½ in.; joint bonding, two 10-in. plug bonds, brazed with thermit; cross-bonding, two 300,000-cm. cables every 200 ft. of track; joint plates, continuous, suspended; bolts, 1 x 4½ in., oval neck, rolled thread; tie rods, ⅜ x 2 in. with ¾-in. terminals.

All track construction and reconstruction is carried out by the company's forces. Excavation is taken out with a No. A-1 Thew steam shovel to a depth of 20⅜ in. For doing the necessary concrete work before and after the track is laid five Koehring special street paving mixers, No. 14, are employed. Rails and ties are delivered on the job with a steam and an electric Brownhoist derrick and

ft. lengths, are fastened to the ties by 9/16-in. x 5½-in. spikes, four per tie, with 2-in. by ⅜-in. tie rods having ⅞-in. ends and spaced 6 ft. centre to centre. Thack joints are of the Falk cast welded type, weighing 190 lb. per joint and being placed opposite to each other. The space between the rail and the granite blocks is filled with a 1:4 cement grout while the interstices between the paving blocks are filled with a 1:1½ cement grout.

Davenport, Iowa.—The Tri-City Railway Company uses both the concrete base and ballast construction in its track work. Except in cases of badly drained or a settling sub-grade, the ballast construction is preferred, and as a general thing a concrete paving base is employed only when required. In all cases the company favors the concrete paving base, as shown in the accompanying drawing.

In the ballast type of construction, a trench, 8 ft. 6 in. wide by 29 in. deep, is excavated. After rolling, 6 in. of crushed rock, broken to pass through a 2-in. ring, is laid as the first course. On this are laid 6-in. x 8-in. x 8-ft. ties, and crushed rock is placed around them 2⅞ in. above their base. On top of this is placed a 1:3:5 concrete, 5 in. in depth; then a ½-in. sand cushion on which to lay the paving brick. The ties are, for the most part,

No. 1 6-in. x 8-in. x 8-ft. red oak, zinc chloride treated, and are spaced from 24 in. to 30 in., according to the prospective duty of the track. Standard spikes are used, without plates.

In the concrete base type the trench is made 9 ft. wide and 17 in. deep, from the top of rail. The concrete, a 1:3:5 mixture, entirely covers the ties, with 4 in. underneath and 6 in. at the ends. At the centre line of track

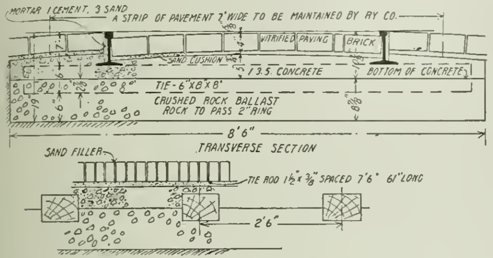

Fig. 3.—Tri-City Railway Company, Davenport, Iowa.

the concrete comes 11⅞ in. above the trench bottom. The concrete runs about 29.4 cu. yd. per 100 ft. There is ¾-in. sand cushion on top of the concrete, on which the paving brick are laid.

Of late years the Tri-City company has favored the six-hole continuous suspended joint with a concealed bond. There has been no one standard of bond, as the soldered, pin expanded and compressed terminal types have been used, each in considerable numbers.

While T-rail is generally preferred and used, when required by ordinance or possibly in case of very heavy street traffic, a 7-in. girder, Pennsylvania section 80-238, is used. Also, where required with the Shanghai rail, a special nose brick may be used, but the company's preference is the plain brick, as shown.

In general, it is the plan to secure permanence of construction by careful workmanship along the line of accepted standards rather than through attempting radical departures.

The rails used are the British standard section, girder type, 60 ft. in length. The straight track section weighs 110 lb. per yd., and the curving section weighs 116 lb. per yd., the extra weight on the latter section being due to the thicker lip or guard. The fishplates are 2 ft. in length, and are secured with six 1-in. bolts.

The Glasgow Tramways have recently decided to weld all joints on renewals and on new track. The welding may be either electric or by the thermit process. In the former case the fishplates are put on in the usual way, then welded in position; in the latter case, no fishplates are used.

About three years ago, a portion of track in the centre of Glasgow, where the traffic amounts to about four cars per minute, was welded by the former process, and up to recently there had been little or no expense for repairs.

Crown bonds are used at each joint whether the joints are welded or fishplated, in addition to cross-bonds at frequent intervals. The tie-rods, of mild steel, are 2½ x ½ in. in section and are spaced on 5-ft. centres. These are screwed at both ends with thick plate washers on each side of the rail web.

In new work, the class of paving will be the ordinary dressed granite sets, measuring 6½ in. deep, 3½ in. thick and varying from 6½ to 9½ in. in length. The tendency, however, in the city is to put down what is termed nidged granite blocks, the dimensions of which are 6 in. in depth, 6 in. in width and from 7 to 10 in. in length. These sets are hammer-dressed on five sides, ends, sides and top. Particular attention is paid to the top surface to have it perfectly flat. They are very closely jointed together in a bed of cement mortar, the proportions of the mortar being four parts of sand and one part of cement. They can either be grouted with cement or pitch, according to the time the traffic can be kept off. When sets of this kind are laid the street has a perfectly smooth surface. They are, however, very expensive, costing more than double the ordinary sets.

Some years ago, the Glasgow Tramways laid several miles of track on cross-timber ties. These extensions were several miles from the centre of the city, consequently the traffic is not so great. The track, however, has needed little or no repair all these years, but there is

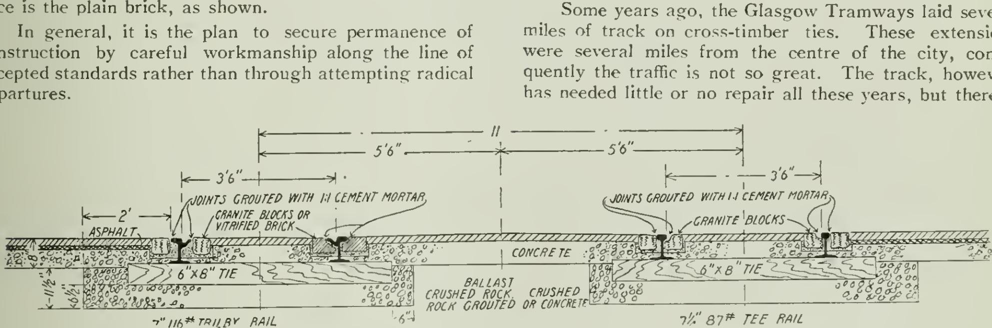

Fig. 4.—Los Angeles Railway Corporation, Trilby and High T-Rails in Paved Streets.

Glasgow, Scotland.—The method of track construction of the Corporation Tramways of Glasgow is practically the standard construction in that country, viz.: For double tracks, an excavation is made about 17 ft. in width by about 14 in. in average depth. The concrete base, about 7 in. in thickness, is made up as follows: Four parts of underneath the base with small granite chips, sand and one part of cement.

After the concrete has set hard, rails are laid in position to line and level, after which they are packed underneath the base with small granite chips, sand and cement, mixed in the proportion of 4:2:1.

now considerable difficulty in obtaining the necessary ties, and on new extensions it is planned to use only concrete base, as already described.

Los Angeles, Cal.—Fig. 4 shows the types of track construction to be used by the Los Angeles Railway Company during the present year. Both trilby and T-rail will be laid, but a city ordinance compels the use of the former section in paved streets, so that the greater part of the track to be laid this season will be of that type of construction. The trilby rail used is a 7-in. 116-lb. section, while the T-rail is a 7¼-in. 87-lb. section. With the trilby rail a six-hole continuous joint and brace tie plates,

spaced every third tie, are used; the T-rails are thermit welded.

For ballast the company uses crushed rock, crushed rock grouted, or concrete, to a depth of 6½ in. below the ties. In the two types of construction shown in the accompanying drawing, crushed rock is used under, around and between the ties to within 1 in. of their top. On top of this is poured concrete which embeds the base of the rails and forms the immediate foundation for the paving.

streets are shown in Fig. 5. In paved streets the earth is excavated to a depth of 20¼ in. below the top of the rail. In this trench is placed 9 in. of gravel ballast, which extends around the ties 1 in. above their base, while pit run gravel concrete, with proportions of 9:1, is used level with the top of the ties. The ties are long leaf Texas pine, 6 in. by 8 in. by 6½ ft., the track gauge being 3 ft. 6 in. They are treated in an open tank with hot carbolineum. The rails are 73-lb. T, with the ends sawed to

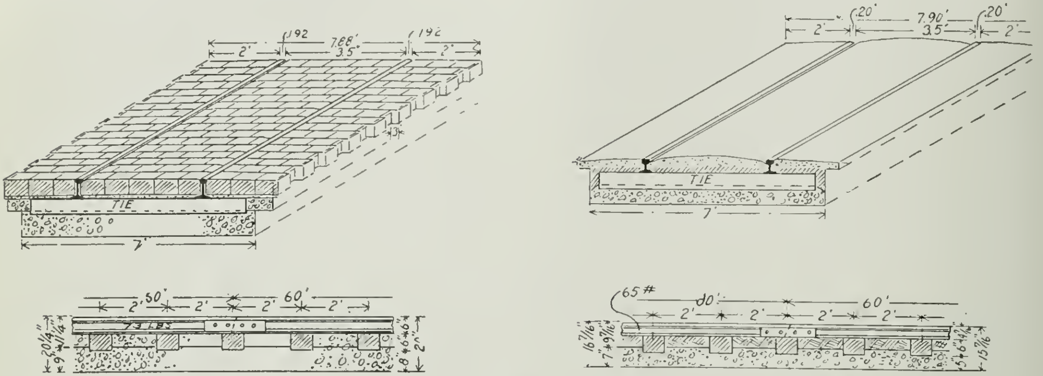

Fig. 5.—Denver City Tramway Company—Track Construction for Paved and Surfaced Streets.

Redwood ties, 6 x 8 in., are used; they are spaced at 20-in. centres.

The company paves its track to a point 2 ft. beyond the outside head of the rail, in accordance with city specifications. Where it paves in the trilby rail granite

a 10-deg. bevel, to provide for the bevel joint which is peculiar to the Denver construction. A 22-in. angle bar, weighing 11 lb. per ft., is used, together with 1-in. bolts. Under the splice plates 4/0 electric brazed bonds are used. The paving is crowned in the centre ¼ in. above the rail,

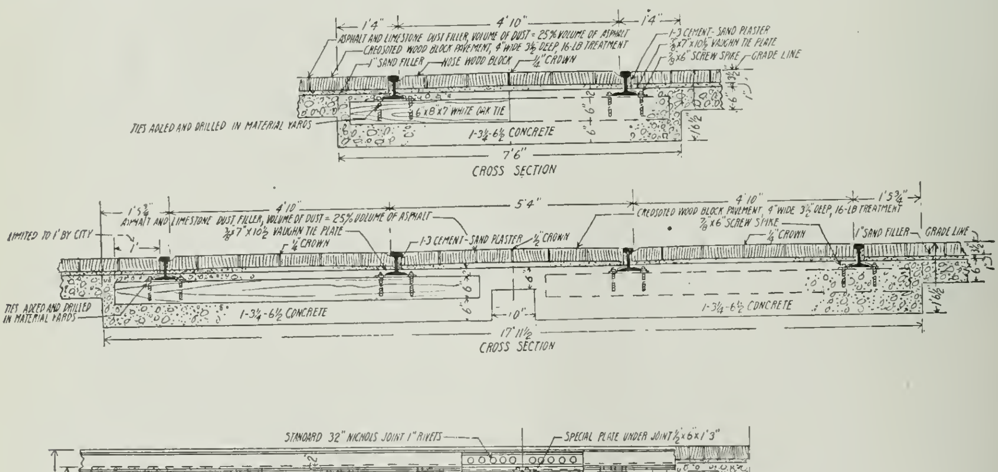

Fig. 6.—United Railways Company of St. Louis, Track Construction for 7-in. Trilby Rail.

blocks, vitrified or treated brick toothing are used; for the T-rail, bull nosed granite blocks are used. All are grouted with 1:1 cement mortar.

Denver, Colo.—The standard constructions of the Denver City Tramway Company in paved and surfaced

while the paving blocks are cut basalt, 5 in. deep, seven to the yard. These are laid on a 1-in. sand cushion and are grouted.

The construction in surfaced streets differs from that in paved streets in a number of particulars. The gravel

ballast under and around the base of the ties is 7 in. deep. In place of the concrete on top of this, as in the other type, earth is used, with 3 in. of screened gravel on top. This is crowned in the centre ½ in. above the rail. A 19-in. angle bar, 9.2 lb. per ft., is used, together with ⅞-in. bolts. The rail is a 65-lb. T-section.

A number of variations in the type of paving aside from that shown are used under different conditions.

The company's franchise provides that it shall maintain paving between the tracks and 2 ft. on the outside of each rail. Sometimes the company lays the paving to this 2-ft. line, and at other times makes arrangements with the city's contractor to pave a portion of this strip in. deep, with 6 in. under the ties and 5 in. above them.

The pavement of the tracks consists of brick, granite blocks or creosoted wood blocks, depending upon the pavement of the street outside of the tracks. The creosote wooden flange, shown in the drawing of the T-rail construction, will not be used on the work planned for this year as the city authorities have agreed to the trying out of granite flange blocks along the rail with wood blocks, brick or granite blocks in the centre of the track between the rows of flange blocks.

The main features of the various types of construction for girder tracks are the use of the solid concrete type of foundation; untreated white oak ties, of standard dimensions, laid 2 ft. centre to centre, the ties being

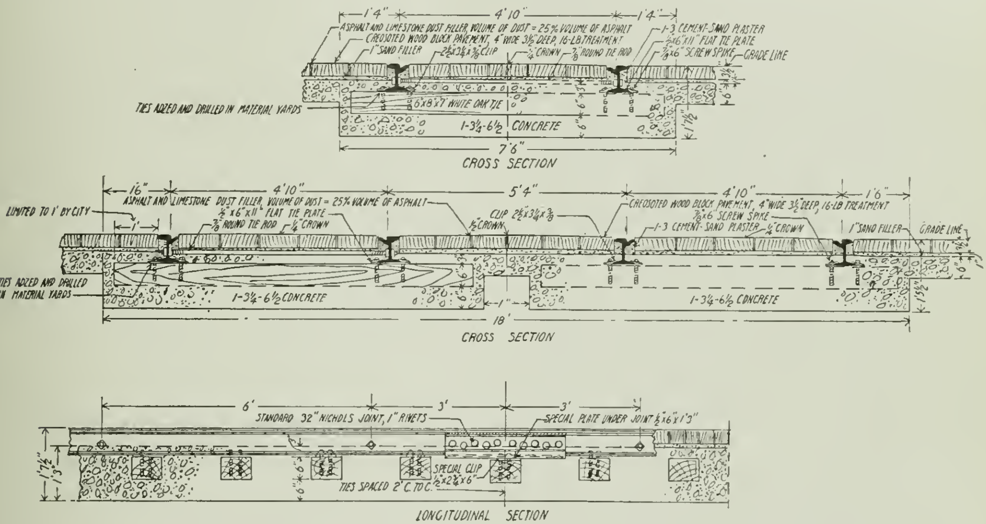

Fig. 7.—United Railways Company of St. Louis, Track Construction for 6-in. T-Rail.

with asphalt or whatever material is being used on the balance of the streets.

St. Louis, Mo.—During the past two years three types of track construction, for 9-in. trilby rail (Lorain section 132-440), 7-in. trilby rail (Lorain section 103-426) and 6-in. 100-lb. A. R. A. T-rail, have been used by the United States Railways Company of St. Louis, and these types of construction will be used on the work planned for the present year. Drawings of the 7-in. trilby and 6-in. T-rail types are shown in Figs. 6 and 7. The 7-in. and 9-in. trilby rail types differ only in the depth of the concrete foundation, the former being 15 in. deep, with 6 in. under the ties and 3 in. above them; the latter type is 17 adzed for tie plates by a machine in the material yard; ⅞ x 6-in. screw spikes; ½ x 6 x 11-in. flat tie plates on all ties; ⅜ x 2 x ¼ x 3¼-in. steel screw clips; 32-in. Nichols joint plates and ⅞-in. round tie rods.

The main features of the T-rail track construction are the same as those for the girder rail type, except that no tie rods are used, and instead of the ½ x 6 x 11-in. flat tie plates and the screw spike clips, a special patented tie plate is used. This tie plate consists of a ⅜ x 7 x 10½-in. flat soft steel plate sheared at the ends so that four ⅜ x 1⅛ x 2½-in. strips can be bent down over the rail base. The screw spike holes in the tie plates are located 1½ in. outside of the rail base.

INVESTIGATION FOR COAL IN NORTHERN CANADA.

A report from St. John's, Nfld., states that a schooner is now being equipped for a prospecting expedition to Hudson Bay, the main object of which is to investigate coal deposits in that area which can be utilized in connection with the operation of the Hudson Bay Railway, now under construction. A supply will also be required for the steamers. At present all the coal that is required in connection with steamer traffic to the Bay has to be conveyed there by Newfoundland sealing steamers that are used for freighting purposes in the summer months. They are the only vessels available that can withstand the wear and tear of navigation in these northern ice-laden waters.

Coal for the needs of the railway construction forces is conveyed by train from Winnipeg and Le Pas as the railroad progresses. When the line is opened to Port Nelson and terminals constructed there provision for a large storage for coal will be made. Its cost, however, in view of the lengthy transportation from Cape Breton by water and from Western Canada by rail will be a considerable item. Hence the present efforts to locate coal deposits near Port Nelson.

FUEL-BRIQUETTING INVESTIGATIONS.

THE manufacture of fuel-briquettes is now well established as a commercial process on the Continent of Europe, and, so far as the demand permits, in Great Britain, according to "Engineering," London. But in the United States, in spite of the vast fields of lignite, or brown coal, which are available, the industry cannot be said to have attained a proper foothold. Up to 1912, in fact, there were only twenty-four American plants in operation. For this reason the government arranged an exhaustive series of experiments on the briquetting of American fuels, and a mass of useful information has been collected. The results, which are given in great detail, are published in Bulletin No. 58 of the U.S.A. Bureau of Mines, and cover a period of eight years' work, from July, 1904, till July, 1912.

Briquettes are made by compressing the finely ground material into solid blocks, under a sufficiently high pressure. The blocks, if made from lignite suitably treated, are then cohesive, withstand handling, and keep their shape in the fire. But with anthracite, bituminous, and sub-bituminous coals, and even with certain lignites, sohesive blocks cannot be made without the use of a suitable binding material to keep the particles together. More binding material is required with anthracite than with bituminous coals, but peat, like lignite, can be briquetted by pressure alone. The binder which has been most commonly in use up to now is pitch; but, unfortunately, briquettes made with this material are very smoky in burning. Hence many of the United States experiments have been devoted to discovering suitable substitutes. In this respect the chief difficulty which has been encountered is that smokeless binders are generally not waterproof, and can be made so only at a more or less prohibitive cost. As shown by the experiments, however, the difficulty is not an insurmountable one.

The use of briquettes, so far as anthracite and bituminous coals are concerned, lies in the utilization of the fine or small coal. Although some fine coals coke when burning, most of them remain in their natural state, with the result that the dust clogs the draught, or falls through the bars with the ashes. Well-made briquettes, on the other hand, retain their form in the fire, and allow of a good air circulation being established. It follows that, where the difference in price between lump and fine coal is sufficient, they can be manufactured and sold at a profit. Other advantages which briquettes possess over ordinary coal are that they burn to a fine ash without clinker; the stoker's work is easier; the evaporative power, owing to the higher calorific value of the binder and the loss of moisture, is increased; more resistance is offered to weather; and the risk of spontaneous combustion is eliminated.

In the case of lignite, which requires no binder, and in its natural state contains a high percentage of moisture, the advantage of briquetting requires no demonstration. A series of tests reported in the United States bulletin shows that, where the moisture content of the samples varied from 33 per cent. to 42 per cent., from 24 per cent. to 32 per cent. was removed in briquetting, and the heating value of the fuel was increased by from 36.5 per cent. to 52.4 per cent.

These experiments are of the highest importance to Americans, but, in view of the smallness of our lignite supplies, do not possess the same interest for us. The principal European lignite fields are located in Germany and Austria-Hungary. In this country, where chiefly bituminous and anthracite coals are produced, it is with the working up of the "smalls" of these coals that we are concerned. Our output is smaller in proportion than that of other European countries, for the reason that briquettes have not been adopted to any great extent in our locomotives and steamships.

The plant required for making briquettes from anthracite or sub-bituminous coals includes a coal-elevator, pitch-cracker, pitch-elevator, measurer, mixer, disintegrator, compo-elevator, vertical heater, briquetting-machine, and briquette-conveyer. The coal is fed into the elevator direct from the wagons, and the pitch, after going through the cracker, falls into the boot of the pitch-elevator. Both are then discharged into the mixer and measurer, which consists of two screw-conveyers—a large one for the coal, and a smaller one for the pitch. The pitch falls from the smaller conveyer on to the coal in the larger conveyer below, and so becomes mixed with it. The compo is then elevated and discharged into the vertical heater, which forms commonly a part of the briquetting-machine itself. In the heater the mixture is heated up, either by a steam-jacket or by the injection of live steam, preferably superheated, and is at the same time more intimately mixed by revolving beaters. The semi-plastic material is finally fed into the moulds of the briquetting-machine, which are arranged on either a vertical or horizontal table, and a system of levers press it from both sides into rectangular blocks, under a pressure of about 2 tons per square inch. Facilities are provided for filling and discharging the moulds, for giving a rotatory feed to the table, and for varying the pressure. For the smaller eggette or ovoid briquettes, which are now in many cases replacing those of rectangular shape, a different type of machine is used, and the moulds are formed in the peripheries of rollers, which press on tangential feed-slides. In the case of lignite and peat briquetting, the material is forced through a tapered tube in a continuous stream, and is cut off by a wire cutter into cylindrical briquettes of the required length. Portable plants for railway use have also been designed, and a typical example was described in "Engineering" for April 3, 1914.

The English plant, by Messrs. William Johnson and Sons (Leeds), Limited, used in the American experiments, was substantially as above described, except that it was modified in several respects to meet the needs of the experimenters. The principal alteration made was in the measurement of the coal and binder. To ensure absolute accuracy, this was effected by the use of separate scales, instead of by differential conveyers. In the first American plant, by the Renfrow Briquet Machine Company, St. Louis, horizontal heating cylinders were used, fitted with worm-conveyers, instead of beaters. Otherwise the arrangement closely resembled that of the Johnson plant. But in the case of the second American machine, by the American Compressed Fuel Company, Chicago, a different design was adopted. After being measured, the coal was dumped into a steam-jacketed mixer, where the pitch, which had previously been melted and measured, was mixed with it. The mixture was then fed into a roller-press, and formed into briquettes of the eggette type.

For lignite, a German plant by the Maschinenfabrik Buckau Actien-Gesellschaft, of Madgeburg, was used. The lignite, before entering the tube-press, which created a pressure of 14,000 lb. to 28,000 lb. per square inch, was treated in a set of crushing rolls, a rotary drier, sieve, auxiliary crushing-rolls, and cooling-plates with scrapers. The equipment also comprised a small hydraulic hand-press for making preliminary experiments.

The experiments were divided into three periods. From 1904 to 1907 the work was carried on at St. Louis, and the Johnson, American Compressed Fuel Company, and Renfrow machines were used. From 1907 to 1910 at Norfolk, the Johnson and Renfrow (improved) plants were employed, together with a German Schlickeysen peat-machine. And at Pittsburgh, from 1910 onwards, the experiments were confined to the German lignite plant and to the small hand-press, although the English machine has been placed on its foundation.

The physical tests to which the briquettes were subjected were called the "drop" and the "tumbler," the absorption, density, weathering and compression tests. In the first, the briquettes were dropped on the floor, and the pieces, which were held by a screen with 1-in. square holes, were dropped again. This procedure was repeated five times, and the weight of the pieces, which, after the fifth drop, would not pass through the screen, was determined. In the tumbler test a weighed quantity of the briquettes (about 50 lb.) was rotated for two minutes at 28 revolutions per minute in a sheet-steel cylinder. The parts which were held by a 1-in. screen and a 10-mesh sieve were then weighed. The absorptive qualities of the briquette were tested by weighing, and the rate of absorption each day, and the time required for the absorption to become complete, or for the briquette to disintegrate, were determined. The density was taken by means of a Nicholson hydrometer, and the weather-resisting qualities were assessed by observation extending sometimes for as long as 286 days. For measuring the crushing strength a 200,000-lb. Olsen testing-machine was employed, although it is stated that the amount of handling which the briquettes will stand is given more accurately by the tumbler and drop tests.

The chemical tests included analyses and moisture tests, and extraction tests, using carbon bisulphide as a reagent, were made to determine the percentage of bitumen in the raw and the briquetted fuel. To determine the evaporative and burning qualities, the briquettes were burned under a stationary boiler. Special tests were also made on locomotives and on a torpedo-boat, and in domestic furnaces and foundry cupolas. The locomotive tests show that the evaporative efficiency of briquetted as compared with raw fuel is greater; that firing is easier; and that both the clinker and smoke produced are less. On the torpedo-boat it was found that there was no gain in smoke production, or in efficiency, but that the work of the stokers was lightened, and the boiler capacity increased. The domestic furnace tests proved that, for the low temperatures common in house-heating boilers, pitch is an unsuitable binder, as it volatilized and escaped unburned, or became deposited as tar. It also gave rise to too much smoke.

In the experiments the question of what binder can be used has naturally been investigated in great detail. The coal-tar pitch binders at present employed give briquettes which are waterproof, do not crumble during transport, leave little ash, and can be manufactured at a reasonable cost. Other binders, notably cereals and "sulphite pitch" (selpech) have an advantage over pitch, inasmuch as they are smokeless in burning, but they are unfortunately not waterproof, so that the briquettes crumble after exposure to the weather. Such briquettes can easily be rendered waterproof, but the cost has hitherto been considered prohibitive. The American experimenters, however, state that their investigations on this head show that the discovery of a cheap waterproofing process is not an impossible achievement. And the patentee of Middleton's starch binder declares that he has already solved the problem, using 2 per cent. of cereal and ½ per cent. of tar, against, in the ordinary process, 8 per cent. of pitch. The cost of manufacture, he claims, is cheaper than in the pitch process so long as the price of pitch is above 42s. 6d. per ton. He states that the fuel, after exposure to the weather for several weeks, shows practically no deterioration.

In addition to detailed experiments with various kinds and percentages of pitch, the bulletin reports the testing of a large number of other binders. These include creosote, asphalt, petroleum (both of paraffin and asphalt bases), lime, clay, wax tailings, and sludge; various wood products, such as resin, tars, wood pulps, and sulphite liquor; various sugar-factory residues, such as beet pulp, lime cake, and the different molasses; starches, slaughter-house refuse, and petroleum products.

In the tests of pitches it was found that the pitch obtained from the distillation of petroleum gas-tar gave the best results, although other pitches distilled from by-product coke-oven tar, illuminating-gas tar, and producer-gas tar proved quite satisfactory. Water-gas pitch, another binder tested, has an advantage over ordinary coal-tar pitch in that the production of free carbon present is only 10 per cent., as against as much as 30 to 40 per cent. with the ordinary material. The free carbon is useless as a binder, and acts merely as a diluent of the bituminous matter. In all pitches it is important to select a material that is not too hard. The actual hardness required varies with the time of year and the climate; but, generally speaking, it was found that pitch which becomes brittle when dropped into water at 55 deg. Fahr. is of the correct texture. The harder pitches have been robbed of the creosote and lighter oils during distillation, so that pitches from which these oils have been distilled off should be avoided. It is also better for briquetting purposes that the pitch should be prepared in this way rather than by distilling all the oil, and then reducing the pitch with the naphthaline and creosote oils, as is sometimes done. As an example of the disadvantage of using the harder pitches, it may be said that in one experiment with a pitch of this kind, 13 to 18 per cent. was found necessary to make good briquettes, while, when a pitch with the proper amount of light oils was tried, 6 to 9 per cent. proved sufficient. Other experiments show that from 7½ to 14 per cent. of volatile oils is the correct proportion to give the proper binding qualities, and that from 6 to 9 per cent. of pitch of this kind will make good briquettes from most bituminous and anthracite coals. To mix with a non-coking coal 10 to 20 per cent. of a coking coal is better than increasing the percentage of pitch.

Of the other binders tried, it was found that clay, lime, cement, magnesium oxide, plaster-of-paris, acid sludge, sugar-factory residues, slaughter-house refuse, and wood products are all unsatisfactory, although some of the last-named give good results in combination with other binders, and seem for that reason to deserve further investigation. Wax-tailings give fair results, but are not considered altogether satisfactory, while crude petroleum, although answering well, is deemed unsuitable for working on a commercial scale. Resin, used in conjunction with pitch or petroleum, and a percentage of lime to prevent smoking, makes a good binder; but here, again, the cost makes commercial application impossible. Asphalts are also rather too expensive in most places, and give only fair briquettes, but asphaltic tar was found useful as a waterproofing material in briquettes made with starch.

In fact, the only really good binders besides pitch were found to be starch or flour, and sulphite pitch. None

of these is waterproof, but a careful study was made of waterproofing processes, and, as stated above, it is believed that a successful and inexpensive process can be discovered. When using corn starch only 2 to 4 per cent. is required with ordinary coals. The briquettes made with this binder were found to be smokeless. They held their shape well in the fire until completely consumed, and, although the heat value of the binder is small, it leaves no ash. Messrs. Yeadon, Son and Co., of Leeds, are, we understand, constructing a plant for Russia to briquette lignite, with a binder made of finely ground meal and mazut, and a small proportion of pitch.

Sulphite pitch, also known as cell pitch, is made from the waste liquors which are produced in the sulphite process of manufacturing paper pulp from wood. Until recently these liquors had no commercial value, and their proper disposal was a serious matter, since, if discharged into rivers, they polluted the water and killed such fish as were contained in it. In making the pitch, the liquor is concentrated to a syrup in a sextuple-effect evaporator, and solidified into pitch as a thin film on two rotating steam-heated drums. With some coals, less than half the quantity of cell pitch is required as compared with ordinary pitch; but with others, in the American experiments, the percentage necessary was the same for each material. German experiments, on the other hand, incline to the smaller value. Briquettes made with this binder are smokeless and odorless, and the price of the material, if there are cellulose mills at hand, is low. In the Pollacsek process, used by the Hungarian government for its collieries, sulphite liquor is employed, and from 3 to 5 per cent. is found to give good briquettes. The briquettes made with sulphite pitch can be rendered waterproof by drying at a temperature of 300 deg. Cent., or by the addition of certain chemicals, the nature of which at present is not divulged. With the latter process, the cost of waterproofing is estimated at 1s. 6d. per ton of briquettes. It is thought at present that the sulphite process will be more useful for anthracite than for bituminous coals, but that it also will be widely employed in preference to pitch in briquetting ores for smelting.

The cost of manufacturing briquettes in England, exclusive of materials, is estimated at about 1s. 6d. per ton of briquettes, and, using 8 per cent. of pitch, the cost of the binder will be about 3s. per ton of briquettes. The cost of the binder, using 2 per cent. of cereal and ½ per cent. of tar, will be about the same, on Middleton's process, when the cereal costs 7*l*. 10s. per ton. In Germany the cost of making lignite briquettes, including all materials, works out at 7s. 6d. per ton, the lignite being taken at 1½d. per bushel.

There is evidently a large field for the development of this industry, and the briquetting of ores for smelting, which has not been investigated in the American experiments, is likely to be even more important than the briquetting of coals. Not only iron, but copper, nickel, and other ores can be made into briquettes with advantage.

EXPERIMENTS ON PAINT PROTECTION.

Some experiments recently carried out in Europe indicate that a single coat of paint gives iron greater protection from rusting than several coats. Different samples of iron were painted with one, two, three and four coats, respectively, and after a certain time it appeared that the iron under four coats was completely covered with rust, that under three coats was less affected, that under two coats was partly rusted, but the iron under one coat was free from rust. The theory suggested is that increase in the number of coats gives more corroding electric currents at the surface of the metal.

COST OF GOOD ROADS IN UNITED STATES.

Approximately $206,000,000 was spent last year on public roads in the United States, according to statistics prepared by the U.S. Department of Agriculture. In 1904 the total was only $79,000,000 In nine years the increase has been over 250 per cent.

This awakening on the part of the country to the importance of good roads has, experts say, been due in great measure to the principle of state aid to counties and other local communities. New Jersey began the movement in 1891, when it passed its State Highway Law. Massachusetts and Vermont followed a year later, but for the most part the other states were slow to move. In 1904, only fifteen had state highway departments; to-day there are only six that have not. In 1913, the individual states appropriated a total of $38,755,088, to supplement local expenditures.

The value of this state aid is, however, not to be measured by the figures alone, for the bulk of the money comes, and always must come, from the counties and townships. Thus, in 1912, the cash outlay by counties, districts and townships, was $137,493,985. Complete figures for 1913 are not yet available, but it is safe to estimate the sum at approximately $151,000,000. To this must be added some $15,000,000 to represent the value of the labor contributed instead of cash in districts where this practice prevails. Last year, therefore, local communities contributed, in round numbers, one hundred and sixty-six millions of dollars, as against appropriations from state treasuries of $38,755,088. The true importance of this thirty-eight millions lies in the fact that it means expert supervision of the expenditure of a considerable portion of the vast sum of two hundred millions. When each county built as it chose and when it chose, the services of trained engineers were usually out of the question. There was little opportunity to test innovations, little advance in the science of road-building, and there was also difficulty in arousing each county individually to do its best to improve conditions within its own limits. State aid has changed all this. The best engineering skill is available for all works of importance, there is co-operation and a constant stimulus to further improvements. The money contributed by the state not only builds more roads, but it makes better those that other money builds.

At the present time there are in the United States 20,741 miles of roads improved either wholly or in part by state aid. This is nearly the mileage of the French routes nationales, the system of great national highways which is the envy of every civilized nation. The routes nationales are, of course, only a small part of the total mileage of France, where practically every road of any importance is an improved road. Of the 2,226,842 miles of roads in the United States, 233,774 miles, or approximately 10 per cent., are classed as improved.

ONTARIO MUNICIPAL ASSOCIATION.

An interesting meeting, to be held in the first week of September, will be the annual convention of the Ontario Municipal Association. This association is made up of members of county, city, town, township and incorporated village councils and municipal officials. At its meetings addresses are delivered by specialists in various features of local government and administration, and the discussion of these addresses is always practical and generally very interesting and instructive. The association is also an important agency in the promoting of improvements in municipal legislation. The coming convention, which will be held on September 2nd and 3rd, at Toronto, promises to be unusually large and attractive.

A NEW DEFLECTION FORMULA FOR CONCRETE BEAMS.

In a paper read by Mr. G. A. Maney at the 17th annual convention of the American Society for Testing Materials a new formula was given whereby deflection can be calculated from the known loading and beam dimensions. The deflection, according to it, equals the product of the sum of the deformations at the two extreme fibers of the concrete, into a constant. It is based upon the property of the M/EI curve for any beam, that the deflection of the beam is proportional to the statical moment of the area under the M/EI curve. This curve is obtained by dividing each ordinate of the bending-moment curve by the product of the corresponding values of E and I, which are the modulus of elasticity of the material and the moment of inertia of the sectional area of the beam, respectively. The statical moment of the area under the M/EI curve between any two points on the elastic curve, taken about one of these points, is equal to the vertical deflection of this point from a tangent to the elastic curve at the other point, the beam being assumed to be horizontal.

The unit stress on the extreme fiber is equal to Mc/I. The unit deformation, e, of that fiber is therefore equal to Mc/EI and the total deformation in the distance dS along the elastic curve equals $McdS/EI$. Referring to Fig. 1, it is seen that this total deformation of the extreme fiber, divided by the distance c from that fiber to the neutral axis, is equal to the change of slope, $d\theta$, in the distance dS. Or

$$d\theta = \frac{Mc\,dS}{EI} \div c = \frac{M\,dS}{EI}$$

It will be seen that the term $M\,dS/EI$ is equal to the area under the M/EI curve for the distance dS along it; that is, $d\theta$ is equal to a differential element of the area under that curve.

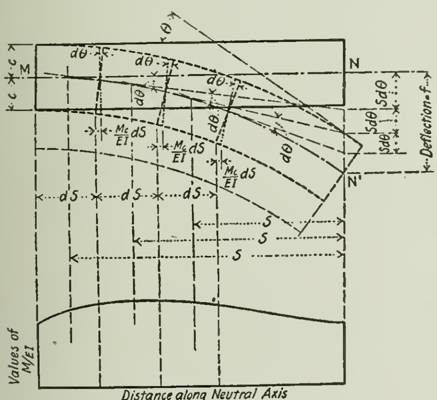

Fig. 1.—The M/EI Curve for Beam.

Now, let S equal the distance from any differential element dS to the point at which the deflection is desired. Then, referring to Fig. 1, it is clear that the deflection of N' from the tangent MN at M is equal to the sum of the products of each $Sd\theta$ along the elastic curve from M to N, S being measured from N'. Or

$$f = \Sigma\, S\, d\theta$$

But $S\,d\theta$ is equal to the statical moment of the differential element of the area under the M/EI curve about N', by the definition of statical moment. Therefore, the deflection of any point from the tangent to the elastic curve at any other point is equal to the statical moment of the area under the M/EI curve about the first point. (In this proof, as in all treatments of the elastic theory, it is assumed that the projection of the neutral axis after bending, upon its original position, is the same as its length before bending.)

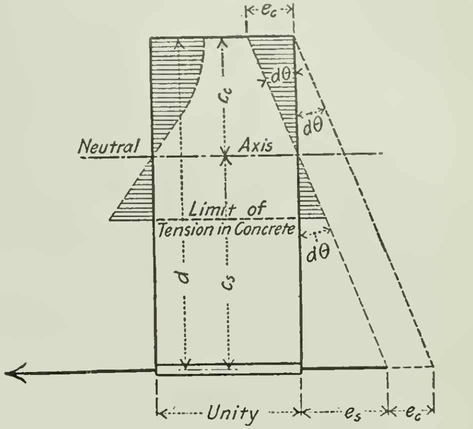

Fig. 2.—Showing Variation of Deformation and Stress.

This property for homogeneous beams may be expressed:

$$f = kl^2\,(M/EI)$$

The value for M/EI in equation (3) will be taken for the point in the beam at which the bending moment is maximum. Then the value of k is such that the statical moment of the M/EI area between any two points, which is equal to the deflection of one point with respect to the tangent to the elastic curve at the other, is expressed in terms of this maximum value of M/EI and the span of the beam, l.

It is evident that the value of k for any case is equal to the coefficient of deflection for homogeneous beams in the well-known equation $f = k_1 W l^3/EI$, divided by the coefficient for the maximum bending moment, which in general may be expressed as $M = k_2 Wl$, from which $W = M/k_2 l$. Substituting this in the last equation for deflection,

$$f = k_1 \cdot \frac{M}{k_2 l} \cdot \frac{l^3}{EI} = \frac{k_1}{k_2}\, l^2 \left(\frac{M}{EI}\right)$$

Comparing equations (4) and (3), it is seen that $k = k_1/k_2$. To illustrate, consider the deflection at the centre of a freely supported beam with a single concentrated load at the centre; that is, the deflection of the support with respect to the tangent to the elastic curve at the centre. The coefficient k_1 is 1/48, and k_2 is 1/4. Therefore the coefficient k in equation (3) will become $1/12 = 0.0833$ (see Fig. 3b).

The maximum deflection of a simple beam is equal to the deflection of the support from the horizontal tangent to the elastic curve. Usually the maximum deflection occurs at the centre of the beam, as in all cases of symmetrical loading. With irregular loading, it usually occurs near the centre of the beam. Then, by the property of the M/EI curve above referred to, we may express this deflection as the statical moment about the support of the area under the M/EI curve between the

point at or near the centre of the span, where the slope is zero, and the support. If this statical moment is expressed in terms of the maximum ordinate of the M/EI curve and the whole span, an expression is obtained of the form of equation (3), in which the coefficient k will equal k_1/k_2.

It may be of interest here to point out that M/EI equals the rate of change of the slope of the elastic curve, or the change of slope per unit distance. This may be seen by dividing equation (1) by dS, which gives $d\theta/dS = M/EI$.

The application of this principle to the deflection of reinforced-concrete beams consists in finding a convenient expression for the value of M/EI.

Let e_c and c_c be the unit deformation in the extreme fiber and the distance from the extreme fiber to the neutral axis, respectively, for the concrete, and let e_s and c_s be the same quantities for the steel. In a homogeneous beam, as above indicated, $e/c = M/EI = d\theta$, and is the same for both extreme fibers. In this case, since the

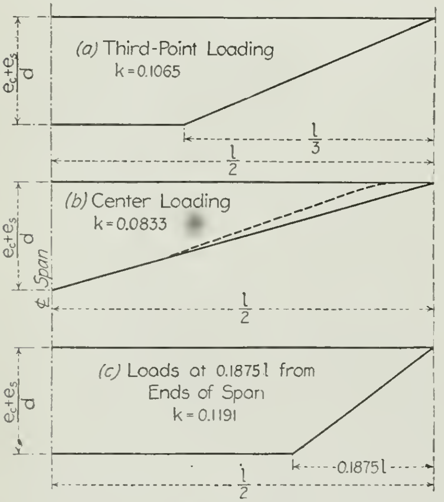

Fig. 3.—Showing Variation in Values of (Ec + Es)/D.

values of EI are constant throughout the length of the beam, e/c varies directly as M throughout the span.

In a reinforced-concrete beam (see Fig. 2),

$$\frac{M}{EI} = d\theta = \frac{e_c}{c_c} = \frac{e_s}{c_s} = \frac{e_c + e_s}{d}$$

Substituting this value of M/EI in equation (3), the following expression for the deflection of a reinforced-concrete beam is obtained:

$$f = k\frac{l^2}{d}(e_c + e_s)$$

This is based on the usual assumption that a plane before bending remains a plane after bending, which seems justifiable from the evidence of reliable tests herein referred to.

From the preceding analysis it is evident that the deformations of the extreme fibers are the only determining factors in the deflection, except the span, depth of beam, and load-distribution. It is also evident that the distribution of the stresses in the steel and concrete over the section has no influence on the deflection, except in so far as the stresses influence the deformations of the extreme fibers.

The influence of tension in the concrete might well be discussed here. From the principles of equilibrium it is known (see Fig. 2) that the effect of the tension in the concrete at low stresses is to reduce to some extent the compressive stresses in the concrete and the tensile stresses in the steel. This means that a stiffer beam might be expected in the earlier stages of the loading, as the steeper slope of deflection and deformation curves show.

For the reason, therefore, that tension exists in the concrete and that usually near the end of the beam the roads are bent up, the value of the $(e_c + e_s)/d$ curve, from which the deflection is obtained, will not have the same variation as the values of M.

Near the supports of a simple beam and at all points where the bending moment is small, we would expect considerably smaller values of $(e_c + e_s)/d$ than the value of M at such a point, relative to the value of M at the point of maximum moment would indicate. The values of $(e_c + e_s)/d$ would probably follow the dotted lines indicated in Fig. 3b, because of the tension in the concrete. A glance at Fig. 3b will show, and computations will prove that a small decrease in values of $(e_c + e_s)/d$ $(= d\theta)$ near the point about which moments are taken (the support, in this case), changes the value of this moment only slightly.

Values of k for maximum deflections under several conditions of loading are here given:

Beam with uniform load:
- Ends freely supported, $k = 5/48$ or 0.1041;
- Ends fixed, $k = 1/32$ or 0.0313.

Beam loaded at the third points:
- Ends freely supported, $k = 23/216$ or 0.1065;
- Ends fixed, $k = 5/144$ or 0.0347.

Beam loaded at the middle:
- Ends freely supported, $k = 1/12$ or 0.0833;
- Ends fixed, $k = 1/24$ or 0.0416.

DOMINION GOVERNMENT BUYS INTERNATIONAL RAILWAY.

On August 1st the International Railway became a part of the Intercolonial Railway and will be operated by the Dominion Government in future. Mr. Evan Price, superintendent of the Canada Eastern Division of the Intercolonial Railway, will superintend the operation of the new portion, which is 112 mi. in length.

OGDEN POINT BREAKWATER, VICTORIA, B.C.

The site of the proposed breakwater at Ogden Point is now the scene of considerable activity, the contractors having started work last week. Rip-rap is being hauled by towboats and scows from the Albert Head Quarries. The facilities for the transportation of this material are adequate for conveying 50,000 tons per month. Pile-driving to indicate the line of the breakwater has been completed, the extreme point being about 1,750 ft. from shore. The shore work in connection with the breakwater is almost complete, the site having been levelled off and the fillings completed. These fillings have greatly enlarged the land surface at the disposal of the government for the piers in connection with the breakwater.

It is expected that the work will be nearing completion in about eighteen months. The breakwater is of concrete construction, faced with large granite blocks

Editorial

ENGINEERING AT HOME AND WAR ABROAD.

What will be the effect of the great international struggle in Europe upon engineering undertakings proposed and in course of construction in Canada? It is difficult to predict with any guarantee of accuracy, because the present situation is unparalleled, not only in the history of Canada but also in that of the whole world. We can but analyze the situation so far as available data will allow. In the matter of works of construction the natural division seems to be as follows:

(1) Work in progress and possible of postponement.
(2) Work in progress and necessary to continue.
(3) Proposed works, capable of postponement.
(4) Proposed works, necessary to continue.
(5) New work undertaken, due to war.

Obviously, all these divisions are dependent upon successful financing. It is likely that some of the undertakings now in course of construction, and which might even be postponed without disadvantage, will proceed if the funds for the work were obtained prior to the outbreak of war. On the other hand, those enterprises which have not been financed and which, to any degree of convenience can be postponed, will undoubtedly be stopped. There are certain works which must continue, and it is probable that these have been financed completely, except unusually large undertakings, such as the Toronto Union Station, the Greater Winnipeg Water District scheme, and the Harbor Board's development at Toronto. The total cost of these and similar undertakings in each case is high. The Toronto Harbor Board raised funds by the sale, some months ago, of several million dollars worth of bonds, which will finance their work for some little time to come. The Greater Winnipeg Water District Board obtained $2,000,000 in London last month, and that sum will finance their work for some months. The railway companies interested in Toronto's Union Station probably have enough money to proceed, slowly at any rate, with the work of construction.

Works which have been proposed but which are capable of convenient postponement, will undoubtedly be delayed to some extent, if not lengthily postponed. This applies more particularly to the undertakings of private corporations. There are certain proposed works which it is highly desirable to continue, such as, for instance, certain improvements and extensions of the Ontario Hydro-Electric Commission's general scheme. Private corporations probably will not consider it justifiable, in view of events in Europe, to proceed with any extensive proposed works and which were thought perhaps to be necessary.

Some new work may be undertaken in Canada due directly to the outbreak of hostilities. This would likely be in ship-yards chiefly, in connection with naval and military operations generally, and with war engineering.

In considering these factors, we must subdivide them again into:

(1) Works of private capital.
(2) Works of government authorities.

The writer has been of opinion always that governments in times of extreme trade depression should spend money on public works, so far as proper economy dictates. In a time such as the present, and in view of the fact that the theatre of war is not actually on Canadian soil, the Dominion Government well might employ fairly substantial sums upon certain public works. Private borrowers will hesitate considerably at present because Canada's chief lender (Great Britain) has a bigger job on hand now than loaning money to its overseas dominions. Indeed, private borrowers, in which are included corporations, are almost helpless, except for funds in hand and for the possibility of borrowing elsewhere than in Great Britain.

On the other hand, the Dominion's credit is better than that of any other borrower in the Dominion, and there are several methods, such as the raising of temporary loans, which the government might use in case of necessity. The citizens of Canada likely would not protest against any action taken by the government to give employment to the citizens and to their industries, in such a time as this, any more than they will protest when the government imposes a special tax on tea and other commodities for war purposes in the British Empire.

Aside from that particular phase, the situation is regulated considerably by the fact that Great Britain, which has loaned Canada altogether £500,000,000, cannot, for the time being, continue to lend. One naturally turns to our nearest neighbor, the United States, which in its time has borrowed enormous sums of money from Great Britain, and which has in recent years become one of the two minor lending countries, the other being France, Great Britain taking first place. The United States has enjoyed for several years sixty per cent. of Canada's import trade. If the United States is able at this time to finance the immediate needs of Canada, there is a pleasing likelihood that a fairly substantial amount of construction work will proceed. This will be further emphasized if the Dominion Government, having due regard to the menace of war, will go on with a certain amount of public work.

THE QUEBEC STREAMS COMMISSION.

The second report of the Quebec Streams Commission, organized in December, 1911, has just been issued, and contains a statement of the studies of a general nature that were carried on during 1913. The personnel of the Commission consists of Chairman, S. N. Parent, C.E.; Commissioners, Ernest Bélanger, C.E., and Wm. I. Bishop, C.E.; Engineer, Olivier Lefebvre, C.E.; Secretary, H. L. de Martigny. It submits a somewhat lengthy investigation on the determination of the legal character of rivers in Quebec and their classification. Other studies are based upon the regulation of the construction of dams and other hydraulic works on these rivers, and upon the improvement of rivers for floating logs, and the authorized tolls. Still others include the regulation of the flow of the St. Francis River and its tributary, the Magog, by means of storage dams to be erected at the outlet of the principal lakes which feed them. Such a problem requires the consideration of several distinct elements, as, for instance, the general usefulness of the project, the technical difficulties to be overcome, the cost of the proposed works, the practical results, the revenue to be derived, and the methods of financing and carrying out the undertaking.

The object of the St. Francis River equalization is primarily to reduce the height of flood waters, thus minimizing the risk to bridges and other structures along the waterway, preventing overflow upon adjacent lands and minimizing present losses to lumbering operators caused by the breaking of booms, etc. It would increase the present low-water flow to approximately double the present figures, increasing the available continuous water power, and the capacity of manufacturing plants, as well as the advantages that would accrue to log driving by increasing the length of time each year for operations. Besides, the petitioners claim that the prevention of extreme low-water periods would greatly improve sanitary conditions and domestic water supplies in towns and villages along the river.

TO ESTABLISH A MERIDIAN AT ANY TIME, BY HOUR ANGLE.

By J. A. Macdonald, Ottawa, Ont.

By the peculiar and ingenious arrangement, prepared originally by Mr. J. B. Shinn, of the U.S. General Land Office, Washington, and issued by the commissioner, a new set of tables designed to enable observations for azimuth to the nearest minute to be made at any hour by an observation of Polaris is now obtainable. By the use of this table, an observation for azimuth can be made at any time when Polaris is visible. All the data necessary to make the observation are presented on two pages. Every surveyor knows how inconvenient it is to await the time of elongation of Polaris, especially in the cold, winter weather, while at times both elongations occur in the daylight hours. By means of this simple table, the observation can be taken at pleasure, simply noting the time (local mean time); the azimuth of the star may be taken out later for that particular time. The annexed diagram shows in their proper relation the various aspects of Polaris in its daily apparent motion around the North Pole.

Hour Angle of Polaris.—In the figure the full vertical line represents a portion of the meridian passing through the zenith, Z (the point directly overhead), and intersecting the northern horizon at the north point N, from which, for surveying or draughting purposes, the azimuths of Polaris are reckoned east and west. The meridian is pointed by the plumb line when it is in the same plane with the eye of the observer and Polaris on the meridian, and a visual representation is also seen in the vertical wire of the transit, when it covers the star on the meridian.

When Polaris crosses the meridian it is said to culminate; above the pole, at S, the passage is called the Upper Culmination, in contradistinction to the Lower Culmination, at S'. The engineer will better understand the diagram by holding it up perpendicular to the line of sight when he looks toward the pole—Polaris is supposed to be on the meridian, where it will be about noon on April 10th of each year. The star appears to revolve around the pole in the direction of the arrows, once in every 23 hours 56.1 minutes, mean solar time. It consequently comes to and crosses the meridian, or culminates, nearly four minutes earlier each successive day. One-quarter of the circle will be described in 5 hours 59 minutes, one-half in 11 hours 58 minutes, and three-quarters in 17 hours 57 minutes.

The hour angles of Polaris expressed in mean solar time (common clock) are counted from the upper meridian, at S, to the west, around the circle from 0 hours 0 minutes to 23 hours 56.1 minutes, and may have any value between the limits named. The hour angles measured by the arcs are 1 hour 8 minutes; 5 hours 55 minutes; 9 hours 4 minutes; 14 hours 52 minutes; 18 hours 1 minute; and 22 hours 48 minutes respectively; their extent is indicated graphically.

All the surveyor has to do, then, is to subtract the time of upper culmination (as found in the tables) from the correct local mean time of observation. The remainder will be the hour angle of Polaris expressed in

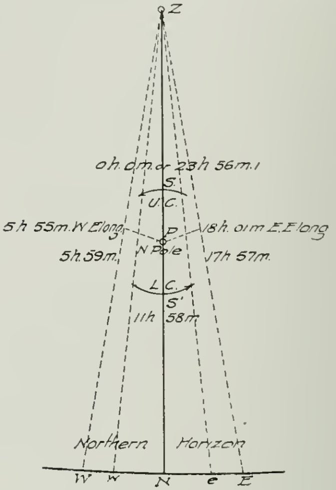

Fig. 1.

time. The table of culminations answers for all latitudes, and in general, for all longitudes, hence its simplicity. The table, Part II., answers for latitudes 30 deg. to 50 deg., and also distinctly for each year.

Example.—Required the hour angle and azimuth of Polaris for a point in latitude 41 deg. 12 minutes N, at 6 hours 16 minutes a.m., November 19th.

	h.	m.
Astronomical time of observation, Nov. 18th..	18	16.0
Astronomical time U.C. Polaris (Table, Part I.)	9	34.6
(Subtracting)	8	41.4

With this hour angle of Polaris, 8 h. 41.4 m., enter table Part II. Azimuth of Polaris at observation (Table, Part II.) 74 m. or 1 deg. 14 m. W.

These tables combine in two operations the essentials which, under ordinary methods, would require about twenty.

The watch time to be used when making observations should be as accurate as can be obtained, for to obtain the azimuth to the nearest whole minute of arc, the local mean time, upon which all depends, except for elongation, should be known within two minutes. When standard railway time is used, as probable in most cases, the observer will correct the same for difference of longitude at the rate of 4 minutes of time for each degree of difference in arc. This difference of longitude can be nearly always taken from a map. The correction will be subtracted from the standard railway time of observation when the surveyor's station is west, and added when east of the standard meridian, to obtain local time.

MINING IN QUEBEC, 1913.

A STATISTICAL review of mining operations in the Province of Quebec during the year 1913, is contained in the recent report of the mines branch of the Provincial Department of Colonization, Mines and Fisheries. According to it, the value of the products of the mines and quarries of the province reached a total of $13,119,811 during the year ending December 31st, 1913. It is the highest annual production recorded to date and exceeds that of 1912 by $1,932,701, or a proportional increase of 17%.

The Mining Law is quite explicit in respect to sending in reports of production. Article 2163 of the Quebec Mining Law states that "Every owner of mining rights, whether he mines himself or by others, and every person working mines shall, during the first ten days of January in each year, furnish a sworn statement of his operations for the past year, mentioning the quantity of mineral extracted, its value at the mine, the quantity and value of the marketable product, and the number of workmen employed, as well as a list of the names of persons killed in working the mines."

As a rule, returns are made promptly. But a few belated reports usually delay the final compilation of the figures. For this reason a preliminary statement is issued each year so as to place the statistics before the interested public at as early a date as possible. Although not quite complete, the early statistical data are sufficiently near the truth to give a very good idea of the state of the industry. This year's preliminary report, noted in brief in a preceding issue of this journal, appeared in the latter part of February. In 1913, there is a difference of 1.6% between the total of the early statement and the figures as finally compiled. In 1912, they differed by 1½%, and as a rule, the difference is less than 2%.

The table of production shows the greater proportion of the total is made up of the value of the structural materials. They make up 63%. The products of metalliferous mines enter for 7½% only in the total. It is a slight increase as compared with the previous year, 6.09%, and quite an appreciable one as compared with 1911, when the proportion was only 3.17%. This increase is due solely to the further development of old districts, for we have yet no production to record from the northern fields. That these will eventually contribute to the mineral production, there is no doubt. Promising geological and mineralogical conditions exist in the Kienawisik Lake region, whence discoveries of gold have been reported. In this connection, it may be mentioned that, in the Report of Mining Operations in the Province of Quebec for 1912, a report on the northwestern part of the Province of Quebec, by Dr. Bancroft, was published, as well as some notes on the gold discoveries at Lake Kienawisik.

The following table gives the annual value of the mineral production of the Province of Quebec for the last ten years:

Year.	Value.	Year.	Value.
1904	$ 3,023,568	1909	$ 5,552,062
1905	3,750,300	1910	7,323,281
1906	5,019,932	1911	8,679,786
1907	5,391,368	1912	11,187,110
1908	5,458,998	1913	13,119,811

We note that since 1904 there is an unbroken series of increases of each year over the preceding one. In ten years the mineral production of the province has more than quadrupled. It is especially gratifying to note that the general business depression which prevailed during the greater part of the year 1913 does not seem to have affected the mining industry in the province. Comparing the production of 1913 with that of the previous year, the Province of Quebec shows a higher proportional increase than any of the other provinces. Quebec's increase in 1913 over 1912 amounted to 17%; Ontario 12.5%; Nova Scotia 2%; British Columbia shows a decrease of 5½%.

Table of Mineral Production of the Province of Quebec During 1913.

Substances.	No. of workmen.	Salaries.	Quantities.	Value.	Value in 1912.
Asbestos, tons	2,909	$1,686,251	136,609	$3,830,504	$3,059,084
Asbestic, tons	....	....	28,473	20,346	23,358
Copper and sulphur ore, tons	292	163,997	87,550	812,899	631,963

Zinc and lead ores, tons	59	35,500	335	7,370	......
Structural Materials:					
Brick, M.	1,843	590,003	159,408	1,297,592	1,284,232
Cement, bbls.	1,278	1,136,117	2,881,480	3,361,292	3,098,350
Flagstone	....	......	......	......	600
Granite	645	365,378	......	496,588	358,749
Marble	209	108,154	......	120,541	252,041
Lime, bushels	317	163,431	1,922,837	464,424	455,570
Limestone	1,414	747,418	......	1,704,207	1,363,555
Sand	171	65,966	......	405,750	170,600
Sandstone	10	370	......	5,072	......
Slate, sq.	20	12,660	1,337	6,286	8,939
Tile, drain and sewer pipe, pottery, etc.	237	138,114	......	326,165	203,100
	9,925	$5,401,702	......	$13,119,811	$11,187,110

Building construction to the extent of $2,000,000 is under way in Moose Jaw, chief among which is the $1,250,000 Government elevator.

Coast to Coast

Lethbridge, Alta.—The street railway deficit for the year at Lethbridge was estimated in January at $40.000; and for the first six months of this year, the deficit has amounted to $19.185.35.

Winnipeg, Man.—The Grain Growers' Grain Company has secured a further lease of the Manitoba grain elevator system from the Manitoba Government on practically the same terms as previously. No definite period for the renewal was specified.

Gibson, N.B.—Concrete Builders, Limited, has installed a new block tamping machine and brick attachment at its plant at Gibson, N.B. The block tamper is capable of producing 500 concrete blocks per day; and the brick attachment, of 10,000 bricks per day.

Regina, Sask.—The 5,000,000-gallon reservoir which is being built at Regina by day labor comprises an area for excavation of 250 feet by 150 feet. The soil from the excavation which will total 11,000 cubic yards when completed, is being removed to form a covering for nuisance grounds in the city north of Fourth Avenue.

Winnipeg, Man.—On many portions of that part of the C.N.R. which lies in the district west of the western boundary of Manitoba from the Great Lakes, the work of replacing the 60-pound rails on the main line with 90-pound rails, has been proceeding. It is said that before winter the company will have laid in all 300 miles of this heavy steel.

Halifax, N.S.—Building operations are quite brisk and several buildings are now under construction, the principal building being the large Acadia School, which will be a first-class structure, with the most modern improvements. There are also two schools which will have large additions attached to them. St. Joseph's Temperance Hall is well under construction.

Regina, Sask.—The city of Regina has decided to proceed at once with its programme of water main construction for 1914. The work is being done partly by day labor under the direction of the city's waterworks department, and partly by John Brodt, who is employing machines. This is being done that the department may get a comparison of prices in the work on each class of pipe, with the exception of the 24-inch pipe which amounts to only two blocks and will be laid entirely by the city.

Lacombe, Alta.—The first gasoline electric railway to be constructed in Alberta is the line now under construction from Lacombe West to Gull Lake, Bentley, and Rimbey, a distance of around 45 miles. It is reported as well under way, over half the distance being graded, and ties being on the ground the full length of the route. Moreover, the rails are in the yards, and one of the cars is now on the way from England, where it was manufactured; so that it is fully expected to have the line in operation early this fall.

Guelph, Ont.—Operations have ceased for a time on the drilling being done by Peat and Son of Petrolia, who were given the contract to bore the artesian well at the Guelph waterworks pumping station. The drill had reached a depth of 870 feet, and indications did not promise that a pure flow of water would be encountered at a lower depth. It is declared that the mineralized water which has already been struck in the city can be utilized; and it is thought that the flow will reach at least 50,000 or 60,000 gallons per day.

Toronto, Ont.—The local hydro-electric commission has recently been experimenting with "half-watt" lamps for street lighting, and the entire Avenue Road hill district and several sections of streets in other parts of the city have been furnished with these. The effect has been to produce on the Avenue Road hill twice as much light as previously. The new nitrogen or "half-watt" lamps give, when new, a radiance of some 200 candle power; while the former tungsten bulb was equal in radiance to 80 candle power.

Toronto, Ont.—The orders recently placed by the C.N.R. company for equipment were given as follows: to the Canadian Car and Foundry Co. for between 25 and 30 passenger and sleeping cars at a money value of about $500,000; to the National Steel Car Co. of Hamilton for 10 baggage cars at a cost of between $50,000 and $60,000; and to the Crossen Car Company and the Preston Car and Coach Company for smaller orders of passenger equipment. The company has not as yet placed any orders for freight equipment, and is not expected to do so for some time.

Toronto, Ont.—The most recent report upon the colonization roads work in progress in Northern Ontario announces that the Port Arthur and Fort William road is being stoned and gravelled; and new roads are being cut into the Pigeon River country, connecting Fort William with the Minnesota State road, which will run through 57 miles of new country in Canada. The State road leads to Duluth, and is 100 miles long. The Sydney to North Bay trunk road will be completed within a year, while the trunk road between North Bay and Mattawa is now finished. Early this season the Sudbury to the Soo road will be open.

Calgary, Alta.—City Commissioner Graves, of Calgary, calls attention to the announcement in our "Coast to Coast" columns of July 9th regarding the surplus for 1913 of the Calgary Electric Railway. The figures given, $177,000, presumably relate to the city electric light department, whose surplus was in the vicinity of that figure. That of the street railway was $71,627.81 at December 31st, 1913, according to the Commissioner. In regard to the deficit of $70,000, reported in our issue of July 2nd, the city authorities are not in a position to state what the outcome for the year will be, under which circumstances the figure mentioned is not justified.

Montreal, Que.—The Hon. J. A. Tessier, provincial Minister of roads, recently stated in connection with the progress that is being made on the road under construction between Levis and Jackman, Que., that already 13 miles of the road have been completed, and 30 more have been graded ready for the top macadam dressing, the present progress warranting the hope that the entire 70 miles between the two points would be finished this year. The minister also said that at present he is engaged upon plans for the new highway from Montreal to Quebec; and that the whole question of road construction in the province is advancing as never before.

Toronto, Ont.—Three years will be required to complete the proposed project for disposing of garbage in Toronto. The scheme will not only entail the construction of a new central plant, but will necessitate the construction of special cars for the conveyance of garbage; since the transit must be made along street railway lines and must be odorless. The plans also include the installing of special cans for household service, so as to make the new system thoroughly modern, clean and effective. The new method of special preparation of the garbage, and the separation of its various elements, will also make the disposal profitable. The sale of grease and fertilizer will reduce the cost of incineration; and all smell will be eliminated in the process by the deodorizing of gases.

Calgary, Alta.—The Bow Island Natural Gas and Calgary Oil Company, Limited, has altered its proposal to meet the requirements of the city of Calgary that the word "exclusive" should be cut from the franchise it seeks to make

with the city for the supply of gas at the city boundary. It will either construct a pipe line from Bow Island to the city limits and supply gas at 10 cents per 1,000 cubic feet, or sell gas at Bow Island at 2½ cents per 1,000 cubic feet, the city to construct the pipe line. The city is asked, however, to contract for a minimum amount of gas, not as yet determined; and, if this amount is exceeded, the city is to be free to continue taking its supply from the company, or if dissatisfied with the service or price, from some other company. The company has already sunk one well which is capable of producing 10,000,000 cubic feet of gas per day, and is anxious to secure a market without delay.

Porcupine, Ont.—A twenty stamp addition to the Hollinger mill has been completed, and will be running in a few weeks. Then the foundations will be laid for the twenty stamps which are to be reserved for the ore from the Acme gold mine, the private property of the syndicate. There is already enough ore on the Acme blocked out to keep them going for some time. Basing calculations upon the stamp duty of the present Hollinger mill, the combined plant will then have a capacity of over a thousand tons a day. It is not expected that the whole of the eighty stamps will be in operation until next February. The main vein of the Hollinger has been cut at the 675 feet level. It is about twelve feet wide, and appears to carry much the usual grade of ore. No. 41 vein has also been picked up on the 200-foot level, and this discovery will add considerably to the probable ore reserves of the mine. Another shaft is being sunk to open up the Hollinger property from the south.

Edmonton, Alta.—An inspection of the Alberta and Great Waterways Railway, now under construction from Edmonton to Fort McMurray, was made recently as far north as Lac La Biche by W. R. Smith, chief engineer of the line, who reports that the first 14 miles of grading is completed. Track is now completed to mile 14, at which point ballasting of the completed portion will be commenced and proceeded with with all possible despatch. Beyond mile 14, despite the handicap of an exceptionally wet season, work is progressing favorably. The completed portions of grade aggregate well over 50 miles. It is thought that the grade will reach the lake by the fall; and the intention is to rush track-laying to mile 26, where the Redwater River crossing will delay operations for a few days, while a bridge is being driven across the stream. When the bridge is completed the track-laying machine will follow the grade northward as it is made ready for the steel.

Ottawa, Ont.—A project of the United States Government to construct a waterway to connect Montreal and New York, has recently been discussed at Ottawa, the representatives from the United States in connection with the scheme being Colonel W. M. Black, of the United States army engineering corps, New York, and Lieutenant-Colonel Harry Taylor, assistant chief engineer at Washington. It is planned that the waterway will be 12 feet deep, and will go by way of the Richelieu. The present water communication is not deep enough to be very practicable. The plan was first proposed some few years ago in Canada; but after a government investigation of its possibilities, nothing was done. The scheme involves the building of a movable dam near St. John, so as to increase the level of the Richelieu River where it leaves Lake Champlain, and thus overcome the rapids around which the Chambly Canal now provides a route. A short canal to La Prairie instead of by way of Sorel is also mooted.

Montreal, Que.—Messrs. Warren and Wetmore have completed plans for the temporary passenger station which is to be erected at Montreal by the C.N.R. The structure will be a modern one of steel and concrete 150 feet front by 100 feet depth, and will have two storeys above and one below street level. From the front street, there will be seven doors leading into a vestibule 21 feet wide and 100 feet long and thence into the passenger waiting room, 60 by 100 feet and 30 feet high. This will be flanked by all the various rooms and offices customary at railroad stations. Immediately below the vestibule is the concourse with easy ramps leading to the platforms. There will be 3 double platforms and 6 tracks; and it is understood that these tracks will be permanent and will form a part of the future track system of the C.N.R. permanent terminals in this city. The baggage will be handled in a separate portion of the building in the rear approached by special driveways; and from the platforms it will be handled by lifts.

Vancouver, B.C.—Work has commenced on the wharves and slipways which constitute part of the drydock construction being undertaken by the Dominion Shipbuilding Company at Vancouver. The amount to be expended on the enterprise will be $2,500,000; and it will be a couple of years before the plant is prepared to handle ships. According to the plans of the company a big floating drydock, capable of lifting big vessels, will be built; and shops equipped to carry out the largest kind of repair jobs will be erected. The work of dredging, filling and laying out of the foundations of the buildings is being done by the British Columbia Granitoid and Contracting Co., Limited, of Seattle. The first two buildings to be erected will be the machine shop and boiler shop; and the plant of the Mainland Ironworks, of Vancouver, which has been absorbed by the new undertaking, will be moved at once to the north shore site in order that the new company will be able to proceed with this branch of the work. Lynn Creek will be dredged over an area 2,900 feet long, 100 feet wide and 25 feet deep; and all the sand and gravel taken from these dredging operations will be conveyed by suction and placed over the entire site.

Montreal, Que.—The chief features of a scheme of tunnel and terminal construction which has been devised by Napoleon Hebert, a controller of Montreal, are:—(1) a union station on the site of the present Place Viger station to accommodate passenger traffic of the Canadian Pacific, Canadian Northern, and Grand Trunk and the various lines, including the Intercolonial, that have running rights; (2) the purchase of the Bonaventure station site and the present rights-of-way as far as St. Henry, the demolition of the structures, and the removal of the tracks; (3) a provision for more freight terminal space in compensation for the expropriation of the Grand Trunk Bonaventure station, probably in St. Gabriel ward; (4) a line to provide connection with the proposed union station, opening from St. Henry, and proceeding by elevated tracks along the river-front streets; (5) the removal from the river-front of the Canadian Pacific tracks and the establishment of a new entrance to Place Viger by constructing a tunnel or subway from Mile End; (6) the removal of Moreau Street station of the Canadian Northern and the construction of a tunnel to give a new entrance to the proposed union station; (7) a provision of space in the tunnel for the Tramways Company, running northwards from Place Viger to Mile End.

Moncton, N.B.—The city council of Moncton has adopted a proposition which will be submitted to Mr. F. P. Gutelius, General Manager of Government Railways, for ratification; and, pending the agreement being satisfactory to him, a plebiscite vote will be taken on the proposition at as early a date as possible. The proposition deals with the question which has been discussed at different meetings of the city council and representatives of the I.C.R.—i.e., the elimination of level crossings in the city of Moncton; and provides for, first, the elimination of all grade crossings, save one, between Main and Union Streets; secondly, a permanent overhead bridge, 70 feet wide, at Union Street; thirdly, an overhead bridge at St. George Street, and one at Victoria Street; fourthly, a sub-

way at Main Street and a slight change in Archibald Street; fifthly, a 6-foot concrete sidewalk on railway property from Robinson Street to Main Street on the western side of the Railway; sixthly, a pedestrian subway under Lutz Street, Queen Street to remain open for 3 years or until some arrangement is reached between the railway and city council; and last, the entire programme of construction to be done by the railway, and the city to contribute $5,000 to the company upon the completion of the work.

PERSONAL.

D. ROSS has been appointed locomotive foreman in charge of work at the Southwark terminals of the Grand Trunk Railway.

J. R. ESSON, ROBT. McKAIG, and ROY ROBERTSON, of Petrolia, left last week for Mexico to carry on oil-drilling operations there.

R. H. SPERLING, general manager of the British Columbia Electric Railway Co., has resigned and is being succeeded by Mr. George Kidd.

H. H. BOYD, of Saskatoon, has taken up, at Moose Jaw, the duties of superintendent of the Moose Jaw division of the Canadian Pacific Railway.

A. N. BEER, who has been engineer in charge of the Waterworks Department of the City of Ottawa during the past year, has handed in his resignation.

M. C. McCONNELL, of the Geological Survey of Canada, is in the Omineca Mining Division of British Columbia investigating the geology of the Hudson Bay mountain.

R. H. CAMPBELL, Superintendent of Forestry, Ottawa, has been made an honorary member of the Royal Scottish Arboriculture Society at its recent conference at Edinburgh.

C. A. MEADOWS, B.A.Sc., has just returned from Europe, where he has spent three months on an investigation of improved machinery for wire and ornamental iron work.

WILLIS CHIPMAN, C.E., Consulting Engineer, Toronto, has been retained by the City of Edmonton to report upon the several electric power schemes now under consideration.

C. G. TITUS, B.A.Sc., for three years engineer and assistant manager of the Temiskaming Mines, Cobalt, Ont., has been appointed superintendent of the Renfrew Molybdenum Mines.

CHAS. GRASS, of Waasis, N.B., formerly concrete inspector on the I.C.R., has been appointed assistant bridge inspector, under Mr. Eugene Savage, on the Canada Eastern Division of the I.C.R.

WM. SNAITH, secretary-treasurer of the Thor Iron Works, Toronto, has just returned from a five months' absence in California, where he was superintending for his company the construction of a number of large oil tanks at Oilfields, Cal.

FRANK SCOTT, of Montreal, treasurer of the Grand Trunk Railway for 13 years, and of the Grand Trunk Pacific since 1906, has been appointed the vice-president and treasurer of the company, a new position occasioned by the death of Mr. M. M. Reynolds, formerly vice-president.

S. NAKAGAMI, vice-councillor of the Imperial Government Railways of Japan, arrived in Canada from Tokio last week and will remain in this country for several months investigating its railway systems. Interviewed in Montreal, Mr. Nakagami stated that Japan had now about 6,000 mi. of railway in addition to several new lines under construction and others in contemplation. It is in connection with this contemplated work that the present visit of Mr. Nakagami is involved.

OBITUARY.

The death occurred in Victoria, B.C., recently of Mr. John Niblock, a prominent railroad man in Western Canada. Mr. Niblock, born near Toronto in 1849, entered the service of the Canadian Pacific Railway in its early days and was train-master at Winnipeg for a number of years. Later he was placed in charge of the shops at Medicine Hat. Afterwards he was superintendent of the C.P.R. from Swift Current to Laggan.

PEAT CONVENTION AT DULUTH.

The American Peat Society will hold its eighth annual meeting in Duluth, Minn., August 20th, 21st and 22nd. Important papers on the peat industry, peat lands, and the use of peat for fuel will be presented by numerous investigators and experts from various countries. There will also be an exhibition of peat, peat products, and machinery and apparatus for its preparation and development.

ASSOCIATION OF RAILROAD SUPERINTENDENTS.

The twenty-seventh annual meeting of the American Association of Railroad Superintendents is to be held in New York City on August 20th and 21st, at the Hotel Woodward.

COMING MEETINGS.

WESTERN CANADA IRRIGATION ASSOCIATION.—Eighth Annual Meeting to be held at Penticton, B.C., on August 17, 18 and 19. Secretary, Norman S. Rankin, P.O. Box 1317, Calgary, Alta.

AMERICAN PEAT SOCIETY.—Eight Annual Meeting will be held in Duluth, Minn., on August 20th, 21st and 22nd, 1914. Secretary-Treasurer, Julius Bordollo, 17 Battery Place, New York, N.Y.

CANADIAN FORESTRY ASSOCIATION.—Annual Convention to be held in Halifax, N.S., September 1st to 4th, 1914. Secretary, James Lawler, Journal Building, Ottawa.

NATIONAL PAVING BRICK MANUFACTURERS' ASSOCIATION.—Secretary, Will P. Blair, 832 B. of L.E. Building, Cleveland, Ohio. Eleventh annual convention and paving conference, Buffalo, N.Y., September 9th, 10th, 11th, 1914.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown, Indianapolis, Ind., Secretary.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—11th Annual Convention; 5th American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau St., New York, N.Y.

SURGE TANK PROBLEMS

AN INVESTIGATION OF SURGE TANK REGULATION DETERMINING BY GRAPHICAL AND ANALYTICAL METHODS PROPER SOLUTIONS OF PROBLEMS CREATED BY LONG PIPE LINES.

By PROF. FRANZ PRASIL,

Authorized Translation by E. R. Weinmann and D. R. Cooper, Hydraulic Engineers, New York City.

PART I.

IN case the main conduit leading to a turbine is comparatively long, beginning at the intake on a comparatively light slope (canal, tunnel or low-pressure pipe) and concluding in a short steep slope leading directly to the turbines, (high-pressure pipe or penstock), it is common practice to construct at the junction an open tank, called the surge tank, by which the main conduit is separated into two parts, in which with a constant discharge of the turbines the flow in the conduit is constant, and with a variable turbine discharge a variable conduit flow results. In the first case, the water surface in the surge tank is lower than the water surface at the intake by an amount dependent upon the flow in the low-pressure pipe. This difference of head is determined by the friction head in the main conduit. In an increment of time just as much water flows into the surge tank as flows out of it through the penstocks to the turbines.

In the second case, the inertia of the moving mass in the main conduit prevents this equality of inflow and outflow. The water surface in the surge tank has variable heights, that is, it rises or falls above and below the elevation due to the steady flow. The extent of this fluctuation of the water surface depends upon the dimensions of the main conduit, the amount of flow, and also on the size and form of the surge tank. In this case, if an overflow or an excessive lowering or too large fluctuations of the water surface are to be prevented, the surge tank must be dimensioned according to the area and length of the main conduit and according to the inflow and outflow. In this article the problems leading to the determination of the dimensions will be discussed, and the methods, partly analytical and partly graphical, involved in the solution of these problems, will be developed upon the assumption that the main conduit from the intake to the surge tank consists of a pipe or tunnel running full under pressure.

I. Introduction.

The investigation is developed (see Fig. 1) under the following additional assumptions:

(1) The intake is provided with a spillway whose dimensions are such that the elevation $n-n$ in the forebay may be considered as constant during the period under investigation.

(2) The sectional area of the main conduit is constant

(3) The volume of the conduit, compared to the volume of the surge tank and compared to that part of the volume of the forebay which is affected, is so large that the influence of both of these masses of water toward decreasing the flow may be neglected.

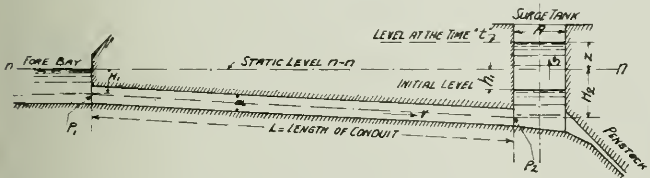

Fig. 1.

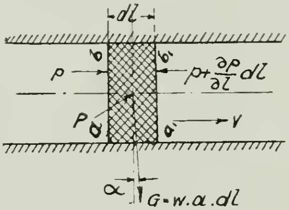

Fig. 2.

(4) Elastic and temperature conditions are neglected.

In the derivations of the formulæ, the following abbreviations are used:

L = Length of main conduit in feet.

a = Sectional area of main conduit in square feet.

p = Wetted perimeter of main conduit in feet.

v = Velocity of water in main conduit in feet per second at the time "t".

v_1 = Normal velocity of water in the main conduit in feet per second, during the period of steady flow.

v_2 = Initial velocity in the main conduit in feet per second, at the time $t = o$.

(v, v_1 and v_2 are average values and are assumed as constant throughout the entire length of the main conduit).

H_1 = Vertical distance from the water surface $n-n$ in the forebay to the centre of gravity of the entrance to the main conduit.

H_2 = Vertical distance from the water surface $n-n$ in the forebay to the centre of gravity of the entrance to the surge tank.

Q, Q_1, Q_2 = Volumes of water, corresponding to time t, the time during steady flow, and for time $t = o$ (beginning).

h, h_1 and h_2 = Friction heads corresponding to the pipe dimensions and velocities v, v_1 and v_2.

z = Vertical distance from the elevation $n-n$, of the water surface in the surge tank at the time t, taken positive above $n-n$ and negative below $n-n$.

A = Sectional area of surge tank in square feet for the elevation determined by z, so that in general A is a function of z.

s = Velocity of the water surface elevation in the surge tank, positive when rising, negative when falling, as an average value assumed constant in the section A.

q = Volume of discharge through the penstock at the time t, in cubic feet per second.

$c = \dfrac{q}{A}$ = the discharge velocity of the volume q, in feet per second, with respect to A.

More notations will be introduced during the course of the investigations.

II. Derivation of Principal Equations.—Referring to Fig. 2, the distance between two adjacent cross-sections of the main conduit $= dl$, and therefore $\dfrac{w.a.dl}{g}$ = mass of the water between the two sections (w = weight of cubic unit of water, g = acceleration due to gravity).

At the left side cross-section at the time t, there exists the pressure p in pounds per square foot, an average value, assumed constant for the entire cross-section. In the right, the pressure is p' at the same time t. The whole of p' is in general different from that of p, by the amount dp. The pressure p is a function of the location of the cross-section, that is to say, depends upon l; (l = the distance of the left side cross-section from the entrance of the main conduit) and depends further upon the time t (the flow varies with the time).

$$dp = \frac{\delta p}{\delta l} dl + \frac{\delta p}{\delta t} .dt \quad - \quad - \quad (1)$$

Since p and p' occur at the same time, p' is different from p by the difference due to the distance between the cross-sections, and therefore in the foregoing formula the differential dt of the time $= o$. Therefore, $dp = \dfrac{\delta p}{\delta l}.dl$ (2).

The following forces act upon an element of unit mass, in the direction of flow, that is, in the direction of v:

1st. The weight component $P_1 = w.a.dl \sin \alpha$ (3) where α = the inclination of the axis of the main conduit from the horizontal, $dl.\sin \alpha = dH$ = vertical distance between the centres of gravity of the sections $a\,b$ and $a_1\,b_1$.

$$P_1 = w.a.dH \quad - \quad - \quad (4)$$

2nd. The difference between the reactions due to the pressure p and $p + \dfrac{\delta p}{\delta l}.dl$ which is

$$P_2 = p.a - \left(p + \frac{\delta p}{\delta l}.dl\right) a = - a \frac{\delta p}{\delta l} dl \quad - \quad (5)$$

Contrary to the direction of motion the friction exerts a force. Let K be the amount of the friction in terms of the velocity v and we get $P = - wa.dl.K$ (6) where K represents a pure number with respect to its dimension.

According to the general fundamental law: mass × acceleration = acting force, it results (as $\dfrac{dv}{dt}$ is the acceleration with respect to the velocity v at the time t) that,

$$m.\frac{dv}{dt} = P_1 + P_2 - P \quad - \quad - \quad - \quad - \quad (7)$$

$$\frac{dv}{dt} \times \frac{w.a.dl}{g} = w.a.dH - a \frac{\delta p}{\delta l} dl - w.a\, dl.K \quad (8)$$

$$\frac{dl}{g} . \frac{dv}{dt} = dH - \frac{1}{w} \frac{\delta p}{\delta l} dl - K\,dl \quad - \quad - \quad (9)$$

The velocity v has the same value at the time t in the whole length of the main conduit. ~~The case is therefore the same~~ So also have for $\dfrac{dv}{dt}$ and K. Therefore, if we integrate between the limiting values $l = o$ and $l = L$ or $H = H_1$ and $H = H_2$ relative to a motion from the intake to the main conduit, we get the following:

$$\frac{L}{g}.\frac{dv}{dt} = H_2 - H_1 - \frac{1}{w} \int_0^L \frac{\delta p}{\delta l} dl - KL \qquad (10)$$

In the integral $\displaystyle\int_0^L \frac{\delta p}{\delta l} . dl$, p is, as demonstrated, a function of t and l. But as the integration relates to the condition at a certain time t, t is to be considered as a constant and therefore

$$\int_0^L \frac{\delta p}{\delta l} dl = p_2 - p_1 \quad - \quad - \quad (11)$$

where p_2 = pressure at the entrance to the surge tank p_1 at the entrance to the main conduit, KL is nothing other than the friction head h for the entire main conduit at the time t. Now, we may say that

$$\frac{p_2}{w} = H_2 + z + \frac{p_0}{w}; \quad \frac{p_1}{w} = H_1 + \frac{p_0}{w} \qquad (12)$$

in which $\dfrac{p_0}{w}$ equals the water column equivalent to the atmospheric pressure, and the following equation results:

$$\frac{L}{g} . \frac{dv}{dt} + z + h = o \quad - \quad - \quad (13)$$

Having assumed a flow in the main conduit from the intake to the surge tank, we consider now the flow as reversed (from the surge tank to the intake) and keep the direction for the measurement of the length l the same, then we must consider that the friction now acts in the

direction of an increase of l, contrary to the first instance. In this case we get the equation

$$\frac{L}{g}\frac{dv}{dt} + z - h = o \qquad (14)$$

For any case we may combine both equations into a fundamental formula:

$$\frac{L}{g} \cdot \frac{dv}{dt} + z \pm h = o \qquad (15)$$

in which the plus refers to the velocity from intake to surge tank and the minus sign for the reverse movement. If we now introduce for h a function, the value of which has the same sign as v, then the double sign may be dropped and the whole movement may be represented by the equation:

$$\frac{L}{g} \cdot \frac{dv}{dt} + z + h = o \qquad (16)$$

A second fundamental equation may be developed from the condition of continuous flow, that is to say, the volume of water which flows to the surge tank in the time element dt must be equal to the sum of the changes of volume in the surge tank and in the volume flowing out of the tank at the same time ∴

$$v.a.dt = s\,A\,dt + q.dt.$$

$$a.v = As + q = A(s + c) \qquad (17)$$

The questions which are of principal interest are:

1st. How is the movement of the water surface in the surge tank with regard to time affected by given dimensions of the main conduit and the surge tank and given conditions as to overflow?

2nd. What dimensions must the surge tank have to agree with given conditions as to the main conduit and outflow, in order that the fluctuation of water level does not exceed certain amounts, determined by local conditions? The following cases will be investigated:

(a) Sudden partial or entire cessation of the outflow.

(b) Sudden starting of the outflow.

(c) Gradual cessation, or starting, variable outflowing conditions; and

(d) Influence of a spillway built in the surge tank.

The formulæ will be developed in the first case for a constant sectional area of surge tank, and under the assumption that h is proportional to v, i.e., $h = n.v$.

It will be shown that it is possible to investigate all cases according to a uniform method, analytically and graphically, with the assistance of the well-known theory of damped and forced undulations. The inaccuracies which result because h is proportional to v^2 and the corrections which must be applied to the results of the first method will be shown in the final study. With the simplifying assumptions already mentioned, we get from equation (17)

$$v = \frac{A}{a}(s + c) \qquad \frac{dv}{dt} = \frac{A}{a}\left(\frac{ds}{dt} + \frac{dc}{dt}\right) \qquad (18)$$

This applied in equation (16) and the whole equation divided by

$$T^2 = \frac{L}{g} \cdot \frac{A}{a} \text{ (19), we get } \frac{ds}{dt} + \frac{dc}{dt} + \frac{z}{T^2} + \frac{h}{T^2} =$$

$$\frac{ds}{dt} + \frac{n.A}{T^2 .\, a} \cdot s + \frac{z}{T^2} + \frac{n\,A}{T^2 a} \cdot c + \frac{dc}{dt} = o \qquad (20)$$

If we introduce as an abbreviation:

$$T_o = \frac{T^2 .\, a}{n\,.\,A} \qquad (21)$$

and consider that

$$s = \frac{dz}{dt} \qquad \frac{ds}{dt} = \frac{d^2z}{dt^2} \qquad (22)$$

then follows the principal equation:

$$\frac{d^2z}{dt^2} + \frac{1}{T_o} \cdot \frac{dz}{dt} + \frac{z}{T^2} + \frac{c}{T_o} + \frac{dc}{dt} = o \qquad (23)$$

The values n and $T = \sqrt{\frac{A\,L}{a.g}}$

$$\text{and } T_o = \frac{T^2}{n} \cdot \frac{a}{A} = \frac{L}{n.g} \qquad (24)$$

are times with regard to their dimensions. Starting with this principal equation, we may investigate the different cases as follows:

III. Special Cases.

Case A.—Sudden Shut-down.

Preceding a shut-down, Q_1 cubic feet per second flows out of the surge tank. During the normal condition in the main conduit, the velocity $= v_1 = \frac{Q_1}{a}$ wherefore $q = Q_1$. The water surface in the surge tank is h_1 feet lower than the static level $n - n$. The time t is measured from the beginning of the shut-down, therefore from $t = 0$, q becomes ϵq if ϵ is the proportion of the steady flow subsequent to the shut-down in relation to the flow preceding the shut-down.

After the sudden shut-down, the following phenomena occur in the surge tank: The water surface rises with variable velocity until it reaches a maximum height. When the highest elevation is reached, the reverse movement occurs. The velocity increases as the water level recedes, then decreases until the lowest level is reached, after which an ascending movement occurs but to a somewhat less height than before, and so on, until the normal conditions with the constant flow $\epsilon . Q_1$ become established. The movement of the water level belongs in the category of the damped oscillations.

(1) Analytical Investigation.—The formula (23) for this case, under the condition that

$$c = \frac{q}{A} = \frac{\epsilon\,Q_1}{A} = \epsilon\,c_1 = \text{a constant } \left(\frac{dc}{dt} = o\right) \qquad (25)$$

becomes

$$\frac{d^2z}{dt^2} + \frac{1}{T_o}\frac{dz}{dt} + \frac{z}{T^2} + \epsilon\frac{c_1}{T_o} = o \qquad (26)$$

Since $h_1 = n.v_1 = n\,c_1\,\frac{A}{a} = c_1\,\frac{T^2}{T_o}$, it follows that

$$\frac{\epsilon c_1}{T_0} = \frac{\epsilon h_1}{T^2} \qquad (27)$$

If we introduce $z = y - \epsilon h_1$, therefore $\frac{dz}{dt} = \frac{dy}{dt}$;

$$\frac{d^2z}{dt^2} = \frac{d^2y}{dt^2} \quad - \quad - \qquad (28)$$

from (26) follows a differential equation of the second order

$$\frac{d^2y}{dt^2} + \frac{1}{T_0} \cdot \frac{dy}{dt} + \frac{y}{T^2} = 0 \quad - \qquad (29)$$

This is a linear differential equation of the second order with constant coefficients. For the solution we say:

$$r^2 + \frac{1}{T_0} r + \frac{1}{T^2} = 0$$

The solution of this quadratic equation will give us the values of the differential equation:

$$r = -\frac{1}{2\,T_0} \pm \sqrt{\frac{1}{(2T_0)^2} - \frac{1}{T^2}}$$

We know that according to the theory of the linear differential equations three solutions may be found.

If the radical is positive or zero, the solution of the differential equation represents a non-periodical function, that is:

$$y = R_1 . e^{-\frac{t}{2\,T_0}} + R_2\, t\, e^{-\frac{t}{2\,T_0}}$$

$$\text{if } \frac{1}{T_1^2} = \frac{1}{T^2} - \frac{1}{(2\,T_0)^2} = 0 \quad (30a)$$

$$y = (R_1\, e^{+\frac{t}{T_1}} + R_2\, e^{-\frac{t}{T_1}})\, e^{-\frac{t}{2\,T_0}}$$

$$\text{if } \frac{1}{T_1^2} = \frac{1}{T^2} - \frac{1}{(2\,T_0)^2} = \text{negative} \quad (30b)$$

But,

$$y = R\, e^{-\frac{t}{2\,T_0}} . \sin(\beta + t/T_1)$$

$$\text{if } \frac{1}{T_1^2} = \frac{1}{T^2} - \frac{1}{(2\,T_0)^2} = \text{positive} \quad (30c)$$

represents a damped harmonic.

These three conditions, due to the different values of the radical of the quadratic equation can be written also, substituting for T and T_0 the values of equations 24:

$\frac{1}{T_1^2}$ becomes zero if $T = 2\,T_0$ or $\frac{A}{a} = \frac{4\,L}{n^2 g}$ (31a)

$\frac{1}{T_1^2}$ becomes negative if $T > 2T_0$ or $\frac{A}{a} > \frac{4\,L}{n^2 g}$ (31b)

$\frac{1}{T_1^2}$ becomes positive if $T < 2T_0$ or $\frac{A}{a} < \frac{4\,L}{n^2 g}$ (31c)

As mentioned before, equations 30a and 30b, with the conditions of 31a and 31b, represent non-periodical function, that is:

Form 1 is the expression for a damped oscillation;

Forms 2 and 3 represent non-periodical movements, i.e., a transition from one quiescent level to another without any oscillations.

As will be seen later from an example, n has in most cases a value which lies between 2 and 1 seconds; therefore, the condition for a non-periodic water level fluctuation is:

$\frac{A}{a}$ is equal to or greater than $\frac{L}{35}$.

Now, for $L = x$ miles

A should be equal to or greater than $150 . x . a$.

This case may well occur when a pond is used as the surge tank. With artificially constructed surge tanks $\frac{A}{a}$ is considerably smaller; the following investigations are therefore limited to the first form of oscillations. As $z = y - \epsilon h_1$, equation (30) may be written

$$z = -\epsilon h_1 + R\, e^{-\frac{t}{2\,T_0}} \sin(\beta + t/T_1) \quad - \quad (32)$$

and the differentiation with respect to t gives (since $\frac{dz}{dt} = s$)

$$s = R e^{-\frac{t}{2\,T_0}} \frac{1}{2\,T_0} \left\{ \frac{2\,T_0}{T_1} \cos(\beta + t/T_1) - \sin(\beta + t/T_1) \right\} (33)$$

If we substitute $tg\gamma = \frac{2\,T_0}{T_1}$ and consider that

$$\frac{1}{T_1^2} = \frac{1}{T^2} - \frac{1}{4\,T_0^2} \quad - \quad - \qquad (34)$$

we get:

$$s = \frac{R}{T} . e^{-\frac{t}{2\,T_0}} \sin(\gamma - \beta - t/T_1) \qquad (35)$$

and the integration constants R and β are determined from the initial conditions, i.e., from the location and the condition of movement of the water level in the surge tank at the time $t = 0$.

It will be noted from the description of the phenomena for that case that for the shut-down and in the very moment of it, the water surface is at the distance h_1 under the elevation $n - n$. Therefore, for $t = 0$, $z = z_0 = -h_1$. The initial value for $s = s_0$ at the time $t = 0$, must be assumed as

$$s_0 = \frac{Q_1 - \epsilon\, Q_1}{A} = (1 - \epsilon)\, c_1 \quad - \qquad (36)$$

This assumption does not only consider a sudden shut-down, but assumes also a sudden beginning of a

uniformly distributed velocity in the water surface of surge tank. This assumption is true for the limiting cases because a short duration of the shut-down does not appreciably affect the results, as we shall see from the investigation of the influence of a shut-down of short duration. Here follow the equations for the determination of the integration constant when $t = o$:

$$R \sin \beta = -(1 - \epsilon)\, h_1 \qquad (37)$$

$$R \sin (\gamma - \beta) = +(1 - \epsilon)\, c_1 T \qquad (38)$$

The latter equation may be transformed to:

$$R \cos \beta = (1 - \epsilon)\left[\frac{T_0}{T^2} - \frac{1}{2\,T_0}\right] h_1\, T_1 \qquad (39)$$

By introducing the values in the bracketed term, we find that this term is proportional to the difference

$$\left(\frac{a}{A} - \frac{n^2 g}{2\,L}\right) \qquad (40)$$

The difference is therefore positive if $\frac{A}{a}$ is less than $\frac{2\,L}{n^2 g}$, i.e., with the same assumptions for n and g as before:

$$A < 17.5.x.a$$

This has influence on the determination of the value of β, as in the case mentioned $\sin \beta$ is negative and with $\frac{A}{a} < \frac{2\,L}{n^2 g}$ the $\cos \beta$ becomes positive, i.e., β must lie in the fourth quadrant. If $\frac{4\,L}{n^2 g} > \frac{A}{a} > \frac{2\,L}{n^2 g}$, the bracketed expression and $\therefore \cos \beta$ must be negative, β lies in the third quadrant. For the last formula, we may find for the determination of R and β the equations:

$$R = (1 - \epsilon)\, h_1 \frac{T_1\, T_0}{T^2} \qquad (41)$$

$$tg\beta = -\frac{1}{T_0/T_1 - \frac{1}{4}\, T_1/T_0} \qquad (42)$$

41 is obtained by addition of the squared equations 37 and 39;

42 is the quotient of $\frac{\text{equation } 37}{\text{equation } 39}$

We see that the amount of shut-down has influence on the size of R, but not on the size of β. With respect to the occurrence of the movements (see equations 32 and 35) we find that the movement is a damped oscillation with a duration of δ secs $= 2\,\pi\, T_1$.

Maximum and minimum values of z or y occur when $\frac{dz}{dt} = o$.

This is the case when $\sin (\gamma - \beta - t/T_1) = o$. See Equation 35.

$$\frac{t}{T_1} = \gamma - \beta = \gamma - \beta + \pi = \gamma - \beta + 2\pi = \text{etc.} \qquad (43)$$

This value used for equation 32 gives the following maximum values:

$$z\ \max_1 = -\epsilon h_1 + Re^{-\frac{T_1}{2\,T_0}(\gamma - \beta)} \sin \gamma$$

$$z\ \max_2 = -\epsilon h_1 + Re^{-\frac{T_1}{2\,T_0}(\gamma - \beta + 2\pi)} \sin \gamma, \text{ etc.} \qquad (44)$$

and the following minimum values:

$$z\ \min_1 = -\epsilon h_1 - Re^{-\frac{T_1}{2\,T_0}(\gamma - \beta + \pi)} \sin \gamma$$

$$z\ \min_2 = -\epsilon h_1 - Re^{-\frac{T_1}{2\,T_0}(\gamma - \beta + 3\,\pi)} \sin \gamma, \text{ etc.} \qquad (45)$$

Due to $z = y - \epsilon h_1$

$$\frac{y\ \max_2}{y\ \max_1} = \frac{y\ \max_3}{y\ \max_2} = \ldots\ldots\ldots$$

$$= e^{-\frac{T_1}{2\,T_0}.2\pi} = \frac{y\ \min_2}{y\ \min_1} = \frac{y\ \min_3}{y\ \min_2} = \ldots. \qquad (46)$$

The amplitude of this oscillatory motion is decreasing.

If t = infin. z becomes $-\epsilon h_1$
s becomes zero

(To be continued.)

STRENGTHENING THE FORTH BRIDGE.

When the Forth Bridge was designed, 32 years ago, the loads and the train speeds calculated for were considerably in excess of those then assumed as probable for a long period, but the advance in these respects, particularly in the weight and power of locomotives and the loads behind them, has been enormous. Therefore, although the limits have not yet been reached so far as the strength of the bridge is concerned, the directors of the Forth Bridge Company have decided further to anticipate the developments of the locomotive engineer, and to reconstruct part of the flooring and troughs in which the railway track is laid over the bridge. It has been decided at once to proceed with a trial section, to be followed by a reconstruction from end to end of the bridge. The directors have arranged for the carrying out of the work by the original builders, Sir William Arrol and Co., Limited, Glasgow, and Messrs. Baker and Hurtzig will be the engineers, in association with the engineer-in-chief of the North British Railway Company, Mr. W. A. Fraser.

It is estimated that 2,500 tons of structural steel will be required for the renewal of troughs and floor from end to end of the bridge; of this total, the addition to the weight of the present steelwork of the bridge is only 750 tons. The work will take some years to execute, as operations can only be carried on during summer months, and it is proposed not to interfere with traffic on week-days, while even on Sundays one line only will be closed.

TIME OF SETTING CEMENT.

It was pointed out by Mr. S. M. Williams, in a paper read before the American Society for Testing Materials, that the factors accountable for the variable results obtained in the time of cement setting make a marked difference in the laboratory results. His paper summed up the results of considerable investigation throughout which the various influences were properly controlled and recognized. The following factors are enumerated as likely to cause errors of considerable magnitude.

1. Variation in the amount of work done on the material may cause a difference of more than two hours in the time of initial setting and cause a normal cement to appear quick setting;

2. Variation in atmospheric moisture or humidity of storage during the setting period may cause the inital time of setting to vary as much as two hours;

3. Variation in atmospheric heat or temperature of storage during the setting period may vary the time of setting as much as 1 or 2 hours.

The determination is also affected, to a less extent, by factors peculiar to the Vicat and Gillmore methods.

Throughout this series of determinations an attempt was made to keep all conditions uniform except the one whose effect was to be noted. In practice, the results obtained on two consecutive days may be affected by several factors which might combine to increase or decrease the range of values. For instance, a cool, damp day may be followed by a warmer day with a high relative humidity. The two factors on the first day both tend to retard the setting of the cement, while the high temperature of the second day, tending to shorten the time of setting, is opposed by the high humidity which reduces the amount of evaporation. To avoid the effects of these variables requires the use of a storage closet whose temperature and humidity can be controlled.

The variation in time of setting as determined by the same observer, thereby eliminating all errors due to personal equation introduced by several observers, is clearly shown, and indicates that neither method will give results consistent enough to justify the reporting of results within the limits of a few minutes.

The other variables, such as formation of the test specimen and manipulation of apparatus, are of smaller importance, compared with those of mixing and curing, but these errors may combine to increase those caused by the above.

The results obtained by varying the amount of work indicate that the test, as made at present, can be relied upon only to identify normal or slow-setting cements. The necessity for vigorous working in order that a normal cement may not be judged quick setting, defeats the object of the test when it is applied to a very quicksetting material, and may cause the set to be broken.

A study of the results makes it evident that neither the Gillmore or Vicat methods can be relied upon to give uniform results unless all factors which influence the rate of hardening are taken into account and controlled, and they further explain why comparative tests in a number of laboratories upon the same material have been found to give most variable, non-dependable results, cement often being adjudged quick-setting in one laboratory and slow-setting in another.

The British Columbia Manufacturers' Association will hold its annual convention in Victoria, September 22 and 23. One of the chief subjects proposed for discussion is "Transportation."

CHARACTERISTICS OF SAFE DRINKING WATER.*

By Dr. Allan J. McLaughlin,
Chief Sanitary Engineer and Director of Field Work, International Joint Commission.

Cities using sewage-polluted water without purification invariably have very high typhoid fever rates. The installation of a filtration plant to purify the polluted water supply almost without exception effects a prompt and remarkable reduction in the typhoid fever rate. This reduction is usually so great that municipal officials are satisfied that their water supply is perfect, when in reality there is still something to be desired. When a city with typhoid fever rates consistently above 100 deaths per 100,000 population has a reduction coincident with the installation of a filtration plant to a rate between 20 and 30, there is good ground for general rejoicing because of the undeniable saving of human lives. Nevertheless, the raw water may be of such a character that an unreasonable burden is imposed on the filtration plant, and under such circumstances, in spite of fair efficiency, the plant delivers an effluent which is unsafe at times.

With the general sanitary conditions which pertain in American cities and a safe public water supply, there is no valid excuse for typhoid rates above 20 deaths per 100,000 population. There is excellent evidence to show that if all the water-borne typhoid were eliminated in northern cities the rate for typhoid fever would be less than 10. As a matter of fact, there is a group of American cities which is fast approaching European cities in the matter of low typhoid fever rates. These are the cities which have gone farthest in making their water supply safe, and while their yearly typhoid fever rates are not always expressed in a single figure, their rates are usually below 12. In these cities with safe water supplies the general sanitary conditions, exclusive of water supply, are not conspicuously better and in some instances are very much worse than those found in cities with polluted water supplies and high typhoid fever rates.

There is a large group of cities in which, following the substitution of a filtered for a polluted public water supply, the rates have been greatly reduced but still remain too high. These cities should not be satisfied with typhoid fever rates of from 15 to 30, but it behooves them to make a searching investigation to determine whether the raw water imposes an unreasonable burden on their filtration plant, or if their plant is efficiently operated and delivering a safe water at all times.

This brings us to the question of what is safe dringing water? In order to say that a drinking water is hygienically safe one must be assured that it contains no pathogenic bacteria. The efficiency of water purification plants varies from day to day and from hour to hour, and an opinion upon the absolute safety of a given water supply can not be rendered unless many bacteriologic analyses, made at short intervals during each 24 hours, show an absence of B. coli. While an absolute dictum is thus most difficult to secure, it is not difficult by daily bacteriologic analysis to determine that a water does or does not give a reasonable index of safety. Instead of attempting to find the germs of typhoid fever, Asiatic cholera, and dysentery in water, we accept the presence of B. coli as an index of pollution with sewage, for the reason that the chances of finding B. coli are very much

*Presented at a conference of the International Joint Commission at New York City, May 26 and 27, 1914.

better than the chances of finding the specific germs in the small quantity of water examined.

When we consider the grossly polluted water supplies used by many of our large cities until recent years, we must admit that even if the present effluents from filter plants do not show constant absence of B. coli, still they must be classed as reasonably safe, or relatively safe water.

In order to secure statistics from some of our largest filtration and purification plants a circular letter was sent out to about 40 cities. About 15 responded, and in most instances the statistics covered at least one year. The list included mechanical or "rapid" sand filtration, slow sand filtration, precipitation and disinfection, and disinfection alone.

Table I. shows the average number of B. coli per 100 c.c. in both raw water and filtered or treated water.

Table I.

City.	Number of samples.	Type of filtration.	B. coli per 100 c.c. of— Raw water.	Filtered or treated water.
Toledo, Ohio	342	Mechanical filtration.	804	0.02
Minneapolis, Minn..	418	do	75	.1

Baltimore, Md.	306	Alum and hypochlorite.	1,349	2.5
Richmond, Va.	237	do	460	8.0

Some of the results are of special interest, and the statistics for these cities are presented by months.

Toledo, Ohio.—The Toledo plant is of the mechanical-gravity type. Hypochlorite is applied to the raw water before sedimentation in quantities of 15 to 30 pounds per 1,000,000 gallons. Then aluminum sulphate is used as a coagulant.

Table II. shows the results by months in Toledo.

1914—			
March	31	1,000	0
January, 1913, to March, 1914	342	804	.029

The Toledo plant, by the use of heroic doses of hypochlorite, is able to convert a bad raw water into a safe effluent, but in spite of this fact the necessity for constant efficiency in treating such a raw water every hour in every day from January to June places an unreasonable responsibility on the plant. From June to October a fair raw water is furnished. In November and December the B. coli per 100 c.c. in raw water was again too high.

Minneapolis, Minn.—Excellent results are also obtained in Minneapolis by a mechanical or rapid sand filtration plant. Minneapolis differs from Toledo in that the hypochlorite is applied to the filtered water and not to the raw water in quantities of three-tenths to four-tenths parts per million available chlorine. The raw water at Minneapolis is very much better than that of Toledo.

Table III. gives the average number of B. coli per 100 c. c. in both raw and filtered water by months in Minneapolis.

Table III.

March	31	242	.6
February, 1913, to March, 1914	418	75	.19

Cincinnati, Ohio.—The Cincinnati plant utilizes plain sedimentation followed by coagulation and mechanical filtration. Sulphate of iron and caustic lime are used, the latter to assist the action of the iron sulphate and not for softening purposes. Hypochlorite is added to the filtered water for about five months in the year. About 1 pound is used to each million gallons of water. Hypochlorite is used during January, February, March, April, and May, which covers the period of muddy water and high bacterial counts.

Table IV.

Season	Number of days' samples.	Average B. coli per 100 c.c. of Raw water.	Filtered water without "hypo."	With "hypo."
1913—				
September	28	964	2.1	...
October	31	358	1.5	...
November	30	1,990	2.7	...
December	31	1,841	3.0	...
1914—				
January	31	1,232	9.1	0.6
February	28	1,260	3.5	1.2
March	31	825	2.4	.06
April	30	933	20.0	.4
Sept., 1913, to April, 1914 ..	240	1,175	5.6	1.4

The results are very interesting. A bad raw water which threatens to overtax the purifying capacity of the filters is successfully handled by the use of hypochlorite as an auxiliary. The results shown in Table IV. indicate that in January, February, March, and especially April, 1914, the plant without the aid of "hypo" was unable to successfully cope with the bad raw water. With the aid of "hypo" a good effluent was secured.

Columbus, Ohio.—At the mechanical filtration plant of Columbus, Ohio, lime, soda ash, and aluminum sulphate are used. Hypochlorite is occasionally used applied to the settled water before filtration. Table V. gives results by months for the year 1913. With a bad raw water excellent results are obtained. Mr. Hoover, the chemist in charge, attributes these results to the free use of lime. This seems probable as very little hypochlorite is used.

Washington, D.C.—Washington, D.C., has a slow sand filtration plant. There is large reservoir capacity and some alum is used in times of high turbidity. No hypochlorite or chlorine is used at any time. The general average for the Washington plant for 348 samples shows

1.4 B. coli per 100 c. c., which must be classed as a very good effluent. A close study of the results for individual months shows that there is great fluctuation in the character of the raw water. There was a very bad raw water in January, 1913, and April, 1913, and the results show that this unreasonable burden was probably too much for the purifying capacity of the plant. Table VI. shows the results of filtration in Washington, D.C., by months:

Birmingham, Ala.—The water supply for Birmingham is derived from two separate sources, as follows:

(*a*) Five Mile Creek, which is a stream to the north of the city, having a minimum flow of four and one-half million gallons, with a watershed area of 16.1 square miles and a population density of 31.9 per square mile. Five million gallons daily is supplied from this stream except during the dryest seasons. The waters of Five Mile Creek are diverted at a point 6 miles from the city and brought by gravity through a closed conduit to the North Birmingham purification plant, which consists of sedimentation basins and rapid sand filters of 5,000,000 gallons nominal capacity and sterilization by hypochlorite. The analysis marked "North Birmingham" show the raw and the treated water of this supply during the year 1913.

(*b*) Cahaba River: The watersheds of Cahaba River lie to the east of Birmingham. The west prong or Big Cahaba furnishes the supply, except when its minimum flow is less than the daily pumpage, in which case the East Cahaba is drawn upon by means of a small diversion dam below the junction of the two rivers. To supplement the dry-weather flow, a dam has been built on the east fork, or Little Cahaba, and a large impounding reservoir of 1,250,000 gallons created, known as Lake Purdy. The total watershed area is 205 square miles. The area above Lake Purdy is 49.7 square miles. The density of population on the entire shed is estimated at about 20 per square mile.

The pumping station on the Big Cahaba, 2 miles above the diversion dam at the junction of the two forks, forces the water to a purification plant on Shades Mountain. The purification plant consists of two large sedimentation reservoirs, holding 118,000,000 and 28,000,000 gallons from which the water flows by gravity through a rapid sand filtration plant, having a present nominal capacity of 19,000,000 gallons daily, with eight additional million under construction. The filters discharge into a clear-water basin of 3,000,000 gallons capacity, from which the water flows by gravity to the city, a distance of four miles.

Cahaba Plant.
(No chlorination.)

Jan. 1 to Dec. 31	174	400	.2

The two Birmingham plants furnish very interesting data also on the value of hypochlorite as an aid in handling a bad raw water. The Cahaba plant uses no hypochlorite. In December, 1913, raw water, with an average of 323 B. coli per 100 cubic centimeters, seemed to overtax the purifying capacity of the plant. A load of 204 B. coli per 100 cubic centimeters in June and July seemed to be about the limit that the plant could care for, although in the period from January 1 to April 10 an average of 305 in the raw water was reduced to less than 1 B. coli per 100 cubic centimeters in the effluent. The North Birmingham plant has a worse raw water to deal with. This plant uses hypochlorite as an adjuvant. The average for raw water of 700, 800, and 1,337 B. coli per 100 cubic centimeters was reduced to less than 1 B. coli per 100 cubic centimeters in the effluent. From September to December, with a fair raw water averaging 240 and 288 B. coli per 100 cubic centimeters, a perfect result was obtained with entire absence of B. coli in the 71 samples.

Following a sanitary survey of the cities and towns in the basin of the Great Lakes, the writer recommended, among other things necessary, that a standard for filtered or treated water be established which should be a minimum requirement for the prevention of the spread of water-borne disease in interstate traffic. The Surgeon General of the Public Health Service appointed a commission in January, 1913, to fix such a standard. The report of this commission will be published soon. The majority of the members favored a standard of four negatives out of five 10-cubic-centimeter tests for B. coli. The writer expressed this standard in a different way, recommending a standard of not more than 2 B. coli per 100 cubic centimeters of water, taking the average of many samples by Phelps' method.

Allowing a sufficient margin of safety, filter plants with a decent raw water should produce effluents of less than 2 B. coli per 100 cubic centimeters, and it is the opinion of the writer that a modern water-purification plant which delivers an effluent which has more than 2 B. coli per 100 cubic centimeters is either inefficiently operated or is dealing with a raw water which imposes an unreasonable burden upon the plant. Accepting tentatively the standard of less than 2 B. coli per 100 cubic centimeters as a good drinking water, although not perhaps an ideal drinking water or a safe drinking water at all times, the results indicate that this standard is attained by both "rapid" sand and slow sand plants, even with a very bad raw water. Cincinnati and Washington, D.C., are good examples of each type. Close examination of the daily records at Washington and Cincinnati show that while this excellent average is attained for the year, there are periods when the capacity for purification seems to be overtaxed by the very bad raw water. At Cincinnati, the use of hypochlorite seems to compensate for the deficiency in purification by the standard process, but in Washington the excellent general average of 1.4 is only attained by the almost perfect purification effected during periods when the raw water is fairly good.

There is a strong tendency in America to accept any raw water, however bad, as a source for a municipal filtration plant. This often imposes an unreasonable burden and responsibility upon the water-purification plant. Now, filter plants are not infallible. They are mechanisms which must be properly constructed and efficiently operated under careful bacteriologic control in order to secure a safe effluent. They are operated by human agency and subject to the results of human error. It is true that properly constructed and efficiently operated filter plants can produce safe water from a very bad raw water, especially by the use of hypochlorite or liquid chlorine as an adjuvant. The responsibility of effecting such purification every hour of every day in the year is unreasonable and unfair. Many plants are now struggling with a raw water of such a character that a safe effluent is only obtained at the price of eternal vigilance, perfect operation every day in the year, and the free use of auxiliary chemicals. The raw water demanding such extraordinary treatment is, like a sword of Damocles, constantly threatening disaster. There is no margin of safety under such conditions.

I believe that a sufficient margin of safety should be given to all filter plants by reducing the pollution of the raw water to a point where it would not impose an unreasonable burden or responsibility upon the plant. I believe that in reckoning the bacterial purifying capacities of filtration plants hypochlorite or liquid chlorine should not be considered, but that a raw water should be furnished of such a character that the plant could turn out constantly a safe effluent without the aid of chlorine. This would reserve the chlorination as an additional margin of safety for use in extraordinary fluctuations of the raw water or during accidents to the plant or interruptions in its ordinary efficiency.

GRANITE MINING IN UNITED STATES.

In a recently-issued United States Geological Survey bulletin on Graphite, it is stated that to-day there are more abandoned graphite mines and mills in the United States than the number in operation. The number of times that some of these properties have changed hands in the course of a few years evinces a record of misrepresentation and disappointment that can hardly be equalled in any other branch of mining, and many properties have been notoriously associated with stock manipulations of doubtful character. It should be clearly understood by anyone who contemplates the development of one of the flake graphite deposits that the technology of concentrating such materials is yet in its infancy; that there are no well established systems of treating the materials, such as exist, for example, for the treatment of gold or copper ores; and that the product obtained is variable in quality and in market value and subject to severe competition with foreign graphite. The largest part of the foreign graphite that comes into the country is brought in by firms, who either control or own foreign mines or have purchasing agents abroad. and are, therefore, in a position to take immediate advantage of any change in the markets at home or abroad. In general, the cost of producing flake graphite is so high and the price at which it is sold so low that even under the most economic conditions the margin of profit is small. Moreover, certain rocks that carry graphite contain other minerals in such intimate association with the graphite as to preclude any possibility of successful concentration—such, for example, are rocks in which graphite flakes are interleaved with mica—and a careful study of the material by an expert should precede any attempt at development.

One large power-station after the other is being built in Norway, where the water-power has given a tremendous impetus to the development of the country's industry. The Sandefaldene Company is about to exploit the different falls in the Sande water system, for which the different lakes, some of them lying at a considerable height, will be regulated so as to serve as reservoirs. There will be constructed three power stations in the valley, and a larger one at the sea, the aggregate power being about 80,000 horse-power, divided between the four stations with respectively 42,000, 10,000, 8,000 and 20,000 horse-power. The whole of the power will be transmitted to the sea, where it will be used by an American concern—the Union Carbide Company—which has contracted for 40,000 horse-power, with the option of another 40,000 horse-power. The Sandefaldene Company has secured large areas at the sea for the new town which will no doubt spring up there within the first few years.

DETERMINATION OF THE LEGAL CHARACTER OF QUEBEC RIVERS AND THEIR CLASSIFICATION.

The Quebec Streams Commission was appointed in 1911. One of its duties was to consider whether it was expedient to have the rivers of the Province classified as navigable and floatable rivers, or otherwise, according to uniform rules, and to submit such rules, if advisable. The work, during the past two years, has included an investigation of the nature and causes of existing difficulties, jurisprudence in connection with the legal character of rivers, foreign legislation, character and importance of the rivers, and practical conclusions to be deduced. In the second annual report of the Commission, recently published, these studies are shown to have been quite exhaustive. Classification of rivers was based on the area of the basins drained. Watercourses with drainage basins over 300 square miles in area were considered important, from the viewpoint of the utility of which each is susceptible. From this point of view of importance is deduced the legal character of the stream. The report lists 187 such rivers falling under this category, besides those in the territory of New Quebec. Thirteen of these rivers have drainage basins exceeding 11,000 sq. mi. each in area.

With respect to the investigation, the Commission expresses the belief that it is now necessary:—

1. To proceed to classify rivers according to uniform rules;

2. To change the formula, which serves to determine their legal character in the Province so as to remove the difficulties now encountered in connection with such determination;

3. To adopt a more convenient formula on a fixed, stable and certain basis susceptible of extended and decisive application;

4. To adopt as the principle in classification the importance of the river, stream or watercourse from the standpoint of the various uses of general interest for which it may serve;

5. To adopt a classification which shall be at once collective and individual or nominal without, however, being limitative in so far as the right of the Province to modify it is concerned;

6. To take as the standard for such determination the extent or area of the drainage basin whose waters are received by the river or watercourse;

7. To adopt for individual classification the list laid down by the Commission of the best rivers in the Province, the area of whose basin is known. This would mean recognizing the principle admitted in France that the administrative authority is alone competent to define the natural fact, the actual condition which constitutes sovereignty instead of leaving the duty of defining such legal character as at present;

8. To recognize that these rivers possess or are capable of assuming the importance deemed sufficient to create sovereignty, that is which justifies or compels its recognition.

In the report of the engineer, it is pointed out that in Quebec adequate information has not been previously collected concerning rainfall within the province, and that data covering a lengthy period of years possesses a great value in work of this nature. There are 45 rain-gauging stations in Quebec, 17 of which were established in 1913. He advocates extensive improvements in this respect. Similarly, water gauges for all the principal rivers are a need that is emphasized.

DESIGN AND CONSTRUCTION OF ELEVATED TANKS.*

By W. O. Teague, Boston, Mass.

The elevated or gravity tank for fire protection systems has been from the first an important limited secondary source of water supply, and its value has increased greatly with the increase in number and size of tanks installed generally throughout the country, especially in those cities and districts where the public water supply is of low pressure. The tanks are usually located above buildings in cities and on detached towers in the country.

The tanks were first made of wood, but there are now as many being made of steel. Wooden tanks have been built up to 10,000 gal. capacity, although they are rarely larger than 60,000 gal., for above this capacity the steel tank is cheaper and more practicable. The cost of a 60,000-gal. tank of wood or steel erected on a 75-ft. steel tower is about $3,000. Steel tanks are built in large sizes, one of the largest being of 1,200,000 gal. capacity; this one is 50 ft. in diameter and 90 ft. high, and is supported by a steel tower 130 ft. high.

Failures of tanks in service, involving loss of life and destruction of property, have shown the need of more care in the designing and construction of them. To insure the best results, the following features should have attention:

Wooden Tanks.—The tightness and durability in the wooden tank depends chiefly upon the quality of the lumber and the details of its construction. Selected tank stock only should be used consisting of white cedar, cypress, white pine, Douglas or Washington fir, or redwood, and the lumber should be free from sap, loose or unsound knots, worm-holes and shakes, and be thoroughly air-dried. Both the staves and bottom are usually made up of 2½-in. stock dressed both sides, for tanks up to 16 ft. in diameter and 16 ft. deep; for larger tanks 3-in. stock is used. Plank for this purpose should be full length without splices.

The strength of the wooden tank depends principally upon the size and spacing of the iron hoops. The importance of the matter of the hooping will be appreciated when it is realized that overstressing of even one hoop may result in bursting of the tank. The wooden tank being originally merely a development of the barrel where flat hoops were necessary to permit of tightening by driving them toward the enlarged middle, it was natural to use also flat hoops for the tank and the tank was also made tapered so that the hoops could be tightened by driving, although later they were tightened principally by hoop lugs. It was claimed that the tapered shape had also the advantage of preventing the hoops from dropping down over the tank, if it was allowed to remain empty and the staves to shrink from drying.

The tapered shape of tank is not important, however, since a tank which has been allowed to dry up has been seriously damaged thereby and cannot be made tight without extensive repairs, sometimes necessitating the rebuilding of it. In fact, most tanks are now made without taper and the hoops are found to remain where placed. The tapered tank costs somewhat more to build since the staves must be fitted more carefully and the design undoubtedly would have been entirely discarded long ago, except that some architects and purchasers believe a

*Abstract of paper presented at the Annual Meeting of The American Society of Mechanical Engineers, 1913.

tapered tank presents a more pleasing appearance. The amount of taper is so small, being usually 1 in. per ft., thus giving a batter of ½ in. per ft. to each side of tank, that its absence is hardly noticeable except on very high and small diameter tanks. The only objection to the tapered tank, however, is its extra cost.

In the early studies of this subject, many serious failures of tanks were traced to weakening of the flat hoops by their rusting at the back where they bore against the staves, due to moisture from rain being retained

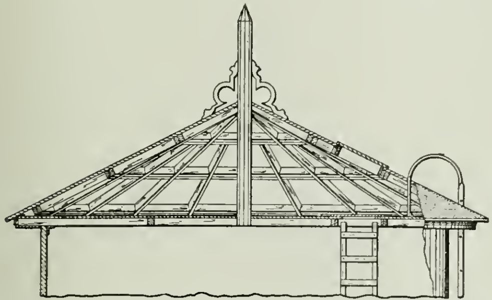

Fig. 1.—A Good Design of Double Roof for Elevated Tank.

between the surfaces of the hoop and staves. These failures were largely unpreventable, as it was difficult to properly inspect the condition of the hoops, and also impossible to paint them while the tank was in service. The use of hoops of round rod without welds has remedied this trouble as their surface is nearly all exposed for inspection and painting, and also they are not so subject to corrosion since the exposed surface of a round rod is much less than that of a flat bar or band of the same cross-sectional area.

Another point of weakness in the flat hoop is at its connection to the cast iron lugs which is usually made by riveting. The use of round rod hoops, however, permits of a satisfactory connection to the lugs, but at first many tank failures resulted from the use of light cast iron lugs. These are now made of malleable iron. The hoops are so placed on the tank that the lugs do not come in a vertical line.

Round rod hoops are so spaced that the stress will not exceed 12,500 lb. per sq. in. when computed from area at the root of the thread. The proper spacing can readily be found from the following formula:

$$\text{Spacing of hoops (in.)} = \frac{\text{Safe load for given hoops (lb.)}}{2.6 \times \text{diameter (ft.)} \times \text{depth (ft.)}}$$

The depth used is the distance from overflow to point where hoop is to be located. The top hoop is placed 2 in. from the top of the staves and the spacing between hoops should in no case exceed 21 in. An extra hoop or two is placed at the croze to take the additional strain due to the swelling of the bottom planks.

The tank roof, since it in no way serves to retain the water, has usually been nothing more than a makeshift cover. In the early days a single flat roof was used on outdoor tanks, but this held the snow and ice and required strong joist supports to keep it tightly in place. The snow also interfered seriously with the opening of the hatch to give access to the interior of the tank. A conical roof was then built over the flat one which remedied these difficulties. It also greatly increases the efficiency of the roof in preventing radiation of heat from the tank water in winter as it provides a dead air space between it and the flat roof in addition to the one between the latter and the water, thus reducing the cost of heating in freezing weather. The conical roof also gives a better appearance to the tank top. A well built roof is shown in Fig. 1. It should be tightly fitted around the tank top to maintain the dead air spaces.

Much trouble has resulted from leakage in the wooden tank, because it has not been firmly supported. The wooden tank is locally weak, not being of unit construction, and the lack of firm support has permitted working of the joints. It is supported only from the bottom, none of the weight being carried by the staves. Wooden beams were first used as supporting members, and these were placed on the roof of a building or tower as a grillage, and the tank bottom set on them. In time the wood rotted because of moisture from the tank bottom, permitting the tank to settle and causing leakage; there was also danger of collapse of tank because of this weakening of the joists. The use of steel I-beams as grillage members, as shown in Fig. 2, avoids these difficulties. The beams should not be spaced over 18 in. clear between edges of flanges, and the tank bottom is placed directly on the steel.

Steel Tanks.—The simplest form of steel tank is the flat bottom one and tanks of this type give satisfactory service, provided the bottom is supported by a steel grillage as in the case of the wooden tank. One possible source of trouble is from corrosion of the bottom, and to prevent this in so far as possible the bottom plates are made somewhat thicker than is necessary for strength alone, and the grillage I-beams are of a height and spacing to permit of inspection and painting of the bottom.

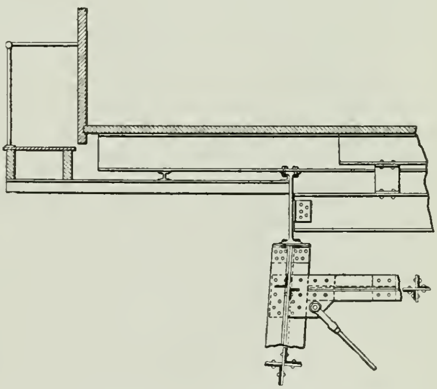

Fig. 2.—Detail View of Arrangement of Steel I-beam Grillage for Support of Tank.

When the tank is to be placed on a concrete tower, it may rest directly on a reinforced concrete slab with the bottom thoroughly grouted in place with neat cement.

The preferred form of a tank to be placed on a steel tower is that having a hemispherical or elliptical bottom. The construction in this form is cheaper than for the flat bottomed tank as the bottom is self-supporting and a steel grillage is unnecessary. The entire bottom is also accessible for inspection and painting, and corrosion is reduced to a minimum since the plates are exposed to the air.

Plates for use in steel tanks are made somewhat thicker than is necessary for strength in order to make

them durable against corrosion. The minimum thickness is 1/4 in., except that 1/8-in. plates are used for roofs. The plates composing the lowest cylindrical ring are 5/16 in. thick for 60,000-gal. tanks and larger, and the bottom plates 5/16 in. thick for tanks 75,000 gal. and larger.

One of the weaknesses of steel tank construction in the past has been poorly designed connections of the tank shell to the posts of the supporting tower. When the posts have a batter, as is usually the case, the inward thrust due to the horizontal component of the weight is provided for by a circular girder consisting of 1/4-in. plate 24 in. wide, attached to the lowest cylindrical ring by an angle and stiffened by angles or a channel at the outside edge, as shown in Fig. 3. The posts also connect to the tank shell at this point and the design is such that the load will be transferred from the shell to the centre line of the posts so as to avoid eccentric loading. A number of tanks built without circular girders have failed by the posts crushing in the tank plates. Others with the girder, but having eccentrically loaded connections to the posts have failed by bending of the upper posts.

As the hydrostatic pressure on the tanks is comparatively small, it is not necessary to provide standard riveting for the thickness of plates used. The joints of the plates should be riveted so that the unit stresses on the net section of the plates and rivets will not exceed 7,500 lb. for shearing and 20,000 lb. for bearing. The horizontal joints are single lap riveted, except between the lowest cylindrical ring and the bottom, which are double lap riveted. The vertical joints also are single lap riveted except those in the lowest cylindrical ring, which are double lap riveted. The rivets are entered from the outside and driven from the inside and inside seams caulked. One of the strong features of the steel tank is that when

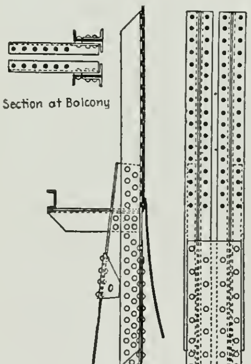

Fig. 3.—Detail of Attachment of Tank Shell to Tower Post and Circular Girder Construction.

once made tight, it gives practically no trouble from leakage.

Towers for Elevated Tanks.—Towers to support wooden tanks were originally built of wood, but with the increases in size of plant buildings and extensions of them, considerably larger tanks and higher towers were required, and the builders, realizing the inadequacy of wooden construction under these conditions, began to make towers of steel. The managements not being experienced in structural steel designing, naturally selected the simplest design possible for the towers. The posts and girts consisted usually of two angle irons, placed apex to apex and strapped together at intervals of several feet by tie-plates shop-riveted to the angles. The column sections were spliced by angles which were shop-riveted at one end to the post; the other end was field-bolted in erecting the tower, as this was the simplest form of connection and the easiest one to make. Furthermore, it had the advantage that the bolting could be done by the regular erecters which made it unnecessary to have first-

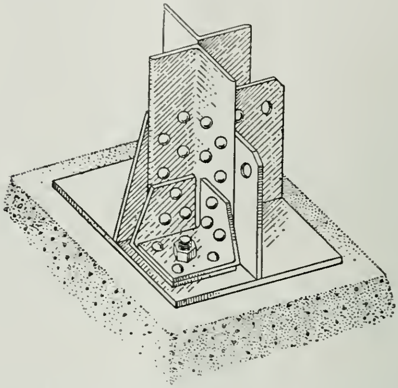

Fig. 4.—Typical Construction of Footing for Angle Iron Column.

class mechanics in the erecting gangs and to carry special tools. This, however, was not good construction and the manufacturers are now field-riveting these connections.

The struts were at first connected directly to the posts by bolts. This construction is objectionable because the bolts are apt to work loose and it does not brace the parts. The construction now used is that of gusset plates riveted to the posts and girts. The wind rods were also connected directly to the posts at the girts. The bolt holes, as originally inserted through the post angles, weakened the posts since they reduced the net section. The rods are now connected to the gusset plates. The arrangement of these parts is shown in Fig. 2. The diameter of bolt and thickness of plate are proportioned to provide proper bearing strength. The posts and girts of steel towers erected to support steel tanks, and to some extent wood tanks, are now largely made of channels latticed on both sides or having a plate on one side. Other shapes such as the Bethlehem H-beam and two channels with an I-beam between to form an H-section are also used to some extent.

Competition in the manufacture of these structures has resulted in the use of too high unit stresses and as a result the posts, figured on a conservative basis as represented in case of their structural work such as bridges, had a factor of safety of less than four and sometimes as low as two and one-half and failure has resulted. To obtain safe towers it became necessary, therefore, to set maximum allowable stresses. The loading of the structure consists of the weight of the structural and ornamental steel work, platforms, roof, piping, etc. The live load consists of the weight of the total volume of water; the movable load on the platform is assumed to be 30 lb. per sq. ft. and the wind load. The wind pressure is assumed at 30 lb. per sq. ft. on flat vertical surface and the

wind load on the tank is taken as this pressure times 6/10 the projected area of tank and roof, and in the case of steel tanks, the curved bottom. The total wind load on the posts, struts, wind rods, ladders and riser boxing is assumed at 200 lb. per linear foot of height of tower.

All parts of the structure are proportioned so that the sum of the dead and live loads shall not cause the stresses to exceed those allowable. The principal stresses in such

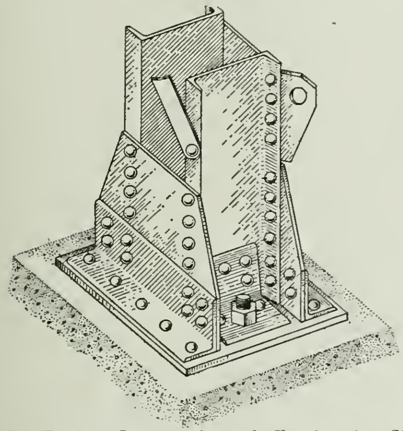

Fig. 5.—Typical Construction of Footing for Channel Column.

a tower structure are axial compression on gross section of columns and struts, axial tension on net section of wind rods, bending on extreme fibres or net section of rolled shapes, built sections and struts, and shearing of rivets. The axial compression on gross section of columns and struts is determined from the following expression: $17,100 - 57\frac{L}{R}$, where L is the unsupported length of the members from centre to centre of connections in inches, and R the least radius of gyration in inches; the ratio $\frac{L}{R}$ should not exceed 125 for columns and 150 for struts and minor members and the maximum compression allowable as thus determined is 12,000 lb. per sq. in. The axial tension on net section of wind rods must not exceed 12,500 lb. per sq. in.; the bending on extreme fibres or net section of rolled shapes, built sections and struts 16,000 lb. per sq. in., and the shearing for shop-driven rivets, 10,000 lb. per sq. in. and field-driven rivets 7,500 lb. per sq. in.

The lower ends of the posts have not been as carefully designed as their importance requires. Frequently, in angle iron towers particularly, no special attempt has been made to properly distribute the load to the base plate attached to the post footing. Cast iron plates were first used and the concentrated loading caused these to crack, resulting in collapse or in throwing the structure dangerously out of plumb with possibility of failure of the foundation under this post. The present use of steel plates has improved conditions, but the design must be such as to distribute the load to them as shown in Figs. 4 and 5, which are designs that are being used quite generally.

In anchoring the columns to the foundations, the diameter of the bolt at root of thread should be such as to withstand the maximum uplift due to the wind with tank empty, and to resist the shearing force at base plate. The bolts should be made from round wrought iron or mild steel rods without upsets.

Foundations and Supports.—The foundation piers to support steel towers are usually made of concrete, consisting of one part portland cement, three parts clean sand and five parts broken stone. They are usually pyramidical in shape and proportioned to suit soil conditions. The allowable bearing pressures on soil will range from 1 to 5 tons per sq. ft., depending on the quality of the soil. Where the soil is moist or rather loose, a girt should be provided at the base of the tower to prevent spreading of the posts. The allowable bearing pressures for footings should not exceed 400 lb. per sq. in. for Portland cement concrete and 200 lb. per sq. in. for ordinary brick work with Portland cement mortar, except when tank is to be rested on building walls, when the bearing plate should be figured on the basis of 125 lb. per sq. in.

The weight of the foundation pier when buried at least two-thirds of its height should be equivalent to the calculated net uplift due to wind pressure with the tank empty, that will be transmitted to it; otherwise it should be one and one-half times that amount.

Where the tank structure is above a building, and the building walls are depended upon to act as supports, great care should be taken to determine that the construction is safe against collapse. In many cases, tanks are supported by building walls not originally built to carry them, but where a sprinkler system was later installed it was considered more convenient and cheaper to use the walls than to erect a detached tower for the tank. This has frequently been done without making a thorough inspection first of the condition of the walls, and, largely through ignorance, the necessary care was not taken to distribute the load. Many failures have consequently resulted and there are no doubt numerous cases of this kind where the tanks are apt to fall at any time.

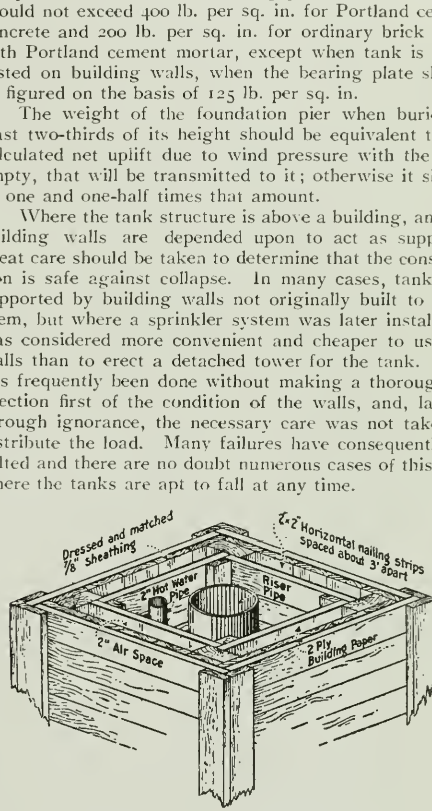

Fig. 6.—Design of Efficient Frost-proof Square Boxing for Enclosure of Riser Pipe to Tank Connection.

Inspection should be made of the quality and condition of the brick and mortar or other material used in the construction. The wall foundations should be examined as to construction and bearing on soil or rock. The condition of the bond between abutting walls should be noted and a general inspection made for sizable cracks in the walls. The thickness of walls and size and spacing of window and door openings should be measured and calculations then made to determine if the load of tank, water and trestle can be safely distributed over the walls. All unnecessary openings should be bricked or otherwise solidly filled in, and it may be necessary to sacrifice some openings to obtain the required strength. When the walls

cannot be altered to support the load, the additional support required can be obtained by carrying steel beams down inside the walls to a solid foundation, provided these do not interfere with occupation of or possesses carried on in the building. Otherwise it will be necessary to provide a separate steel tower.

The proper strength of foundations is especially important because of the greater probability of loss of life from the falling of a tank from above a building as compared with the falling of a tank on a detached tower. The monetary loss is liable, of course, to be also much greater, as the water will undoubtedly wreck the building and cause heavy water damage. The building departments of cities endeavor to obtain proper construction, but unfortunately they do not always succeed. The possibility of trouble is increased because of the divided responsibility of the tank builder and the architect. The former seldom concerns himself as to the strength of the supporting walls, assuming that the latter has given the matter proper attention, so he goes ahead and erects the tank according to contract.

General Features.—Tank fittings should receive careful attention to insure the reliability of the equipment. The discharge or riser pipe is more serviceable if made up of cast or wrought-iron pipe, flanged or coupled, than one made up of bell and spigot pipe, since the latter is apt to leak at the leaded connections, necessitating removal of the frost-proof boxing to permit of repairs. A tank and tower is constantly swaying from side to side and this tends to loosen up leaded joints. Furthermore, the increased rigidity of the flanged and coupled pipe permits the use of a minimum number of tie rods. There are usually four rods connected, one to each post, at girt connections.

The connection of the discharge or riser pipe to wooden tanks has usually been made by extending the pipe through ordinary cast-iron slip flanges bolted to the tank bottom on each side of the opening. The hole in the planks was cut larger than the size of the pipe to form a packing space which was filled when parts were first assembled. A better construction was used for steel tanks having a stuffing box and gland. Both types of joints were found to be unserviceable, however, the former because the joint could not be tightened when leakage occurred, and the latter principally because the iron to iron parts rusted together, which resulted in the breaking of some pipe fittings and the emptying of the tank. Properly designed expansion joints forming tank connections for wooden and steel tanks have a bronze gland and ample clearance between the iron parts to prevent binding by corrosion. The packing space is large and the joint is extended within the tank bottom to form a settling basin, to prevent sediment getting into the yard pipe and clogging the sprinklers at time of fire.

A tightly constructed frost boxing should be placed around the discharge or riser pipe, and arrangements made for keeping the water heated by a hot water heater or a steam coil in the bottom of the tank. Designs of three-ply, two air-space boxings are shown in Fig. 6.

A tank level indicator or telltale is necessary to give a positive indication that the tank is full at all times. After many serious fires it has been learned that the tank had been partially or wholly empty at the start of the fire, and the lack of water had handicapped the fire protection devices. Tanks may be left empty due to neglect, but usually so because of false indication of the telltale. The most used type of device for this purpose is the float in the tank water, operating a target sliding on a scale fixed to the outside of tank. Obviously, these are subject to sticking due to their mechanical construction and exposure to snow and ice in freezing weather. The ordinary pressure gauge has been largely used but cannot be positively depended on, since it is seldom, if ever, tested and the parts stick, causing false readings. There are several types of electrical telltales operated by a float, but these are complicated and easily gotten out of adjustment. Attention is also necessary to maintain the electrical current.

The most reliable telltale is undoubtedly the mercury gauge. It should be placed indoors where it will be observed and cared for. The mercury pot is then piped to the riser pipe on the tank side of the check valve, and the gauge board adjusted after filling the mercury pot. The gauge is readily tested by opening the pet cock on the water pipe. If water continues to flow under constant pressure, the apparatus is in operative condition; otherwise, the pipe is clogged or there is a valve closed.

The painting of steel tanks and towers and of the iron hoops of wooden tanks is very important to prevent corrosion. Steel plates and shapes should be given the usual priming coat at the shop. The surface of the metal should be thoroughly cleaned of mill scale, rust and grease and be perfectly dry before applying the paint. A good paint for the first coat is made by mixing 20 lb. of red lead and 10 lb. of zinc oxide with 3 qt. of boiled linseed oil, the red lead and zinc oxide being ground in. This amount of paint will cover about 50 sq. yd. of surface. A second coat should be applied after structure has been erected. For this a more durable oil or asphaltum paint should be used.

The inside of a steel tank should be repainted, usually every two years, or oftener, if the paint shows signs of peeling or wear. The outside of the tank and the tower should be repainted at about five-year intervals. The surface should be carefully cleaned either by sand blast or by steel brushes or scrapers.

The iron hoops of wooden tanks should receive a priming coat as for structural steel and a second coat after assembly. They should be repainted when necessary. The advisability of painting wooden tanks exposed to the weather is an open question, although a large percentage of the tanks are painted. There is no doubt but that paint protects wood under ordinary conditions, but the objection raised to its use on tanks is on the ground that the tank water percolates through the staves and is prevented from evaporating as it is held under the paint and this is likely to set up dry rot in the wood. It is well-known, however, that dry rot does not occur when wood is completely immersed but rather when it is in a moist condition in the presence of some heat. This objection is not considered well-founded and as a rule the tanks are undoubtedly preserved by painting.

The life of properly constructed equipments depends largely upon the care and attention given to them by property owners. The tanks should be used only for fire protection. The practice of using a foot or so of water from the top of the tank for mill purposes is objectionable as the tank collects a larger amount of sediment from the water which is constantly being supplied than it does when used for fire service only. This sediment is likely to settle in the sprinkler pipes and either clog them completely, or, if the sprinklers are open, seriously interfere with their discharge. If water is drawn from the bottom for mill purposes the tank may be empty when needed for fire service. Furthermore, the fluctuation in water level is apt to result in shrinkage of the upper ends of the staves of wooden tanks, causing leakage and hastening corrosion in the steel tank by the repeated wetting and exposure of the sides to the air.

SLAG AS A ROAD-SURFACING METAL

Slag is a product obtained during the reduction of iron ores, and has been used to a small extent as a surfacing material for highways and to a large extent as ballast for railroads. The slag that is used in this capacity is generally silicate slag, resulting from the smelting of iron ores in blast furnaces, and is produced by a combination of a flux and the earthy matter of the iron ore. As is well known by all persons familiar with the smelting of iron ore, blast furnaces are charged with alternate layers of fuel, ore and a flux, usually limestone, fresh material being added from the top as the charge works down. The blast is introduced through tuyeres near the bottom of the furnace, and except during the time of charging and tapping these furnaces, it is continual. The iron, reduced from its ore by carbonic oxide or other reducing agents, descends toward the furnace together with the slag which results from the union of the earthy matters or the gangue of the ore and the flux; the slag, being of less specific gravity than the molten pig iron, flows upon the surface of it.

The quality of the slag necessarily varies, the variations being due to the complex action of the blast furnace; to differences in quality of the ore, fuel and flux at various intervals; to lack of uniformity in charging and to differences of temperature, atmosphere, etc.

As the slag reaches a certain point in the furnace, it is continually running off, and amounts to approximately one ton for each ton of iron that is made.

From the above, it will be readily seen that the production of blast furnace slag and the reduction of iron ore into pig iron results in an immense tonnage production of this slag material each year.

The physical differences of slags, even upon casual inspection, are very obvious. They differ in hardness, density, porosity and color. Slags which contain approximately 40 per cent. silicate, 40 per cent. lime and 20 per cent. alumina are considered to be about the best for road-surfacing purposes. When these percentages vary greatly, slags are apt to be weak and to disintegrate when exposed to air or water.

There are two methods of disposition of slag as it is drawn from the blast furnace. The one usually used is that in which the slag is drawn off in the molten condition into large automatic dump ladles, holding approximately 150 tons each. These ladles are then hauled along a track to the edge of a bluff, where they are dumped, allowing the slag to run out in thin layers to cool. The surface of the slag bank soon solidifies, although the bank formed remains warm for a considerable length of time, and it is generally believed that slag banks should be allowed to harden for at least two years before the slag can be used to advantage for highway purposes.

The other method of disposing of this slag when it is being drawn from the blast furnace is to run it into a large vat of water, where, due to the action of the liquid, is formed what is known as granulated slag, a fine, crispy, glassy product, which, has been used with some success as a substitute for sand in concrete mixtures, although in general this granulated slag is disposed of as waste material or used to form embankments in place of earth.

Slag as a road surface has been used occasionally during recent years, in localities where there is a scarcity of suitable sand and gravel for road metal. The New York State Highway Commission considered the feasibility of its use last winter, in some of the counties in the south-western part of the State. Samples were tested at Albany to ascertain whether the characteristics of this material were such as to justify its use. The results were such that the Commission authorized the specifying of its use in various types of construction. An article appearing recently in the official organ of the Commission, and written by F. S. Strong, one of its division engineers, is based upon this departure. From it this information has been obtained.

The types in which the use of slag is allowed include plain concrete pavements, concrete pavements with bituminous surfacing, Hassam concrete pavements, water-bound slag macadam with and without glutrin, some with limestone screenings and some with slag screenings, and bituminous-bound slag macadam highways. Much of this work is now under contract, and a considerable portion of it will be completed this year. The material is also being used to some little extent as a surfacing material in the repairing of old macadam pavements.

It is believed that the careful and continuous future inspection of the highways built of slag will produce valuable information and statistics of its merits as a road metal.

A big bulk of the slag available in the section of the State referred to consists of blast furnace slag. However, in the further reduction of pig iron in the production of steel, various processes are used, as, for instance, in the open-hearth furnace, where the crude metal is further purified, here again a flux is used which rises to the surface of the molten mass as slag. Slag formed in this operation has been used but very little on account of the small quantities available for highway purposes, although it possesses many desirable qualities, such as hardness, toughness and excellent cementing qualities.

The use of this latter form of slag will be taken up below in the discussion of streets constructed in the city of Cortland during the last ten years with excellent results.

In the vicinity of Youngstown, Ohio, in 1909, the office of public roads in co-operation with the Carnegie Steel Company conducted a series of experiments to determine the best method of utilizing this slag for road construction. In the experiments at this place, the blast furnace slag was taken from a bank that had aged about two years, the material of which came from six blast furnaces of the same type. A steam shovel was used to load the slag from the bank into large gondola cars. These cars were drawn to a gravity screen, where the slag was dumped into a chute and passed over the screen to separate into proper sizes. After passing over this screen, it was taken by rail to a site about one and one-half miles from the road upon which it was to be used, unloaded and hauled to the road.

These experiments as shown by the bulletins issued by the office of public roads, proved very interesting, and demonstrate that there is a field for blast furnace slag in the construction of highways, and the results were so favorable that the various counties and the State Highway Department of Ohio have adopted standard specifications for the use of this material. Various reports of inspections made of these roads show that they have stood up well, and, owing to the cheapness in the first cost of this material and the lightness in weight, the investment in a slag furnace macadam pavement from an economic standpoint would seem to compare favorably with that of a stone macadam pavement.

Since the completion of these experiments, which were conducted with slag which was not run through a crusher but was taken directly from bank and screened, slag pavements have been constructed from commercial blast furnace slag, the slag being carefully sorted to obtain the best materials and run through a regular stone crusher in order to obtain the proper sizes for use in the various courses of macadam, resulting in superior types

of construction and more uniform and lasting types of pavements.

In the vicinity of Buffalo, where there are many large blast furnaces, this slag has been used to some little extent for highway work, although no intelligent effort was made to obtain a high-class construction, due to the lack of available money for said purposes in the localities where the work was done. Yet this material is found to consolidate under traffic without rolling, harden and smooth out, making an excellent country road. Where incisions were made in some of these roads for various purposes, it was found almost as difficult to cut through this material as to cut through a concrete foundation for brick pavement.

At the beginning of 1913 a plant was established in connection with the Buffalo Union Iron Furnace to take over the slag product of these blast furnaces and produce therefrom a commercial product to be known as crushed screened slag for railroad ballasting and highway surfacing purposes. During the season of 1913 a considerable amount of this material was used on town highways, and reports received from various town and county superintendents in districts where this material was used, stated that satisfactory results were obtained, although thus far it is too early to reach any conclusion as to the definite wearing qualities of this material.

In reference to the use of slag product in the open-hearth process in the manufacture of steel, perhaps some of the most successful work of this kind in the construction of streets or highways is that which has been done in the city of Cortland. In this city the first slag street was constructed ten years ago as a waterbound macadam highway, and, according to the city authorities, has given excellent results ever since. They also have other waterbound slag roads which have been built eight years with practically no repairs of any nature. During the last four or five years the city authorities have used a bituminous material asphaltic binder in the construction of the slag streets, using the penetration method with excellent results. The slag after being cooled is crushed in an ordinary stone-crusher, the larger pieces being used in the bottom course, which is bound with loam. For the body of the top course, a slag varying in sizes from 3/4 in. up to 2 in. is used. This top course has a finished depth of 3 in., and is bound with a gallon to a gallon and a half of asphaltic binder to the square yard; is then filled with slag screenings and rolled. These streets have also the appearance of sheet asphalt pavements and are standing up well under fairly heavy traffic.

The report which was distributed by the international joint commission appointed by the governments of the United States and Canada to investigate the pollution of the international waterways along the boundaries, dealt exhaustively with the sources of water supply and the contamination of these supplies by sewage. It pointed out that steamboats crossing the lakes take drinking water from contaminated areas 16 miles from land, that the water supply at Detroit and Windsor, and the western frontier of Ontario is not only exceedingly bad, but dangerous, and that some deaths are undoubtedly due to the infected water service for drinking purposes on the ferries plying between Windsor and Detroit.

The water power branch of the interior department of the Canadian government is arranging to put in the Canadian building at the Panama Exhibition at San Francisco an exhibit, showing the vast power resources of the Dominion. The exhibit is to include a series of models of typical power plants from the Atlantic to the Pacific. They will be arranged in a semi-circle in front of an enormous landscape painting of the Dominion, which is now being executed by Gibson Catlett, Toronto. The painting will be 75 feet long by 9 feet high.

DETERMINATION OF CARBON IN IRON AND STEEL.

THE following direct method for the determination of carbon content of iron and steel is outlined in an article, by W. D. Brown, appearing in a recent issue of Metallurgical and Chemical Engineering: The essentials for complete combustion are an initial temperature of the furnace of about 1800° F., the burning of the metal in nearly pure oxygen, and an unlimited supply of the latter during combustion. If the metal is pushed into the furnace and a slow stream of oxygen started, combustion will begin before all the air has been displaced and will be in a mixture of air and oxygen; possibly the combustion of the iron will be complete before the oxygen has completely displaced the air and the only work remaining for the oxygen is to displace the carbon dioxide in the tube. When the combustion begins, oxygen should be supplied as fast as the iron will combine with it, that the temperature may be raised to the highest point; about 3000° F. will be momentarily obtained and all the carbon will be oxidized. These requirements of starting combustion in oxygen and an unlimited oxygen supply have been met in the method described below. In addition the supply of oxygen has been made automatic.

Apparatus.—The electric furnace contains a silica tube 7/8 in. in diameter and 24 in. long; in it ignited asbestos is loosely placed from the exit end to within 3 in. of the middle of the furnace; this acts very well as a catalizer, and is necessary when burning pig iron, at least. Oxygen is obtained in 100-ft. cylinders on which is a pressure reducer and regulator which supplies oxygen at a pressure from 1 to 3 lbs. as desired. The regulator is connected to brass piping containing four tees and globe valves for four electric furnaces (more could be added as desired), thereby one tank is used for the four furnaces. Oxygen enters the silica tube through one hole of a two-hole stopper. In the other hole is a 12-in. copper or glass tube, 1/4 in. outside diameter; on the end of the tube is a No. 00 single hole rubber stopper. Through this stopper and tube a plunger rod of No. 9 nichrome wire, 24 in. long, to which is riveted a sheet of nickel about 1/2 in. diameter, is inserted. This is used to push the boat into the hot part of the furnace after the oxygen has displaced the air and while the current is flowing, and can be made in any laboratory; the No. 00 stopper can very well be replaced by a small stuffing box, in which case the copper tubing is shorter. The oxygen being free from CO_2, no purification is necessary. Both ends of the silica tube are cooled by copper water jackets.

The exit end of the tube is connected by a rubber stopper to a glass stopcock, which is used to regulate the flow of gas. The stopcock is connected to a 5-in. drying tube filled loosely with phosphoric anhydride. It has been found that a zinc tube is not necessary, as the sulphur trioxide fumes are caught by the asbestos and phosphoric anhydride.

The drying tube is connected by a rubber tubing, on which is a pinchcock, to a Vanier potash bottle. This bottle contains a solution of potassium hydroxide (purified by lime) of 100 grams per 100 c.c. water. The inner tube is filled with phosphoric anhydride and a covering of glass wool placed thereon. Filled in this manner, the bottle will last for 100 determinations. The part which fails first is the phosphoric anhydride; a solution will form in the bottom of the drying chamber and will gradually grow until there is no more dry anhydride; this marks the life of the bottle.

On the construction of the Vanier bottle depends the success of the method; it must be so made that a speed of 400 c.c. per minute may be obtained without the gases passing out the lower end of the inner coil, which can be done if the lower end points or slants downward instead of being horizontal. The exit end of the coil should also be opposite the entrance to the drying chamber to prevent the splashing of the potassium hydroxide solution into the phosphoric anhydride.

The Method.—A blank is first run in the following manner: With all connections closed, the oxygen is turned on the line and the pressure varied until three lbs. are obtained. One or more bottles are then connected to the furnace or furnaces and the stopper inserted in the entrance of the silica tube, the stopcock in the bottle is then turned, the pinchcock opened, and the globe valves from the oxygen line opened full. Oxygen should then pass through the bottle at a rate of approximately 400 c.c. per minute, the pressure in the line dropping to 2 lbs. If the speed of the gas is not as great as this, the reducing valve should be so regulated as to increase the pressure. It may happen that one bottle will go faster than the other; in that case, the stopcock at the exit end of the furnace is to be partially closed so that all bottles have the same speed. When this condition has been obtained—the right pressure in the oxygen line and the stopcocks just right, no change is made until it is necessary to renew the bottle or tank. The stream of oxygen is continued for five minutes, the oxygen is then shut off at the globe valves on the oxygen line and, as soon as the flow of gas slackens in the bottle, the pinchcock on the rubber tubing leading to bottle is closed and, when the flow has completely stopped in the bottle, the stopcock is turned, the bottle is removed and weighed, preferably with a tare. This is repeated until the variations between weights is not more than three decimiligrams.

For the actual test, 1.36 grams of steel between 20 and 60 mesh or half gram iron, are weighed and transferred to a groove in alundum contained in a nickel boat. The bottle is connected to the furnace as above and the stopper turned, the pinchcock being closed. The boat is placed just within the silica tube, the two-hole stopper carrying the pusher is then inserted in the tube, the pinchcock opened and the oxygen turned on full at the globe valve. Oxygen then passes through at the rate of approximately 400 c.c. per minute; if the rate varies perceptibly from this it can be regulated by stopcocks at exit of silica tube. After gas has passed through for one minute, the boat containing the drillings is pushed into the centre of the furnace by shoving in the nichrome wire mentioned before, while the current of gas continues. In about one minute the drillings have become heated sufficient to burn freely and combustion then is very rapid, being complete in twenty seconds. During the combustion an unlimited supply of oxygen is at hand, as the globe valve is open full and the regulator is set for a definite pressure. The oxygen then passes through to sweep out the carbon dioxide formed, five minutes after the boat is pushed back being sufficient. The globe valve is then shut off and, when the flow of gas has slackened, the pinchcock is closed, followed by the closing of the stopcock as above described. The bottle is disconnected and weighed; increase in weight in grams, multiplied by 20 gives %C. when 1.36 grams steel has been used.

In routine work, one analyst weighs up four (or less) tests, places boats in furnaces and starts the gas flowing. During the one minute's wait, he examines stoppers, etc., for leaks, then pushes boats back and leaves furnaces for other work, returning in five minutes for the completion of the determination. This method can be used for the determination of carbon in steels ranging from 0.07 per cent. to 1 per cent. carbon, as well as on pig iron. Not only is the accuracy greater than with color determinations, but the time required for analysis by combustion is less than by color.

RAILWAY COMMISSIONERS' ORDER RESPECTING LOCOMOTIVE DEFECTS.

An important order has recently been issued by the Board of Railway Commissioners for Canada to railway companies under its jurisdiction. By it locomotive engines of railway companies subject to the jurisdiction of the Board will not be allowed to leave terminals, or to be used at terminals, in traffic service, on which any of the following defects exist, viz.:

1. **Steam Leaks.**—Steam leaks from any part of the locomotive which render it impossible for the engineer to see signals in sufficient time to enable him to bring his train to a stop within the required distance.

2. **Air Brakes.**—Air brakes on locomotives or tenders not in serviceable condition.

3. **Wheel Defects.**—Locomotives with steel or steel-tired leading engine truck wheels, leading or trailing driving wheels, or tender wheels with flanges worn 1/16 below M.C.B. wheel defect gauge for cars of less than 80,000 pounds capacity.

Locomotives with cast iron engine truck wheels and cast iron wheels under tender weighing over 130,000 pounds with flanges worn 1/16 below M.C.B. defect gauge for cars of 80,000 pounds capacity, or over.

Locomotives with cast iron wheels under tender weighing 130,000 pounds, or less, with flanges worn 1/16 below M.C.B. defect gauge for cars of less than 80,000 pounds capacity.

Locomotives with truck or tender wheels having shelled out or flat spots over 2½ in. long, or so numerous as to endanger the safety of the wheel.

Steel tires on locomotives worn hollow ⅜ in. in depth, or which are worn below safe limit of thickness. Railway companies to file with the Board their standard limit of thickness of tires on all classes of locomotives, for approval.

Flat or shelled out spots on locomotive driving wheels 3 inches long.

4. **Springs.**—Locomotives with defective springs on any part of locomotive or tender which are unable to carry their respective weights when locomotive is standing.

It is further ordered that the railway companies are required on or before the first day of January, 1915, to equip their locomotives with double windows in the front of the cabs during the winter season, November 1st to April 30th; the same to be made air-tight.

The order is the result of replies to a circular issued to the railway companies on February 24th last, and the reports of the operating officers of the Board, the railways consenting to the adoption of the regulations regarding locomotive defects as outlined above.

During the past 2 years, approximately $2,500,000 has been spent by the C.P.R. on the Dominion Atlantic Railway. The whole road is being modernized in its bridges and tracks. The biggest individual job was at the Bear River bridge, where $1,500,000 was spent. Other new bridges are those across the Avon, at Windsor, over the Gaspereau River, and at Weymouth. The C.P.R. will formally take over the road when it is brought up to the required standard.

MOOSE JAW 11th AVENUE SUBWAY.

THIS work comprises the construction of a subway 66 ft. wide under the Canadian Pacific Railway tracks and connecting the northern and southern portions of the city as divided by the Canadian Pacific Railway main line. The subway is situated two blocks east of Main Street at the north end at Manitoba Street and 11th Avenue, and passes diagonally under the tracks, connecting with 10th Avenue one block east of Main Street at its south end, which terminates at a concrete bridge over the Moose Jaw River.

The length of the subway is some 1,040 feet. A double line of street car tracks is laid from end to end with steel standards along the centre line. The vehicular roadway has a minimum clearance of 13 ft. 4 in. under the lowest members of the steel bridgework carrying the five C.P.R. tracks. The roadway, which is laid at a 4% grade, is 46 ft. between curbs, and paved with vitrified blocks laid on a concrete base varying from 5 in. to 18 in. in thickness according to the condition of the subsoil. On each side of the roadway 10-ft. concrete sidewalks with curb and gutter are provided for pedestrians.

Reinforced buttressed concrete retaining walls are built along each side, and heavy concrete abutment walls support the bridgework carrying the tracks. The elevation of the crown of the road at the lowest point, that is, under the centre of the tracks, is 1,751.14, being some two feet below the mean water level of the Moose Jaw River, which borders the south end of the subway. At the lowest point of the gutters catch basins are provided to take the storm water, which is thence conducted by 8-in. and 10-in. stoneware sewer pipes laid under the sidewalks, discharging into the low level of the river below the C.P.R. dam some 1,500 feet distant. The sidewalks in the lower portion of the subway have been constructed 3 feet above the roadway so that their lowest level is well above the high-water level of the river, and consequently immune from any possibility of being submerged during any flood.

Iron railings are provided for the protection of the public along the curbs of the raised sidewalks, and along the back edge of the sidewalks at the south end, which is bounded by the river on each side, or more correctly, by Moose Jaw River on the east and Thunder Creek on the west side, which join at the before-mentioned concrete bridge at south end of the subway.

Owing to the close proximity of the river, it was necessary to support the bridge abutments and a considerable portion of the retaining walls on closely piled foundations. These piles varied in length from 12 ft. to 18 ft., being driven to absolute refusal in practically every case. Also, to avoid the ill effect of a saturated sub-base by percolation from the river, Neponset waterproofing was laid on a concrete bed below the main concrete road-base throughout that portion where the road surface was less than 1 foot above the high-water level of the river.

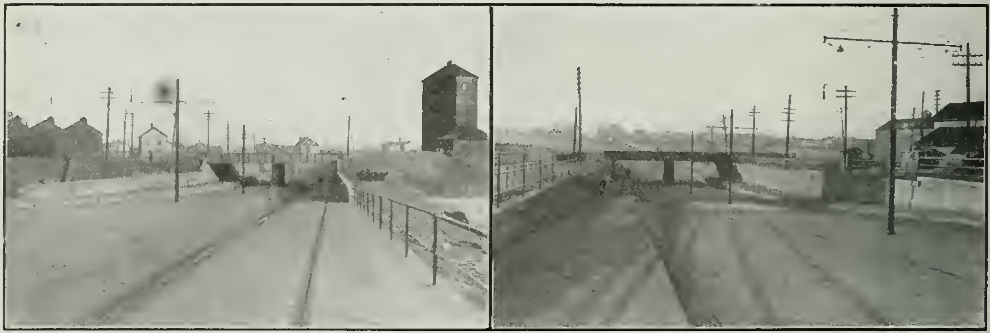
The total cost of construction of the subway amounted to about $130,000, of which the cost of bridgeworks for the C.P.R. tracks was about $38,000.

There were some 22,500 cu. yds. dry excavation moved at about 60 cents per cu. yd., 2,000 cu. yds. of wet excavation at $2.60 per cu. yd., 5,000 sq. yds. of brick paving, which cost about $54 per 1,000 delivered on the site. These paving bricks were obtained from Denver, Colorado, and the price laid on 5-in. concrete base and 1½-in. sand cushion was about $3.50 per sq. yd.

The work was commenced in May, 1912, and completed in October, 1913, being closed down for about five months during the winter. However, practically all the excavation had been completed and sufficient progress made to allow of a good roadway being left open for both vehicular and pedestrian traffic throughout the winter.

The subway forms the main thoroughfare between the north and south of the city, and has, therefore, been so constructed that although subject to continuous heavy traffic the cost of maintenance should be small, and at the same time the initial outlay has not been excessive.

The plans were originally designed in 1911 by Mr. J. M. Wilson, then city engineer, and Mr. R. G. Saunders, his assistant city engineer, being revised by Mr. Antonisen, the city engineer in 1912, and the work carried out by Messrs. Wilson, Townsend and Saunders under the supervision of a member of the city engineer's staff, Mr. B. C. Ward, as resident engineer. Mr. Geo. D. Mackie is now city engineer and commissioner, and to him we are indebted for the above information.



Subway at 11th Avenue, Moose Jaw, Under the Canadian Pacific Railway Tracks.

GRANITE IN BRITISH COLUMBIA.

An important matter to Vancouver is the discovery on Texada Island, 50 miles from the city, of an inexhaustible ledge of mottled ganite. Some of the stone was, says an American consular report, quarried experimentally, and the polished slabs used in the new Victoria Theatre. A $150,000 company has leased the ledge from the Government, and will develop the quarry, building a gravity tram line to the water edge, whence the stone can be transported cheaply to Vancouver for dressing. During the past five years over $3,000,000 worth of marble has been imported into Vancouver for interior work on new buildings. In the future most of the stone for such work will be quarried in British Columbia.

SEWAGE DISPOSAL IN EUROPE.

It is obvious that sanitary engineers of this continent have decided advantages in being able to glean from the European types of sewage disposal works those features that are best and most efficient for use in this country. Proper combinations and adaptations of English and German types, together with whatever improvements ingenuity may suggest, should produce sewage disposal works of the highest order, there being no prejudicial feeling for one type and against another, such as exists in Europe.

A brief review of sewage disposal works in some of the European cities is given by Geo. E. Dalesman, principal assistant engineer, Bureau of Surveys, Philadelphia, in a paper recently presented to the American Waterworks Association. The following observations are conducive to a general understanding of the disposal situation in Europe as it appears to the interested observer:—

The use of underground channels to carry off the liquid wastes from dwellings is a very ancient practice. In the beginnings of ancient Rome there were built large conduits, in use to this day. On the Island of Crete, the home of the Aryan progenitors of the ancient Grecians, recent excavations show that underground drainage channels were systematically constructed at least 3500 years B.C. The construction of these channels as a system, however, may be said to have begun in the nineteenth century.

Scientific and effective treatment and disposal of the liquid wastes was discussed in the last quarter of the nineteenth century, experiments inaugurated and many works constructed during that time; but during the early years of the present century the art has made much progress, works have been built in accordance with the most successful lines of experiment, and many additions made to the earlier works.

Sanitation. — While sanitation comprises many branches, that represented by the term sewage disposal is one of large influence upon the general health of a community.

Prior to the introduction of sewage systems in large cities, death rates were high, and for centuries at intervals of a few ears or decades, their populations were swept away by plague or pestilence, fostered and spread by admixture of noisome liquid wastes with the drinking water. Repetitions of these visitations were accepted as natural, until modern science showed that by the introduction of proper systems for carrying away liquid wastes the mortality could be lessened. Striking examples are the city of Havana and the Canal Zone, made habitable and safe by the introduction of sanitary conveniences.

Municipalities, especially in the crowded European centres, took up the matter of improving old conditions with vigor, full-size experimental installations were made, gradually developing into complete systems for the collection and disposal of the sewage.

The agitation for better sanitary municipal surroundings has given rise to keen debates, and has set up many champions of a radical change, calling for the exclusion of sewage matters from streams and rivers.

Calmer judgment and extensive experiments have tempered these views, until at present it is recognized that the streams themselves are, and have been, effective agents in transforming organic or putrescivle matter into a mineral or innocuous state up to a certain limit, dependent upon the amount of available oxygen in the water.

European Conditions.—The examinations of sewerage systems in European cities are valuable on account of the concentrated population and the results achieved by the introduction of sewage treatment systems in lowering their death rates, even with a water consumption of from one-fourth to one-sixth of that in American cities. This, resulting in a far more concentrated sewage, calling for different treatment than our own, necessitates also the treatment of a volume of storm water when polluted by the sewage, ranging from four to six times the dry weather flow, a condition which does not arise with our more dilute sewages.

By reason of their concentrated populations and the smaller size of European rivers, with their small diluting volumes, the urgency of installing sewage treatment works has been greater, to protect their restricted water supplies and to avoid nuisances that would in some cases make their cities noisome places of abode.

Again, on account of their nearness to Asiatic cities, the homes of plague and pestilence and their open harbors, sanitary safeguards are essential.

Owing to restricted parking areas and the possibilities of river embellishment, by the removal of sewage pollution, they have been enabled to make of their rivers the most attractive features of their cities, for bathing and the enjoyment of people in their hours of relaxation.

American Conditions.—The American cities have grown rapidly from villages, and the village practice of building a culvert to the nearest stream has until recent years survived. The drains from various villages have grown into a system with many outlets discharging crude sewage into the larger streams.

Large streams like the Schuylkill River, suitable for water supply, have gradually been eliminated from the lists of available sources, the rivers themselves have become septic tanks, and of recent years, even rivers like the Delaware and Hudson have been polluted, so as to require effective treatment before their waters can be used for domestic consumption, a prodigal waste of natural resources.

A few years ago the old-fashioned cesspool was in vogue, and we can remember when protests were filed against the building of sewers. Now, since no block of dwellings can be disposed of without them, builders solicit drainage facilities as the first step in the improvement.

A few years ago black, dirty, sewage-polluted water was consumed by local residents without question, and affliction with enteric diseases in consequence was taken as a matter of course. The improved water supply has educated our people to other views.

In port operations, formerly, any filth could be thrown from vessels or dumped into the river. To-day it is recognized that to compete for the world's commerce we must remove from sight and smell all nuisance.

To-day pollution of water supplies will not be tolerated, and a reduction in the deaths due to preventable disease appeals so strongly, that the great insurance companies have banded themselves together, with millions of capital behind them, to study their causes and remedies with a view to stamping them out.

We are just learning to be less prodigal and to devise ways and means to conserve our advantages, to protect our streams, to be dissatisfied with their pollution with sewage; but it will take some educational campaigning before the people at large will understand the value to the communities of sewage treatment.

Advances in the Art.—The advance made in the art, due to large sums spent in full-size experimental installations, in efforts to free natural watercourses from pollution, has been steady and positive, each forward step

taken after experience in operation or research warranted it.

In the first instance, farms irrigated with sewage were operated, but this practice has been abandoned, except where by reason of the great cost of the installation, it is not practicable to change the treatment.

Screening and tank treatment, sometimes coupled with sand filtration, have been substituted in some instances.

Throughout England, where rivers are comparatively small, plants are undergoing reconstruction, and some form of bacterial treatment in beds is being added to the preliminary treatment. In some cases it has been found to be economical to turn the earlier works into scrap and build entirely new as at Leeds.

In English sewage disposal plants, the disposal of sludge, except where it is carried to sea, has been generally inadequate. This is now considered by many the most vital problem.

In Germany, by several processes the problem of sludge disposal has been successfully solved.

As to the present status of the art the following statements may safely be made:—

Sewage even of exceptional concentration can be effectively treated, so as to secure a clear, odorless, sparkling, non-putrescible effluent before discharging into a stream, the securing of which is a matter of cost, and, therefore, an economic as well as a constructive problem.

Sludge resulting from sewage treatment can be rendered innocuous, practically inodorous, wholly unobjectionable, after which it may be dealt with in various ways.

Desired results may be secured by certain combinations of treatment at a fraction of the cost of other recognized scientific methods of treatment in satisfactory operation.

Relation to Water Supply.—It is considered by some eminent sanitary engineers that they are justified in placing sewage disposal next in importance to water supply in the list of public utilities. This is based upon the value of protecting the streams from nuisance, to conserve sources of water supply and to protect the health of the people.

As a water supply is taken from a river, its application to a populous community produces sewage, and, as its natural destination is a return to the stream, used possibly again for water supply, it gives rise to an economic problem as to the proportionate share which should be borne in the treatment of both the water and sewage.

The theory of excluding all sewage from return to a stream, held some years ago, is untenable, and with this recognized and the necessity of utilizing the diluting volume of the river and its available oxygen to continue the treatment begun in disposal works, the problem resolves itself into an economic one.

The uses to which the waters of a river are to be applied are controlling factors in the standard of effluent to be secured.

The comparative economy of treating sewage to a high degree of purification or of taking a lower standard and increasing the degree of water treatment, must be solved by each community.

When comparing the amounts of available chlorine required in water and sewage effluent treatments it has been found that of three turbid raw water supplies, the average amount of available chlorine required to render the manufactured product free from bacteria resembling B. Coli is p.p.m.: of three other raw surface waters, 0.3; of four examples of sand filter effluent, there were required 0.33.

For the effluent of sewage works under average conditions, which had been subjected to settlement, there were required 6 parts; that which had passed percolating filters, 3 parts, and that which had in addition been subjected to secondary settling, 2 parts.

In general, therefore, it is cheaper to treat water when practical disinfection can be secured by the admixture of from 0.3 to 0.7 p.p.m. of available chlorine instead of attempting to secure an uncertain comparative result in the treatment of sewage effluent by the admixture of from 2 to 6 parts, with a probability of having to resort to an equal amount of treatment for the water notwithstanding the sewage treatment.

In Germany, with its concentrated populations, rivers are considered by the rivers boards as proper places for the disposal by dilution of sewage submitted to fine screening and settling tank treatment, from which rivers are taken the water supplies usually from driven wells or filter galleries along their banks.

Judging from the exceptionally low typhoid death rates in these cities, any condemnation of the practice must be supported by arguments from other sources.

Grit Chambers.—Frankfurt, Huddersfield. Sewage reaching treatment works from a combined sewer system must be subjected to passage through a grit chamber to remove sand and coarse gravel. This is accomplished by an increased flow area, to reduce the velocity to 15 inches per second or less. The types in use in Frankfurt, Dusseldorf and in the Emscher district are good examples. Deposited solids are usually removed by elevator bucket dredges having transverse motion on tracks. This admits of operation without putting the grit chamber out of service.

Screens.—Hamburg, Frankfurt, Dresden, Bolton. Screening in England is for the purpose of removing such solids as would clog pumps or would be not readily reduced in tank treatment; therefore, it is coarse screening, the bars being spaced about 2 inches.

In Germany, however, it is considered in many places as a complete and efficient treatment; therefore their manufacture and maintenance have received much more attention. Usually there is a coarse screen of about 3 inches spacing composed of bars to protect pumps or valves. The screening processes proper consist in the main of three types designated as Hamburg, Frankfurt and Dresden.

The Hamburg type consists of a curtain inclined at an angle running over drums, brush-cleaned. The apertures of the screen are about 3/8 inch. Where there is a large tidal range and fluctuating depth in the sewers, this is most effective and can be operated with slight nuisance although it is cleaned by brush with difficulty.

The Frankfurt screen consists of five vanes cleaned by a comb, the prongs of which alternate with the spaces of the screen. The combings are passed to a table, which disappears under a knife edge, the scrapings going to a belt, the screen being easily cleaned and very efficient.

The Dresden screen, introduced in about fifty European plants in Germany, Austria and Russia, is the most improved and simplest in its operation. The cleanliness that can be maintained is hard to believe unless seen, being entirely without nuisance or objectionable features. The spacing is about 1-12 inch. Its efficiency will average over 50 per cent. solids removed. Screens, however effective, cannot compete with properly designed tanks.

Tanks.—Frankfurt, Birmingham, Essen 2. Without entering into the comparative merits of settling, septic, sedimentation, Emscher or other forms of tanks, a number of types are shown.

Where the sizes of rivers and the consequent dilution is large, and water supplies are not jeopardized, the rivers

boards of Germany have after examination pronounced fine screening of sewage a sufficient protection of the rivers.

Where smaller rivers must be used for final disposal or water supplies must be protected there is added some form of tankage treatment.

Septic tanks as at Wilmersdorf deal with a concentrated sewage, are foul smelling, though the final effluent is satisfactory.

In sedimentation tanks as at Frankfurt, each unit has a storage period of one and one-half hour; cleaning is resorted to once a week. The type tank involves the placing of a unit out of service when being cleaned, resulting in odors noticeable underground at 150 feet distance.

Throughout England the septic tank is in use designed for storage periods of from twelve to twenty-four hours.

The difference between the German practice of about two hours and the English practice of eighteen hours' storage, calling for from five to ten times larger tankage area, is due to the smallness of the English rivers and the necessity of taking out as large a percentage of solids as practicable.

Methods of cleaning tanks of deposit are various, that at Bolton consisting of a squeegee having considerable merit.

At Frankfurt the sloping sides and bottom enable the sludge to flow to a central sump, whence it is pumped to centrifugal dryers.

Compare the area of the tanks in Birmingham (12 acres) for 900,000 inhabitants with that of Essen Nord (½ acre) for 190,000, which illustrates the difference in area as given above, required according to the practice in these two countries.

The so-called two-story tanks, called Emscher tanks because used in the Emscher district, are twofold in their operation. They provide a sedimentation chamber for about two hours' storage, and a digestion chamber for sludge, there being a diaphragm to separate the liquid from the solid parts of the sewage. The gases generated by the decomposing sludge do not pass through the sedimentation chamber; therefore the liquid remains fresh as distinguished from septic or smelly sewage. The biological processes carried on in the digestion chamber successfully mineralize the sludge, so that when withdrawn, usually by hydraulic pressure, due to difference in head between tank water and sludge outlet, the product is without objectionable odor, and is like garden soil, suitable for filling in low ground if not utilized for fertilizer.

The tank can be cleaned without placing out of service, and is to-day on many points the most efficient type in use.

Tank treatment, even with long storage periods without supplementary treatment, is not sufficient to prevent extreme pollution of the small English rivers, whereas with the larger German rivers, it is efficient, with short storage periods.

Contact Beds.—Sheffield. A form of bacterial bed in use largely in England and America is the contact bed, consisting of a basin enclosed by walls, filled with cinders, fine stone or other materials, into which sewage, usually after being submitted to tank treatment, is admitted slowly, allowed to stand some hours, then slowly emptied, and allowed to stand empty for some hours, the oxygen admitted during the withdrawal of the liquid serving to provide food for the bacteria acting upon the solids attached to the surface of the material in the bed. The so-called slate beds may be so classed because of the similarity of operation.

Two good examples are at Manchester and at Sheffield, the first caring for the sewage of about 250,000, the latter of about 470,000 inhabitants.

The process is regarded as effective, but as the amounts that can be treated are small, about 500,000 gallons per acre per day, about one-fourth of the amount which may be treated in other more rapid processes, percolating filters, for example, with a consequent larger area and larger maintenance charges, more intensive processes are talked about, but as much capital is locked up in such large plants it is difficult to make radical changes.

Percolating Filters. — Wilmersdorf, Birmingham, Huddersfield, Bolton, Salford. Percolating filters consist of beds of cinder, broken stone, gravel or other hard material, thoroughly underdrained, upon which the sewage, subjected to preliminary treatment, is applied by some form of distributor, usually to spray the liquid; rotating arms, longitudinally travelling trough, fixed nozzles, or by means of a network of perforated pipes laid on the surface of the filter. With the exception of the circular filters, 65 in number, at Wilmersdorf, near Berlin, with rotating arms, and a few small scattered examples there are none of these beds in Germany, although experimental installations have been in use, and their ultimate use is forecasted, notably in Hamburg and Leipzig.

An experimental station of large size has been in operation in connection with the work at Paris, France, as a result of which the speaker was informed by M. Verrière, the chief engineer, that in the forthcoming report for the remodelling of the system percolating filters would be recommended in place of the existing farms.

In England the use of the percolating filter is most extensive, not as a matter of choice, but from necessity.

The prevalence of cities with large populations, and the many manufacturing villages forming a chain between, with the comparatively small sizes of the rivers and the great amount of pollution which reaches them, in some cases equalling their flow volumes, have forced more complete treatment of waste liquids than can be obtained by screening and tank treatment alone. This is especially the case in the manufacturing sections, Warwickshire, Lancashire and Yorkshire. Ten years ago it was the view of Sanitary Engineers that septic tanks would reduce and liquefy 90 per cent. of the sludge deposited in them; now it is known that between 10 and 20 per cent. is the average reduction.

Within twenty years millions of pounds sterling have been expended upon works, but some are being consigned entirely to the scrap heap, as at Leeds, many others are being planned to supplement present treatment by percolating filters, and many are in a process of alteration.

When it is considered that by resorting to these filters the rate of treatment for English sewages can be doubled over the best contact bed system, the matter of area of ground and construction cost alone shows economy.

With strong English sewages composed largely of manufacturing wastes, there is considerable odor from these spraying filters. The small white moths or flies that infest them are an intolerable pest. Experience shows that this nuisance is greatly reduced by surrounding the filters with close stone walls and placing a fine surface medium.

Sludge Disposal.—Of all matters reaching a sewage treatment plant, that of proper disposal of the sludge, or residue from tankage treatment is the most serious. A dozen plants can be named, the efficiency of each of which from an operating standpoint is unquestioned, with the single exception of sludge disposal. The methods of disposal vary with the local conditions. They comprise,

irrigating on farm land, underdrained lagoons, burying in trenches, pressing and drying, centrifugal drying machines, briquetting and burning, canal boats to farms, steamer to sea, digestion in tanks and drying on sand beds then used for filling.

The effectiveness from the standpoint of lack of nuisance about the works is as follows: (1) digestion, drying and filling, (2) steamer to sea, (3) drying under heat. The remaining methods are ineffective.

1. The speaker has stood in the centre of a 6-acre tract of air-dried sludge, 50 per cent. moisture, of depth varying from 3 to 12 feet, in damp weather, without detecting any more odor than would be noticed from a freshly ploughed unfertilized field. Example—All over the Essen district.

2. Pumping to steamer and disposal at sea is positive in the removal of all nuisance except during cleaning of tanks. Examples—London and Manchester.

3. During cleaning of tanks and during drying by centrifugals, it is smelly within the building; after drying by heat, there is no further objectionable odor. Example—Frankfurt a. Main.

It may positively be asserted, therefore, that with certain treatments the sludge problem is satisfactorily solved.

When sufficient fats are present in the sludge (about 25 per cent.) they may be profitably recovered as at Bradford.

Notable Treatment Works.—Notable as being the best of their kinds are the following works:

Hamburg—Grit chamber screening and dilution in the Elbe.

Dresden—Grit chamber and fine screening with dilution in the Elbe.

Vienna—Efficient collecting systems with dilution in the Danube.

Frankfurt a. Main—Grit chambers, screens, settling tanks, sludge dried in centrifugals, further dried by heat and burnt under boilers to produce electric current.

Wilmersdorf—Primary settling tanks, percolating filters, secondary tanks, sand filtration, sludge in lagoons.

Cologne and Dusseldorf—Fine screening and tankage, with dilution in the Rhine.

Berlin and Paris—Farms.

London—Screens and tanks with dilution in the Thames, sludge to sea.

Manchester and Sheffield—Screens, tanks and contact beds.

Birmingham—Detritus tanks, settling tanks and percolating filters, sludge to lagoons.

Salford—Grit chambers, settling tanks, roughing filter, percolating filters, sludge mixed with chemicals, pressed and dried.

Many others will outclass these when new works shall be in operation.

River Fronts.—One of the most noticeable results of the establishment of sewage disposal works, is in the ability to improve and embellish river fronts.

In London not many decades ago the stench from the sewage polluted Thames invaded the Houses of Parliament and pleaded the cause of sewage treatment. The cleaning up of the Seine at Paris, the Spree at Berlin and other rivers was accomplished only after centuries of warning sounded by the periodical visitation of pestilence. River nuisance has been successfully avoided in European cities by the construction of interceptors along the river banks.

Lessons.—The choice of a certain process can not be made because of its reputation for effectiveness, but the design must be determined upon only after all phases of the local conditions are considered, starting with the characteristics, size and volume of the river into which final disposal is to be made, and adopting the most economical system, the effluent from which will not unduly overload the river, and which will utilize the available diluting capacity of said river, or parts of a river.

The lessons learned from an inspection of European cities may be briefly summed up as follows: Collecting systems are designed with the most minute attention to economy, therefore along scientific lines.

The quality of material and workmanship in sewer construction are superfine, due in a measure to mechanics' wages being one-third of ours.

For the best developed screening appliances we must look to Germany.

Tanks, both on account of economies in areas and scientific design for construction and operation have been developed to a better standard in Germany than elsewhere.

Percolating filters, and the operation thereof may be best studied in England. Scientific experimentation on this system has been more thoroughly carried out in Paris.

The investigations upon river dilution have been carried on more thoroughly in Germany.

Sludge disposal, except where it is carried to sea, has not been solved in England. In Germany, it has been satisfactorily solved by several methods.

The English sanitary world is hopeful that we are on the eve of developing a more intensive, economical and effective means of treatment than the percolating filter.

The engineers in charge of the new "third lock" at the Soo Canal in Sault Ste. Marie, Mich., have predicted that before the end of the month, this lock, with a length of 350 feet greater than any other lock in the world, will be open to navigation. The new lock has a total length of 1,350 feet, a width of 80 feet, and a depth sufficient to permit boats of 24-foot draft to pass through it. With the locks already in operation at this point, the new lock will permit a gross tonnage to pass through from the waters of Lake Superior to the lower lakes that is ten times greater than the expected annual tonnage of the Panama Canal. Three locks are now in operation in the canal, two on the American side of the St. Mary's River and one on the Canadian side. Two additional locks are under construction on the American side, one being that known as the "third lock."

The display of Canada's natural resources at the Canadian National Exhibition this year will be a record in its completeness. The farm, the forest, the mine, the fisheries and the sources of other industries will be depicted in a most comprehensive manner. The federal and provincial governments are preparing extensive exhibits.

The Dominion Creosoting Co. (Limited), of Vancouver, has received from the Bengal and Northwestern Railway Co. of India an order for 160,000 creosoted railway ties. The specifications call for the best quality of seasoned Douglas fir, to be treated with 12 pounds of creosote per cubic foot, under specified temperature and pressure conditions. If the Douglas fir ties prove satisfactory for railway construction in India it is probable that other large orders for similar supplies from British Columbia will follow, and the creosoting industry of the province will be given a decided impetus from India.

The loss sustained by the G.T.P. Steamship Co., in the fire which destroyed recently the company's pier at Seattle, Wash., is estimated at $350,000. Damage was also done to the Coleman dock, both the pier and dock being located in the very heart of the Seattle waterfront, which brings the total estimated damage caused by the fire to about $500,000.

VOLUME CHANGES IN CEMENT AND CONCRETE.

PROF. A. H. WHITE, of the University of Michigan, has carried out a scientific investigation, covering many years, into the changes that Portland cement undergoes after hardening in water and being alternately exposed to wet and dry. Three years ago he presented a paper on the subject before the American Society for Testing Materials. Since 1911 he has continued his experiments, to find his earlier results confirmed. Further, it has been shown that the destructive action of these forces of expansion and contraction may be even more serious than was previously thought probable. Prof. White's later results formed the basis of a paper which he read recently at the 17th Annual Convention of the Society. His paper is a continuation of the preceding paper, and discusses the effect of high and low temperatures in addition to the effect of varying moisture. The results are dealt with in detail, and form an extensive treatise. A summary of them are given below:—

The tests confirm the theory that Portland cement in reacting with water forms a colloid which expands when wet and shrinks when dry. It does not become irreversible and lose this property, even after 20 years' exposure to the weather or after heating to 600° F. The length of a bar which has passed through a cycle of drying and wetting is not usually the same as it was before the cycle, but may be longer or shorter. Under ordinary conditions the bar remains elongated because water acts more rapidly, and the compressive strength of the expanding colloid is more than the tensile strength of the contracting colloid. This is especially true in concrete or in mortar where the particles of aggregate forced apart by the expansion lock in their new positions so that the bar remains permanently elongated. With neat cement, where the only aggregates are the unattacked particles of clinker, the bar may be made to grow shorter. By suitable alternations at elevated temperatures a bar of neat cement has been made to shrink in length 4.6 per cent. and under identical conditions, a bar of 1:3 sand mortar to elongate 0.75 per cent. Bars sawed from a sidewalk taken up in good condition after 20 years' service were made to attain a further elongation of 0.175 per cent. for the top coat and 0.130 per cent. for the base after a series of prolonged wettings and dryings at room temperature. This is an expansion equivalent to that which might be expected from a temperature variation of 300° F.

Concrete which has been properly made, and in which the colloid has been properly developed, has its interstitial spaces so filled with dense colloid when it is thoroughly soaked in water that there is no liquid water present in the pores. Such concrete may be frozen without any expansion. In fact, it will contract with temperature change at almost exactly the same rate as cast-iron. If the concrete has been poorly prepared or if there has been insufficient opportunity for the cement to develop its colloid by reacting with water, then its pores when wet will contain liquid water which will expand as usual on freezing, with possible resultant disintegration.

Concrete kept constantly wet from the time it is poured will expand rather slightly, and after a few years will be practically in equilibrium with its surroundings, and will not suffer further change since the pores have become filled with a dense colloid, which prevents water from acting on the unchanged cement. Such concrete will contract at low temperatures at the same rate as cast-iron, but will otherwise be unaffected by freezing, and may be considered a permanent structure. It will be in compression throughout because of the development of the colloid and will, therefore, be strong. The slow development of the colloid of the cement in contact with water explains the decrease in leakage frequently shown by dams and reservoirs after they have been put into service.

Concrete which is allowed to dry soon after it is poured, and which thereafter remains exposed to the air but protected from rain, will be weak because its colloid has been insufficiently developed. Further, it will—if its ends are restrained—be in tension because it shrinks as the colloid becomes dehydrated. Even this concrete will, however, react with the moisture of the air and will probably gain strength in the process, so that concrete used in the interior construction of buildings will probably meet its severest test within the first few months after it is poured. Concrete of this type will nevertheless have a relatively poorly developed colloid and will be porous. If it becomes wet and freezes, it will expand and the expansion may be permanent.

Concrete which is exposed to the weather is put to a very severe test. It expands and contracts when alternately wet and dried, and probably retains this property indefinitely. It has no stable condition, but is always slowly changing. The changes are progressive, especially where the concrete is occasionally kept thoroughly wet for perhaps a month at a time. This period is sufficient to cause the colloid to expand quite fully. At first the only effect is to make the concrete more dense and to fill up the pores. After several years the mass begins to expand as a whole. The particles of gravel are forced apart, and, wedging in their new positions, fail to return when the concrete dries again. The next time the concrete is wet an added quantity of water enters and reacts with still unchanged cement, with the result th[illegible] is larger expansion. This progressive elongation is the cause of the pressure ridges and upheavals found frequently in old cement sidewalks. It has been shown in this paper that sidewalks after 20 years' service still possess this capacity for further progressive expansion. This phenomena is, of course, more serious in damp climates than in dry ones, and in moist locations than those which are well drained. The author has seen cement sidewalks in exceptionally well-drained situations which showed very little signs of deterioration after 20 years of service.

When concrete dries the surface dries relatively rapidly and the shrinkage is considerable, especially if it is rich in cement. This shrinkage of the surface while the rest of the structure is still wet and expanded causes hair-cracks to appear on the surface, even when the unit is small and entirely unrestrained. Each subsequent expansion and contraction will cause this hair-crack to deepen. The disintegrating effect will undoubtedly be accentuated by impacts such as concrete highways receive from traffic.

The changes of volume due to moisture are more apparent with mixtures rich in cement than with lean mixtures. In sidewalks and pavements it would, therefore, be expected that the rich top coat would expand and contract to the greater extent. This is frequently the case, and its results may be seen in sidewalks where the top has split off the base, due to differential expansion. However, the rich mixture with its greater tensile strength tends to contract to its original length more perfectly than the mixture with less cement and more gravel, and in pavements and sidewalks the leaner base is buried in the ground, where it remains wet for a longer period. Under proper conditions, therefore, the base may ultimately expand more than the top coat and give the concave effect to a walk or pavement which is not infrequently observed.

Frost is not much to be feared as an initial instrument of disintegration of properly mixed cement which has been given a fair chance to develop its colloid, since the amount of liquid water in the pores of the concrete is too small to cause serious expansion. If disintegration has started from other causes, water may enter in larger quantities, and on freezing may cause serious injury.

If concrete, and particularly rich concrete, is to remain exposed to the weather, the only way to keep it in good condition is to so place it or protect it so that it will not be subject to great fluctuations in its moisture content. The most trying conditions are those which concrete highways have to meet. As pavements are now being laid, they seem certain in many localities to prove a serious disappointment to those who are building them with the expectation that they will be permanent structures.

MONTREAL TRAMWAYS' GOOD REPORT

A good report has been presented to the shareholders of the Montreal Tramways Company, it having earned over 30 per cent. on its stock, while showing substantial increases both in gross and net earnings. For the year ended June 30th, the gross earnings showed a gain of $388,577, or 5.7 per cent., and the net earnings an increase of $215,127, or 7.9 per cent.

The following table compares the chief items of the reports of the two years:—

	1914.	1913.
Gross earnings	$7,142,804	$6,754,227
Expenses	4,206,114	4,032,664
Net earnings	$2,936,689	$2,721,562
Less—		
City's percentage of earnings	527,383	489,079
Bond interest	787,768	721,151
Debenture interest	800,000	800,000
Taxes	84,700	73,000
Leaving—		
Net income	$ 736,836	$ 638,331
Dividends	242,056	156,382
Surplus	$ 494,780	$ 481,949
Reserves	275,000	223,670
Bond discount	82,236	63,714
Net surplus	$ 137,543	$ 194,564

The company's net income was $736,836 for the year, after payment of the city's percentage of earnings. Interest charges and taxes were $98,505, or 15.3 per cent. higher than the previous year. On the average paid-up capital stock for the year this represented earnings at the rate of 30.4 per cent. After dividends had been paid, a surplus balance of $494,780 remained, or $12,831 more than the previous year. From this balance $275,000 was transferred to reserve funds and $82,236 was applied to write off discount on bonds sold.

The balance sheet reveals an advance in current liabilities from $1,475,995 to $1,646,238, with a decline in current assets from $3,725,925 to $1,893,482. This is explained by the fact that new construction was undertaken last year to the extent of about $1,000,000 more than was originally intended, while in the previous year the company had a large sum credited to its account with its bankers against the projected sale of bonds covering plant additions. As expenditures have now been to an amount in excess of $1,000,000 for which the company has the right to issue bonds or stock, the liquid position can be strengthened by the sale of securities at any time.

The company reports that during the year the sum of $2,711,572 was expended on new construction, against $976,008 the previous year; the sum of $829,706 was also expended on maintenance and charged to operating expenses while a further amount of $417,124, charged to renewal account also went towards the upkeep of the properties.

A SWISS REINFORCED CONCRETE ARCH BRIDGE.

An arch bridge which shows the fine architectural possibilities of reinforced concrete is in course of erection near Langwies, Switzerland, for carrying a metre-gauge electric railway over a valley. The general elevation of one-half of the bridge is shown in Fig. 1, the dimensions being in metres. The main arch is 100 m. (328 ft.) in span between the centres of the rib at the springings, and it was only after a considerable amount of discussion that the Swiss Railway Department allowed the use of reinforced concrete for a span of this magnitude; the rise is 42 m. (138 ft.), and on each side of the main span there are four spans of 16 m. (52 ft.) The arch was designed as an elastic hingeless arch, the platform girders approach spans being treated as continuous beams, expansion joints being provided at the top of the double pillars. The central span comprises two separate arched rings, the thickness of which is about 7 ft. at the crown. The width of either rib at the top of the crown is 3¼ ft., and being battered lengthwise it increases regularly from crown to springing. The two arched rings are tied together by means of rigid cross-beams.

The main girders of the outer spans are constructed in the form of beams with a varying moment of inertia, and are connected with their supports in such a manner that a certain amount of movement is possible. The bearing-plates at the points of support of the pillars of the outer spans have been reduced to a narrow margin of area, with the view of ensuring a hinge effect.

The construction of the viaduct has been designed from the point of view of ensuring a maximum saving of material and a minimum as regards actual stresses. This was rendered more possible owing to the live load on the bridge being a comparatively light one in proportion to its dead weight. This also explains the application of two cross-tied arched ribs instead of a monolithic ring, although the latter form has also been carefully taken into consideration. The stress calculation of the viaduct has been based on the assumption of a test-load train that comprises two locomotives of 65 tons service weight each (the type of the Rhaetic Railways), and an unlimited number of adjoining goods trucks that are coupled in one direction. With regard to the stress calculation of the secondary girders, viz., the railroad deck and the minor spans, an addition to the above live load of 15 per cent. has been considered. The additional forces that have been taken into account comprise:—

(1) A temperature change of + 15 deg. (Centigrade).
(2) Contraction due to setting — 20 deg.
(3) Braking forces—one-seventh of the total weight of the loading train-axles.
(4) Wind pressure: (a) 20 lbs. per sq. ft. when the bridge is in super-loaded condition; (b) 30 lbs. per sq. ft. when the bridge is in unloaded condition.

The modulus of elasticity has been assumed: $m = 15$.

The safe maximal compressive stress of concrete:

c = 500 lbs. per sq. in.,

providing the dead weight of the bridge is combined with the most unfavorable superload (live load);

c = 640 lbs. per sq. in.,

providing all the secondary and additional forces are taken into account, i.e., temperature, contracting due to setting, braking-forces and wind pressure.

The safe shearing stress of concrete is assumed: s = 60 lbs. per sq. in.

Safe tensile stress of steel for reinforcement: t = 14,200 lbs. per sq. in.,

provided the dead weight of the bridge is combined with the most unfavorable super-load (live load);

$t = 17{,}000$ lbs. per sq. in.,

provided all the secondary and additional forces are taken into account.

The above figures are based upon the assumption that the concrete (that is mixed on the spot and is daily controlled and tested by a Martens' set of registering apparatus) shows the following minimum standard strength after 28 days of setting time:—

2,880 lbs. per sq. in.

when being rammed on the spot in a plastic condition (poured concrete);

3,550 lbs. per sq. in.

when being rammed on the spot in a moist condition.

The peculiar arch-centring is interesting. The upper part of the falsework has been constructed in the form of a fan built up with round timbers obtainable on the spot in great lengths, at a low price and of good quality. This timber scaffolding is supported by three reinforced concrete towers which have been constructed in the form of framework or skeleton towers. These reinforced concrete towers were employed for the following reasons: it was not advisable to obstruct the valley too much by the falsework, as the scaffolding is exposed to danger from floods, and is thus liable to damage at times when the snow melts and the two mountain brooks, which join just on the building site, carry down enormous masses of water and pebbles. For this very reason the erection of a scaffolding composed of uprights was out of the question, and the tower system only was suitable. Timber-work towers would have obstructed the passage more than reinforced concrete towers, and furthermore they would not have possessed the same amount of stability. The substructure and the foundations would in any case have required the use of reinforced concrete, even if timber-work towers had been erected, as the driving of wooden piles was absolutely impossible on account of the nature of the subsoil, which is composed of coarse pebbles and is intermixed with loose blocks.

The total settlement of the main arch had to be reduced to a minimum, and this also was another reason for using reinforced concrete for these towers. When the central arch was closed the arch centring showed a total settlement of, roughly, 1.2 inches, inclusive of .4 inches which occurred through the headpieces of the diagonal struts cutting into the capping-pieces of the stringers.

The erection of the viaduct was begun late in 1912, but at the commencement of the work operations had to be confined to foundations of the abutments, winter setting in before time and causing an interruption of the work for several months. Not before April, 1913, could the work be resumed, and the concrete work of the large arch was completed on October 6th, in 1913. The winter, of course, again interrupted the work, but it was continued this season.

We are indebted to Concrete and Constructional Engineering for the above illustration and particulars.

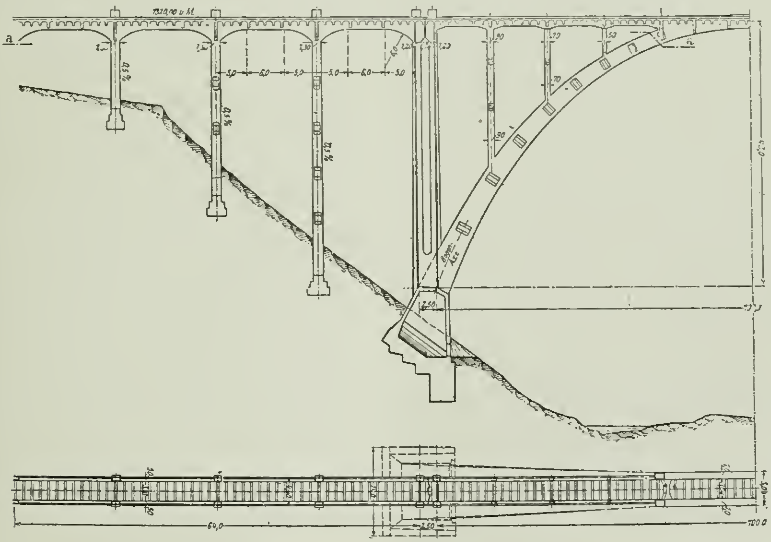


Fig. 1.

Recently the Society of Road Standardization of America sent out from Chicago its first survey in the interest of standardized roads. The road experts engaged upon this initial trip are G. E. Minor, formerly connected with the Old Trails Association, the National Highways Association, and the Indiana Good Roads Association, and H. W. Denis. Their route will proceed through seven states from Chicago to the Pacific coast, the termination of which is to be San Diego, Cal. The primal purpose of the survey is to lay out, map, and log 60,000 miles of the best and most travelled roads in the United States so as to bring to a maximum simplicity the matter of following roads to the destination desired. The society is formed by men interested in the subject of good roads in general and transcontinental highways in particular.

On July 19, the largest electric lamp in the world was lighted and will continue to shed light for some weeks in the New York navy yard. This lamp is a searchlight which has just been installed and is capable of throwing light for a distance of 100 miles. It is called the Beck searchlight, and is the invention of Heinrich Beck, a German scientist, who is conducting tests of his lamp for the United States Government. Measured at 2 miles from the lamp, 450,000,000 candle-power is obtained from a lamp with a 44-inch reflector. The present 44-inch lamp in use on the world's best ships, gives only 60,000,000 candle-power. For coast defence a 60-inch reflector is now in use. Such a reflector hitched to the Beck searchlight gives a billion candle-power, as against 180,000,000 candle-power now obtained.

POLLUTION OF BOUNDARY WATERS.

THE following conclusions relating to water purification and sewage treatment have been arrived at as the result of a conference of consulting sanitary engineers, held at the request of the International Joint Commission in connection with its investigation of the pollution of boundary waters between Canada and the United States. Messrs. George W. Fuller, Earle B. Phelps, George C. Whipple, F. A. Dallyn, W. S. Lea and T. J. Lafreniere are the engineers who participated in the conference, the first three being in practice in the United States, and the second three in Canada. They were submitted a list of questions by the Commission.

The resulting discussion is summed up in the following résumé, which was signed by all except Mr. Dallyn:—

1. Speaking generally, water supplies taken from streams and lakes which receive the drainage of agricultural and grazing lands, rural communities, and unsewered towns are unsafe for use without purification, but are safe for use if purified.

2. Water supplies taken from streams and lakes into which the sewage of cities and towns is directly discharged are safe for use after purification, provided that the load upon the purifying mechanism is not too great and that a sufficient factor of safety is maintained, and, further, provided that the plant is properly operated.

3. As, in general, the boundary waters in their natural state are relatively clear and contain but little organic matter, the best index of pollution now available for the purpose of ascertaining whether a water-purification plant is overloaded is the number of B. coli per 100 c.c. of water expressed as an annual average and determined from a considerable number of confirmatory tests regularly made throughout the year.

4. While present information does not permit a definite limit of safe loading of a water-purification plant to be established, it is our judgment that this limit is exceeded if the annual average number of B. coli in the water delivered to the plant is higher than about 500 per 100 c.c., or if in 0.1 c.c. samples of the water B. coli is found 50 per cent. of the time. With such a limit the number of B. coli would be less than the figure given during a part of the year and would be exceeded during some periods.

5. In waterways where some pollution is inevitable and where the ratio of the volume of water to the volume of sewage is so large that no local nuisance can result, it is our judgment that the method of sewage disposal by dilution represents a natural resource, and that the utilization of this resource is justifiable for economic reasons, provided that an unreasonable burden or responsibility is not placed upon any water-purification plant, and that no menace to the public health is occasioned thereby.

6. While realizing that in certain cases the discharge of crude sewage into the boundary waters may be without danger, it is our judgment that effective sanitary administration requires the adoption of the general policy that no untreated sewage from cities or towns shall be discharged into the boundary waters.

7. The nature of the sewage treatment required should vary according to the local conditions, each community being permitted to take advantage of its situation with respect to local conditions and its remoteness from other communities, with the intent that the cost of sewage treatment may be kept reasonably low.

8. In general, the simplest allowable method of sewage treatment, such as would be suitable for small communities remote from other communities, should be the removal of the larger suspended solids by screening through a ¼-in. mesh or by sedimentation.

9. In general, no more elaborate method of sewage treatment should be required than the removal of the suspended solids by fire screening or by sedimentation, or both, followed by chemical disinfection or sterilization of the clarified sewage. Except in the case of some of the smaller streams on the boundary, it is our judgment that such oxidizing processes as intermittent sand filtration, and treatment by sprinkling filters, contact beds, and the like, are unnecessary, inasmuch as ample dilution in the lakes and large streams will provide sufficient oxygen for the ultimate destruction of the organic matter.

10. Disinfection or sterilization of the sewage of a community should be required wherever there is danger of the boundary waters being so polluted that the load on any water-purification plant becomes greater than the limit above mentioned.

11. It is our opinion that, in general, protection of public water supplies is more economically secured by water purification at the intake than by sewerage purification at the sewer outlet, but that under some conditions both water purification and sewage treatment may be necessary.

12. The bacteriological tests which have been made in large numbers under the direction of the International Joint Commission indicate that in some places the pollution of the boundary waters is such as to be a general menace to the public health should the water be used without purification as sources of public water supply, or should they be used for drinking purposes by persons travelling in boats.

13. It is our judgment that the drinking water used on vessels traversing boundary waters should not be taken indiscriminately from the waters traversed, unless subjected to adequate purification, but should be obtained preferably from safe sources of supply at the terminals.

14. While recognizing that the direct discharge of fecal matter from boats into the boundary waters may often be without danger, yet in the interest of effective sanitary administration it is our judgment that the indiscriminate discharge of unsterilized fecal matter from vessels into the boundary waters should not be permitted.

Mr. Dallyn's revision of the résumé report is not essentially different from the above. He insisted on the elimination of paragraphs 5, 7 and 11, which he considered to be an expression of self-evident facts. He also substituted "monthly" for "yearly" averages in determining the number of B. coli per 100 c.c. of water (clauses 3 and 4).

SHRINKAGE OF ALLOYS.

The excessive shrinkage of brass or bronze alloys necessitates a core which will be crushed readily by the molten metal. Large cores should be made with a soft interior, and this is generally accomplished by filling the interior of the core with cinders, powdered coke, or similar material. The core material must be fine, and this requires the use of finer sands for brass-foundry cores than those usually used in iron foundry work. When a brass casting has been poured and is shaken from the mould, care should be taken to keep the core sand from mixing with the molding sand. The cores for brass and bronze castings are sometimes blown out by shaking out the molds while the castings are still fairly hot, and then dipping the castings in water. The steam generated in the cores blows out the core sand, and gives the castings a better color. Iron castings would be broken by this treatment, but brass castings are rendered softer.—American Machinist

Editorial

THE WAR AND CANADA'S IMPORT TRADE.

The remarkably abrupt quietus which trans-Atlantic commerce received upon the breaking of the war cloud in Europe has been followed by a disturbing indefiniteness as to the duration of the interruption to import trade. In any event, Canadian imports for the year 1914 will be considerably at variance with the uniformly increasing figures for recent years. Last week's announcement of the British naval authorities that the Atlantic routes between England and America were free from danger of molestation by foreign warships is not sufficient assurance for an early resumption of the Atlantic trade other than to and from the British Isles. It is something to be able to send merchandise across safely, but the market conditions at points of destination are considerably more important. Until the war is over and hostilities between the great powers at an end, Canada need not expect that her needs will receive attention, in some European markets at least. Trade with Germany, for instance, is impossible, being stopped completely. In order to continue its present lines of industrial and engineering activity, this country might as well proceed forthwith to look elsewhere for the supplies for which it has been in the habit of paying Germany her good money.

Leaving as unscathed the big bulk of engineering supplies which Canadian manufacturers have provided, and are likely to continue to provide in considerably greater quantities, the remaining needs of national and municipal sustenance and development must be looked after almost entirely by trade with Great Britain and the United States. The latter enjoys over eighty per cent. of Canada's total import trade in engineering supplies. Under present conditions this percentage is likely to increase materially, and Britain's share should undoubtedly do the same. The impression has become prevalent in England during the past week or more that British manufacturers should endeavor at once to secure the overseas' orders which Germany has hitherto had.

The report for the year 1913 of Mr. C. Hamilton Wickes, British Trade Commissioner in Canada and Newfoundland, contains some import statistics that speak for themselves in this respect. The gross receipts of all classes of metal manufactures, machines, machinery, equipment and hardware in 1913 amounted to $198,500,000, an increase of $58,500,000 over 1912. Classifying them and adding percentages, they are as follows, values being given in £:—

(1) Simple Manufactures of Metal.

Source.	Value in £.	Per cent.
United Kingdom	2,410,000	12.7
United States	16,000,000	85.0
Other countries	410,000	2.2

(2) Machines, Machinery and Equipment.

Source.	Value in £.	Per cent.
United Kingdom	1,260,000	8.6
United States	13,160,000	90.3
Other countries	150,000	1.0

(3) Hardware.

Source.	Value in £.	Per cent.
United Kingdom	780,000	12.4
United States	5,160,000	81.8
Other countries	350,000	5.7

Of the gross imports of metals, machinery and hardware, amounting to $198,500,000, those which are classed as "Competitive merchandise" amount to $155,900,000, the United States' share being 83.03 per cent. and Great Britain's, 14.08 per cent.

In connection with this showing, the British Trade Commissioner states: "Only by the share of this trade (Competitive merchandise) which is secured should the efforts of the British manufacturers be judged, and only by these figures should the value of the Dominion market to manufacturers of the United Kingdom be estimated."

With these figures in mind one may venture an opinion as to the effect of the European disturbance upon the general trend of Canadian imports. Evidently the elimination of imports from Continental Europe means an increased demand upon home industries. Second to it, there should be an increased import trade from Great Britain and the United States. For engineering supplies not procurable at home, our cousins to the south will undoubtedly come in for a large share (owing to advantages of easy and rapid access to the market, like currency and similar requirements of customers). British manufacturers will naturally take full advantage of the opportunity now open to supply from her own industries all imports that were hitherto European, and overcome the recognized inconveniences of different standards of manufacture, fluctuation of prices owing to exchange, etc. Obviously, too, better acquaintanceship with the Canadian market and trade conditions will go a long way to minimize the difficulties that one sometimes reads about in the British press. Besides which, the nations which get the business in war time are likely to keep it in peace.

SURGES IN PIPE LINES.

Advancement in the field of hydraulic engineering during the past ten years has been rapid, compared with the history of previous development of this branch of the profession. Turbine efficiencies have been raised from the possible maximum of eighty per cent. to present-day results of ninety-three per cent., or an actual increase of sixteen per cent. in the power which it is possible to derive from any particular development. Runners for a great range of conditions are easily obtained in these times, with specific speeds ranging from ten to one hundred and capacities in single wheels up to almost any horse-power. Hydraulic governors have practically reached the stage of perfection; little more can be asked from the mechanical standpoint for the regulation of water-power plants.

There is one feature of the design of hydro-electric developments, however, that has not progressed with the same rapidity as those just mentioned. We refer to the regulation of the water columns in those plants having long feeder pipe lines and penstocks. For this reason it is with considerable pleasure and satisfaction that we draw the attention of our readers to a treatise on surge tank problems, the first part of which appears in this issue.

Probably the reason for tardy analyses such as this, compared with like investigations in other phases of hydro-electric design, lies in the fact that it is only of recent years that such long penstock lines, with their associated problems, have been installed.

Interest, however, has been aroused to the point of keenness regarding the best method of securing close speed regulation, commercially and economically. A recent discussion in an engineering contemporary, published in the United States, regarding the means used on the Los Angeles aqueduct for regulating the surges due to changes of load on the power plant shows that the methods employed in that instance were far from being economical, at least $200,000 having been spent in excess of what would have been the necessary outlay if another solution to the problem had been applied.

Professor Prasil's work will, therefore, be read with interest and benefit by engineers who have had to do with the design of plants for these conditions. One serious defect in the analysis that will be noted as the discussion continues, is the fact that frictional losses in the pipe or penstock are assumed to vary with the first power of v, instead of 1.8 power or with the square of v, as is actually the case. Evidently the integrations resulting from the use of the correct power have been too difficult for mathematical manipulation and the writer has accordingly been compelled to approximate.

The paper will bear careful study, however, as it throws considerable light upon a most difficult subject, and the translators are to be congratulated upon having put it into shape for readers of English. It is hoped that those who are interested will enter into a discussion of this subject, for as yet far too little is known, or has been published, dealing with the most efficient and proper means of handling the inertia of long water columns.

STEEL CASTINGS FOR THE QUEBEC BRIDGE.

Sixteen grillage castings for the new Quebec Bridge have just been completed. They are worthy of note because they are much larger than any steel castings previously made in Canada. The weight of each is about 43 tons. Each is 21 ft. x 6 ft., 8 in. x 4 ft. in dimensions. Owing to the intricate design of the interior of these castings necessitating a large number of cores the making of the moulds required a high degree of skill and accuracy. The material used in them is a high grade of steel, being scrap metal procured from the wreck of the old Quebec Bridge.

Upon their arrival at the bridge site they will be bolted in pairs, two pairs to each concrete pier carrying the main columns of the bridge.

COMMISSION GOVERNMENT AT EDMONTON.

Following are a number of the clauses adopted by Edmonton as a part of their new commission form of government charter:—

1. That by a two-thirds vote of the electors the charter may be amended without reference to the legislature; except in matters affecting franchises and the borrowing powers of the city.
2. That the commission council shall consist of five commissioners elected at large.
3. That commissioners shall be elected to duties, so that there will be elections to fill the office of commissioner of finance, commissioner of public works, commissioner of utilities, commissioner of safety and health, and commissioner of parks and markets.
4. Commissioners shall be elected for four-year terms.
5. There will no longer be any election for mayor, the commissioners after each annual election selecting their chairman, who is to be called "mayor" from among their own number.
6. Anyone who is qualified to be a candidate for commissioner who is a British subject, is 21 years of age and can read and write English. Commissioners at the time of their election do not have to be residents of the city.

JAPAN'S OIL DISCOVERY.

Not long ago a great flow of oil gushed suddenly from the Kurokawa oil wells in Japan, and has since shown no sign of diminishing in flow. It is not only of such magnitude that it is producing more than twice the volume of all the other wells combined in that empire, but also of great moment in the history of the oil industry the world over, since the oil flow is simply a steady flow, unattended by the pressure, difficult of control, which has always been experienced in similar cases.

A report was made recently by K. Ito, superintendent of the investigation department of the Nippon Oil Company, under which firm the development of the well is being carried out. The company commenced work on the well early in April, and, after drilling through ordinary earth and rock to a depth of some 1,110 feet, a strata, known as the "shell," was encountered at midnight of May 25th. The drill pierced through this shell or crust at a depth of 1,368 feet into what is apparently the lead-bed of an extraordinary deposit. It is from this bed that comes the present flow.

Not only is the manner of the flow from this well most unprecedented, but what is more unusual is the fact that the other five wells of the company located in the same district, which previously required suction pumping, have also commenced a steady, easy flow.

The output was, at first, somewhat difficult to handle, as no provision had been made for such an unusual quantity. A sump at the top of the hill, which had been constructed to receive the flow, was soon filled, and the overflow was conducted down into upper-level paddy fields, where a dyke was quickly erected around the outside of several cho, thus forming a very large sump. This, in turn, was soon filled, and the overflow was again conducted down into the valley below, where another large sump was hastily constructed, enclosing several paddy fields. Four or five other sumps are now being constructed on this lower level, into which the flow will be directed.

The new well has been capped with a four-way head, which has reduced the output from 480,000 to 120,000 gallons per day, and when the sumps now under construction are completed and filled, the flow will again be reduced. The other five wells have had to be checked entirely owing to want of labor to control them.

The company will find no difficulty in utilizing its output to the best advantage. The imperial navy, as well as the imperial railways, are in need of oil for fuel, and this discovery fills a long-felt want. It is the intention of the company to dispose of the greater part of the production in the crude state, refining only that quantity which may be conveniently handled by its refineries at Tsuchizaki.

Of course, where oil is concerned, no definite or positive idea as to the extent of the lead-bed can be ascertained. But American experts, who were engaged by the company to assist the superintendent of the company's investigation department in his examination and tests, are of the opinion that the flow comes from a bed of lead-sand, and will continue for an unlimited length of time.

Trinidad asphalt mastic has been found to be a satisfactory material for lining concrete tanks which are subjected to the action of sulphuric acid. Many other materials were tried, according to the Engineering and Mining Journal, but none were found suitable except the asphalt mastic, which showed no deterioration after a year's test.

Coast to Coast

Mildmay, Ont.—Recently, at Mildmay, the Mildmay Electric Co., Limited, celebrated the inauguration of its new electric power installation in the town.

Sidney, B.C.—At the new industry which has been installed by the Sidney Rubber Roofing Co, Limited, tanks for fuel oil which have the largest capacity of any north of San Francisco, have been installed.

Stratford, Ont.—The new hydro-electric street lighting system was completed and tested in Stratford on July 31. The lamps are strong nitrogen-filled ones and have been pronounced very satisfactory.

Toronto, Ont.—It is stated that it is understood that the Toronto Hydro-Electric Commission will shortly announce its concurrence with the plans of the Ontario Commission and reduce its rates in accordance with the scale suggested by the superior body.

St. John, N.B.—On August 10, the new cable for carrying the telephone business between the eastern and western sides of the harbor was laid. The cable is of special construction, doubly protected in order to ensure its safety on a rough bottom swept by strong currents. It is 3 inches in diameter, 2,100 feet in length and weighs 32,572 pounds. Sixty pairs of 19 gauge wires are carried in the cable, these being entirely for trunk line use between the two exchanges.

Athabasca, Alta.—Of the 258 miles of length of telegraph line between Athabasca and Fort McMurray, upon which, it is reported, work has recommenced, 118 miles were completed last year as far as Duncan's Creek. It is not expected that the work will be completed as far as Fort McMurray this year. Offices will be opened as the line is constructed at Pelican and House River; and operators will be placed in charge at these points. A telegraphic line will also be constructed from Athabasca to Lac la Biche.

Belleville, Ont.—At present, Mr. John Elliott, president of the Belleville board of trade, is chief of a party consisting of other past presidents of the city's board of trade accompanied by an engineer, which is in England examining into the merits of various road-surfacing materials and investigating roads laid therewith. Mr. Elliott is reported to have stated that he is particularly impressed with the Morland-Hughes system of road construction, as shown on the Upper Richmond Road and Putney Heath North, Borough of Wandsworth, and is prepared to recommend the system for Canada.

Victoria, B.C.—On the Pandora Street paving and double-tracking at Victoria, B.C., good progress is reported, and the work is rapidly nearing completion. The street is being paved by sections, and while none of the work is absolutely complete and ready for traffic, the first coating has been laid and is ready for the asphalt in many places. The double-tracking has now been laid over the entire length, with but a few gaps where there has been delay owing to the cement work; and the line will be ready for regular car traffic as soon as the concrete is laid.

Port Arthur, Ont.—The net three months' profit from the operation of the Hydro-Electric Commission of Port Arthur has been reported to the city council of Port Arthur as $12,-803. Details announced for the operation of the system for the last three months state that the gross profits from operating amount to $23,732 from which is deducted the fixed charges representing interest, sinking fund and annual instalments amounting in all to $10,928. The actual revenue which has been gathered by the city official during the period is $43,933, and the operating expenditure for the period was $20,201.

Victoria, B.C.—The E. and N. Railway Company has inaugurated and has commenced service upon 44½ miles of roadbed in British Columbia extending between Parksville and Courtenay. The distance between Victoria and the present northern terminus is 140 miles, and it takes 7 hours to complete the journey. The roadbed is declared to be a permanent form of construction. The steel used is heavy; and concrete and steel trestles span all streams and rivers where bridge construction could not be avoided. There are now over 200 miles of railway in the E. and N. system, a great part of which has been installed since the C.P.R. took over its control some 5 or 6 years ago.

Calgary, Alta.—Manager Director A. W. Dingman, of the Calgary Petroleum Products Company, has issued a statement to the effect that any reports specifying in figures the production of the company's No. 1 discovery well are absolutely incorrect. At present a certain attempt is being made to pump the well, but drilling will have to be carried to a greater depth and the pumping apparatus put in shape before anything concerning the actual production of the well can be ascertained. The company has considerable oil in the first 12,000 gallon tank and a good deal also in the second 12,000 gallon tank, but it is impossible to measure the production of the well yet. However, it is nothing like 250 barrels a day under present conditions. Mr. Dingman said that the drill at No. 2 well of the company has now entered a hard formation and drilling is found to be a little more difficult. This well is 1,560 feet deep.

Montreal, Que.—The new Marconi stations to be constructed by the Dominion Government at Montreal and Quebec, and relative to which it has been stated that plans for the Montreal station are practically completed, will be of the standard 5½ k.w. type. The Montreal station will be equipped for communication with the Kingston and Quebec stations. The apparatus at the present station in Montreal sends messages generally only as far as the Three Rivers station 70 miles away, although it sometimes communicates with vessels more than twice that distance. The Government will build the new stations which will be operated by the Marconi Wireless Company of Canada. The erection of the Montreal and Quebec stations will give the Marconi Company a string of wires capable of communicating, without interruption, from the head of the lakes as far east as Cape Race and Belle Isle. It is not now expected that either station will be constructed previous to next spring, or until the war situation will have cleared.

Nanaimo, B.C.—Messrs. Walter Thomas and A. E. Mainwaring of Nanaimo, B.C., are the joint patentees of a process by means of which gas may be produced in enormous quantities and at a greatly reduced cost. The inventors have in mind an ambitious scheme for the supply of cheap gas for fuel and light for the whole southern end of Vancouver Island; and their expectations are apparently justified by the results of the process as demonstrated in the experimental plant at Nanaimo. The commercial scheme would involve the conveying of gas through suitable mains through great distances as is done already in California, Portland, Tacoma, and Seattle. It is calculated that the installation of a suitable plant for manufacture under the Thomas patents, and conveyance through pipe lines to a sufficiently large number of consumers would place the whole south end of Vancouver Island on a natural gas basis, the estimated charge of fuel and consumers' gas being 50 cents per 1,000 feet. The project, if carried out, will involve the manufacture and distribution of not less than 1,000,000 feet of gas per day.

Hudson Bay, Ont.—Included in the programme of work under way this year at Hudson Bay and Strait and being effected by the Marine and Naval Departments of the Dominion Government, is the locating of 3 wireless stations in

the strait and at the entrance to the bay, so as to give a continuous line of communication from Port Nelson and Port Churchill to the Atlantic; but the construction of these will not commence until next year. The charting of Hudson's Strait is also being done by the steamer Acadia, while other Government vessels are taking soundings and mapping the harbors at Port Nelson, Fort Churchill, and at the mouth of the Nottaway River. Two lighthouses are to be commenced this year, one on each side of the entrance to Port Nelson, while another one will be built on a newly-charted shoal some miles out in the bay. The charting being done at the mouth of the Nottaway River is preparatory to the construction of the proposed railway from there south-east to the National Transcontinental, in connection with the alternative route from Port Nelson across the northern end of James Bay and thence by rail to Montreal, for which last season an appropriation of $1,000,000 was passed by the Government for preliminary surveys.

Edmonton, Alta.—The city commissioners of Edmonton have decided to allow the firm of Sanderson and Porter of New York, and all other concerns intending to submit offers for furnishing power to the city, four weeks from July 21 in which to prepare and submit these, which shall include in the unit prices given the operation and maintenance by the tenderers of the present steam plant as a stand-by plant, the city to retain ownership of the same. To such prices must be added the annual interest and sinking fund incident to the investment of the plant. Also, all firms must submit a statement of financial backing, a certificate or title of lease of the waters and poundage rights, plans, profiles, level covering, the development contemplated, the head proposed to be developed, length of study of the proposed development, and the name of the engineers who will carry out the work; the city to audit all accounts of construction, from the inception to completion; the company to agree not to capitalize by bonds, stock, or otherwise in excess of the actual construction costs; the city to participate in all profits annually over 8 per cent., and the city to have the right to audit all operating accounts as well as to be given power to decide other questions which the commissioner of operation considers imperative in protecting the city's business.

Victoria, B.C.—A report on last month's operations at the Ogden Point breakwater states that such remarkable progress has been witnessed that the foundations of the breakwater were in view at extreme low tide inshore and everthing was in readiness for the commencement of the concrete structure, which will be a huge reinforced wall stretching far out into the harbor. The official statistics for the month of July show that no less than 361,131 tons of rubble were dumped on the site of the breakwater. The actual figures are as follows: core, 22,545 tons; rubble, 338,586 tons. The total rock dumped during the last three weeks of the month exceeded the record month of last year. A grand total of 1,604 tons of granite blocks were also laid by divers during the month just closed. At the present time the operations of the divers are confined to the shore end of the breakwater, where huge granite blocks, weighing anything from 5 to 15 tons each, are being laid in courses; and as the rubble farther out is brought up to the desired level, these courses will be continued seawards. Good progress is also being made in dumping rock at the site of the new piers under construction by Grant Smith and McDonnell. Throughout July a total of 13,332 tons of rubble were deposited; and much faster progress will be maintained now that everything is complete for the shipment of rock from the new quarry at Esquimalt.

Ottawa, Ont.—Tests made recently by the city bacteriologist of Ottawa, Mr. Jos. Race, show that Ottawa River water is four times superior to Ottawa well water in purity. The tests have been made to ascertain whether the supply of water from the river is reasonably safe for drinking and domestic purposes. Mr. Race concludes his report by sanctioning its use as such. Discussion of the report which has been furnished by R. L. Haycock, acting waterworks engineer, to the waterworks committee, on the same question was adjourned until next week when the committee will also make a report to the city council. In the meantime, Mr. John McRae, civil engineer of Ottawa, will co-operate with Mr. Haycock in preparing estimates of the costs of a number of changes which Mr. Haycock suggests in his report. One of the most radical changes proposed is the removal before winter of the concrete beams supporting the intake pipe recently relaid, which, in the opinion of the acting waterworks engineer, will increase the accumulation of ice and frazil and endanger the safety of the intake pipe. An estimate will be made also on the cost of installing an auxiliary electrical pump at the Queen Street West station for use in case one of the hydraulic set of pumps should break down. Further, estimates will be made on the costs of the projects to connect to the 40 and 42-inch intake pipes and to join the two aqueducts at the pumphouse.

Medicine Hat, Alta.—About one-half of the great irrigation canal which has been under construction by the Southern Alberta Land Company for the past 5 years at an expenditure of close to $5,000,000, has been sufficiently completed to hold water; and about two weeks ago water was allowed to flow into Lake McGregor. The entire undertaking is so well advanced that only about $250,000 will now be necessary to complete the system. The work of constructing the canal begins about 22 miles southwest of Gleichen, where a big dam of cement work has been constructed across the Bow River and forms the intake of the canal. From there it continues about 30 miles to Lake McGregor. This lake is about 22 miles long, is formed by the construction of two huge earth dams across what is known as Snake Valley, and is about 40 feet high at the north end and 30 feet at the south; while in places it will be about 2 miles wide. It is estimated that from 3 to 4 months will be required to fill this area for the requirements of the immediate future. From the lake, the canal continues south and east along the Little Bow River, the entire length of the channel being in the neighborhood of 180 miles. The major portion of the work on the east end is now nearing completion, but it is not probable that it will be in readiness to turn into the lower canal until some time next spring. In the construction of this canal there have been some most difficult engineering problems; and some of the heaviest of the work has had to be replaced.

Esquimalt, B.C.—It is expected that an early date will see the completed establishment of the Esquimalt sewerage system. About $60,000 has so far been expended. The municipality was divided into two sections—B and D—for the present sewerage work. Section B empties into the northwestern main, which is the Victoria main outflowing at Macaulay Point. D section enters the sea at the foot of Grafton Street. The contractors for the B section, Messrs. Agnew and Young, had 9 miles of pipe to install, of which they have laid 4½ miles. Most of the light work has been done; and when the rock boring and more difficult excavating for the tunnel through the Macaulay Rocks has been completed—which work is expected to take about 2 months' time—sewer connection will be established for householders through the local sewers with the northwest sewer. City Engineer Rust states that the rock excavation work is proceeding very satisfactorily, and that up to the present the cost has been somewhat less than the estimate. In D section 2 miles of pipe had to be laid, of which 1½ to 1¾ have been

finished. This work will be complete in little over a month. There will for the present be more connection with the D main than with the B section. At the foot of the streets being connected with D section, a rock formation extends along the shore; and here blasting and stone crushing is being carried on, rapid progress being made. On most of the streets the sewer trenches have been filled in, every street in the district having been excavated. Two strong concrete embankments have been built at the foot of the streets leading to the water. The contract will probably be let very shortly for the laying of the pipes in the Esquimalt village section. This section will cover the whole west end of the municipality not drained by the other sections.

PERSONAL.

D. H. MARTIN has been appointed chief engineer for Jas. Corbett and Sons, Limited, who have one of the subcontracts for Section 5 of the Welland Ship Canal.

FRANK C. ASKWITH is provisionally in charge of roads and bridges for the city of Ottawa, since the resignation of Mr. Arch. Currie. R. L. HAYCOCK has been placed provisionally in charge of the waterworks and sewerage department, succeeding Mr. A. N. Beer, resigned.

A.S.T.M. EXECUTIVE.

The officers of the American Society for Testing Materials for the year 1914-15 are:—President, A. W. Gibbs; vice-president, A. A. Stevenson; secretary-treasurer, Edgar Marburg; council, Robt. Job, F. W. Kelley, A. Marston and S. S. Voorhees.

CANADIAN FORESTRY CONVENTION POSTPONED.

Owing to the war the president and directors of the Canadian Forestry Association have, after the most careful consideration, decided to cancel the arrangements for the forestry convention which was to be held in Halifax, September 1st to 4th, 1914, and to postpone the convention indefinitely. Whatever it is decided to do in the future, due notice will be given thereof to the members and all others concerned. Attention is particularly directed to the fact that all railway arrangements as published have been cancelled, and that anyone going to Halifax within the stated dates will have to pay full fare back to starting point. All persons receiving notice are requested to make it known to any others who they know were preparing to go to Halifax.

OBITUARY.

The death is reported of Mr. H. W. Anthes, managing director and secretary-treasurer of the Anthes Foundry, Limited, of Toronto and Winnipeg. Mr. Anthes was in his sixty-fourth year.

HARDNESS OF WOODS.

Woods are going rapidly out of fashion in railroad car construction, when only a few brief years ago they formed the entire structure of cars.

The relative hardness of woods is calculated from hickory which is the toughest and hardest wood in popular use. Estimating hickory at 100, we get for white oak, 84; white ash, 77; dog wood, 74; scrub oak, 73; white hazel, 72; apple, 70; red oak, 69; white birch, 65; black walnut, 65; black birch, 62; yellow and black oak, 60; hard maple, 56; white elm, 58; cedar, 56; cherry, 55; yellow pine, 53; chestnut, 52; yellow poplar, 51.

COAL EXPORTS FROM GREAT BRITAIN.

The total amount of coal exported from Great Britain in 1913 exceeded that of 1912 by ten million tons. Cardiff topped the list as usual, according to a consular report. From the Manchester ship canal the export amounted to about 1,100,000 tons, but these figures are insignificant when the facilities for shipment are taken into account. The quay space at Partington coal basin occupies 20 acres and there are 22 miles of railway sidings. Six tips are in use fitted with hydraulic machinery and each tip has a capacity of 300 tons per hour. Manchester is the nearest point of shipment for the Lancashire, Derbyshire and Staffordshire collieries.

EFFECT OF SODIUM HYDROXIDE ON IRON.

In a paper by J. H. Andrew in the Transactions for March, 1914, of the Faraday Society, it is stated that wrought iron corrodes slowly, becomes highly crystalline, and eventually brittle by immersion in a concentrated aqueous solution of sodium hydroxide at 100° C. for several months. The corrosion is attributed to electrolytic action between the two phases, crystalline and amorphous, of which the metal is constituted, iron going into solution at the anode (forming sodium ferrite), hydrogen being liberated at the cathode. Part of the hydrogen is occluded by the metal, being first absorbed by the amorphous constituent, thereby forcing the crystals apart, and ultimately causing the iron to become crystalline and brittle. The brittleness decreases with time, an equilibrium being finally established between the metal and the gas, and is due rather to the molecular rearrangement induced by mere occlusion or evolution of hydrogen than to the mere presence of the latter in solution. The potential difference between the amorphous and crystalline phases and hence the rate of corrosion decrease as the latter phase becomes hydrogenized, the passivity of iron produced by immersion in caustic soda being due to this cause. Similar results were obtained with electro-deposited iron, but steel containing 0.5 per cent. carbon was much less affected by sodium hydroxide solution. The recrystallization of electro-deposited iron upon cooling through the Ar_3 point is also considered to be due to the evolution of hydrogen.

COMING MEETINGS.

CANADIAN FORESTRY ASSOCIATION.—Annual Convention to be held in Halifax, N.S., September 1st to 4th, 1914. Secretary, James Lawler, Journal Building, Ottawa.

NATIONAL PAVING BRICK MANUFACTURERS' ASSOCIATION.—Secretary, Will P. Blair, 832 B. of L.E. Building, Cleveland, Ohio. Eleventh annual convention and paving conference, Buffalo, N.Y., September 9th, 10th, 11th, 1914.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown, Indianapolis, Ind., Secretary.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—11th Annual Convention; 5th American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau St., New York, N.Y.

ORDERS OF THE RAILWAY COMMISSIONERS OF CANADA

Each week on this page may be found summaries of orders passed by the Board of Railway Commissioners, to date. This will facilitate ready reference and easy filing. Copies of these orders may be secured from *The Canadian Engineer* for small fee.

22294—July 24—Amending Order No. 22160, dated July 8th, 1914, to provide that Henry Ray, Tp. March, Ont., deposit in a chartered bank to credit of Board of Ry. Commrs. for Canada, sum of $500 in lieu of and for purposes of bond required under Order 22160 to be filed with the Company.

22295—July 23—Authorizing C.P.R. to construct spur into premises of International Supply Co., Limited, on Lot F, Medicine Hat, Alberta.

22296—July 27—Directing that C.N.R. construct spur 1,900 ft. long to connect with spur serving Estevan Coal and Brick Co., subject to certain conditions, Ry. Co. to construct and complete spur as soon as Bienfait-Estevan Branch is open.

22297—July 29—Authorizing, until Nov. 30th, 1914, C.N.R. to open for traffic its North Battleford Northwesterly line from Edam, mileage 38, to Turtleford, mileage 57: Provided speed of trains be limited to rate not exceeding 15 miles an hour.

22298—July 31—Authorizing Esquimalt and Nanaimo Ry. to open for traffic, McBride Jct. to Courtenay, Vancouver Island, B.C.; and rescinding Order No. 27546, dated Oct. 13th, 1914.

22299—July 30—Dismissing application G.T.R. for authority to construct, at grade, spur track serving Elias Rogers Co., Coal Dealers, Toronto, Ont., across Toronto, Grey and Bruce Ry. (C.P.R.) at point south of St. Clair Ave., Toronto.

22300—July 28—Authorizing Toronto Eastern Ry. and Oshawa Electric Ry. to operate trains and cars, for period of 6 months from Aug. 6th, 1914, over crossing in Town of Oshawa, Ont., subject to provisions of Section 277 of Railway Act.

22301—July 29—Amending Order No. 22297, dated July 3rd, 1914, by striking out words "Swift Current," in 2nd line of paragraph 2 of operative part of Order, and substituting therefor words "Moose Jaw."

22302—July 27—Directing G.T.P. Ry. to carry out certain conditions for purpose of providing good and sufficient accommodation and facilities at Spruce Grove, Alberta.

22303—July 31—Directing that spur located between King St. and Pembina Bridge, Entwistle, Alta., be removed; that spur for 5 cars be installed east of King St., with trailing point switch toward King St.; G.T.P. Ry. to arrange to handle carload freight for Village of Entwistle and those who require it at that point.

22304—July 31—Authorizing Corporation City of Toronto to reconstruct bridge, partly in City of Toronto and partly in Twp. York, carrying highway over Belt Line of G.T.R.; cost of construction be paid—60 per cent. by Corporation of City of Toronto; 20 per cent. by Twp. York; and 20 per cent. by G.T.R.; cost of maintenance be borne by Corporation of City of Toronto.

General Order, No. 130—July 28—Disallowing schedules of Boston and Maine R.R., C.P.R., Central Vermont, G.T.R., G.T.P. Ry., G.N.R., Maine Central, M.C.R.R., Rutland R.R., N.Y.C. and H.R.R., T., H. and B. Ry., and Wabash Railroad, in so far as their purpose is to increase tolls previously charged for exclusive use of drawing-rooms or compartments in sleeping and parlor cars locally between points both of which are in Canada.

22305—July 31—Authorizing Winnipeg, Selkirk and Lake Winnipeg Ry. to construct and operate its Middlechurch Branch running to Stonewall, across spur of C.P.R. running to stone quarry at Stony Mountain, Man.; if at any future time protection is required at crossing, Applicant company provide same at its own expense.

22306—July 29—Authorizing G.T.P. Saskatchewan Ry. to operate over crossings of C.P.R. Weyburn-Lethbridge and Soo Branches, by its Weyburn Branch, in Sec. 20-8-14, W. 2 M., at Weyburn, Sask, until Oct. 15th, 1914, pending installation of interlocking plant: Provided crossings be protected by flagmen appointed by C.P.R., at expense of G.T.P. Sask. Ry.

22307—July 27—Directing that, within 60 days from date of this Order C.L.O. and W. Ry. install improved type of automatic bell at crossing of Frontenac Road, in Village of Parham, mileage 26.97.

22308—July 29—Authorizing, subject to terms of Indenture of Lease, M.C.R.R. to construct spur for Union Carbide Co. of Canada, Limited, crossing Bain Ave. and Welland Canal Tow Path, Twp. of Crowland, Co. Welland, Ontario.

22309—July 29—Authorizing Alta. Central Ry. to open for traffic its line West of Red Deer, mileage 0.00 to 64.5.

22310—July 31—Authorizing Union Bank of Canada, Moose Jaw Branch, to release and repay to S. A. Hamilton Co., Limited, sum of $1,100 deposited with it to credit of Board, together with accrued bank interest, if any.

22311—July 29—Authorizing Board of Highway Commissioners for Saskatchewan, at own expense, to construct highway over G.T.P. Branch Lines Co.'s Regina Boundary Branch, on Extension of Queen St., Townsite of Colfax, Sask.

22312—July 31—Authorizing G.T.P. Ry. to construct an extension to bridge over Fraser River, mileage 468.4 Prince Rupert East, B.C.

22313—July 30—Authorizing C.N.R. to construct revised line across C.P.R. in S.W. ¼ Sec. 19-40-26, W. 4 M., near Lacombe, Alta., subject to certain conditions.

22314—July 29—Authorizing C.N.R. to operate its trains, temporarily, for construction purposes only, for period of 60 days from date of this Order, pending installation of interlocking plant, over crossing of C.P.R. in Lot 101, Parish of St. Paul, Man.: Provided trains be flagged over crossing by watchmen appointed by C.P.R. at expense of C.N.R.

22315—August 4—Extending the area for the collection and delivery of express freight by Express Companies in the city of Windsor, Ontario, and rescinding Order No. 19533, dated June 9th, 1913.

22316—August 1—Directing that G.T.P. Ry. construct a station, not to be below Standard of No. 1 B.R.C., and a one-pen stock yard at Ribstone, Alta.; work be completed by September 15th, 1914. Ry. Co. stop trains Nos. 1 and 2 on flag signal, at Ribstone, for passengers and express.

22317—July 24—Directing that G.T.R. construct spur into premises of Standard Crushed Stone Co., Limited, near Windmill Point Station, Ontario, subject to certain conditions.

22318—August 1—Extending, until October 31st, 1914, time within which G.T.R. complete subway at Thompson Road, Tp. Bertie, Ont.

22319—July 30—Authorizing C.L.O. & W. Ry. (C.P.R.) to operate its trains across C.N.O.R. in Lot 27, Con. 2, Tp Pickering, until Sept. 15th, 1914, temporarily, pending installation of interlocking plant: Provided crossing be protected by flagmen appointed by C.N.O.R. at expense of C.L.O. & W. Ry.

22320—August 1—Authorizing C.P.R. to construct road diversion in Sec. 34, Tp. 5, and Sec. 3-6-24, W. 3 M.; and construct, by means of grade crossing, its Weyburn-Stirling Branch Line across East and West road allowance between Sec. 34, Tp. 5, and Sec. 3-6-24, W. 3 M., Sask., at mileage 272.7 of said Branch Line.

22321—August 1—Authorizing C.P.R. to construct its Weyburn-Stirling Branch Line across twelve (12) highways, between mileage 65 and mileage 75 (mileage 0 being at Stirling).

Volume 27. Toronto, August 20, 1914 Contents of this issue on page 3

The Canadian Engineer

A weekly paper for engineers and engineering-contractors

BURRARD INLET BRIDGE, VANCOUVER

SOME IMPORTANT DETAILS OF THE PROPOSED DESIGN—TO BE THE LONGEST SWING SPAN IN EXISTENCE—UNFORTUNATE DELAYS IN AWARDING CONTRACT.

THE Corporation of North Vancouver has long been in need of closer connection with the City of Vancouver, from which it is separated by Burrard Inlet. The desired thoroughfare would afford access not only to the railway, but to the business and commercial district of the city. It has only been of recent date, however, that any activity has been commenced. Large increases of traffic, together with the advent into North Vancouver of a branch of the Grand Trunk Pacific, known as the Pacific Great Eastern Railway, has emphasized the importance to both communities of a direct connection. In addition to the access which the proposed bridge will give the Pacific Great Eastern Railway into Vancouver from the North, an electric interurban car line, together with ample driven and pedestrian traffic, is being afforded accommodation in the design under contemplation.

The location that has been chosen is over a section of the Inlet known as the Second Narrows, three miles in distance from the First Narrows, or entrance to the Inlet.

The design itself is for a complete structure to span the Inlet. The approach at the Vancouver side requires considerable embankment and cutting, while on the north side there will be quite a length of trestle work and embankment, chiefly on the railway right-of-way.

The Official Design.—An important feature of the contemplated structure lies in the dimensions of the swing span. The official design was prepared by the English firm of Sir John Wolfe Barry, Lyster and Partners, with whom is associated in Vancouver the firm of Cleveland and Cameron, as consulting engineers to the Board of Directors of the Burrard Inlet Tunnel and Bridge Company.

According to the official design, the length of the swing span will be 581½ ft. between centres of the end bearings. This length exceeds the longest present swing span by 62 ft. In width the structure will be 59½ ft., providing, as stated, for railway, highway, street car and pedestrian traffic accommodation. There will also be two fixed spans 232 ft. in length from centre to centre of bearings. These three Warren type spans; i.e., the single swing and the two fixed spans, approximately cross the entire width of the river at low water, its width at this stage being 1,030 ft. at the proposed site of the bridge. In flood stage, however, it has attained a width of 3,248 ft., the additional flooding occurring for the most part over the north bank of the Inlet. The bridge approach over this low ground consists of a plate girder viaduct, with tower spans of 29 ft. and intermediate spans of 43 ft. 6 in. The highway portion of the approach is 25 ft. 10 in. in width and is carried on vertical posts. The railway portion will rest on posts battered 1:4½. All trestles and posts will be supported by concrete foundations.

The approach to the bridge on the Vancouver side crosses the tracks of the Canadian Pacific Railway by means of two skew bridges, side by side, one to carry the steam traffic of the Pacific Great Eastern Railway and the other the roadway and electric car tracks. The

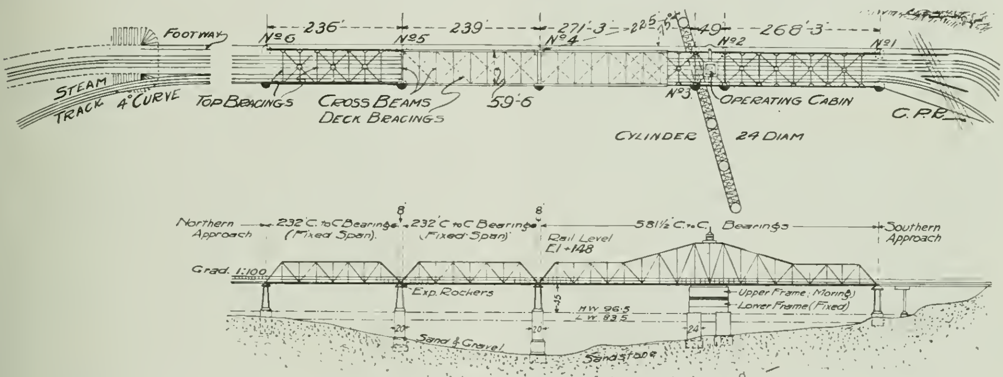

Fig. 1.—Sketch of Plans for the Second Narrows Bridge, Prepared by Sir John Wolfe-Barry, Lyster & Company, England.

railway portion of this span is to be 168 ft. in length and the highway portion will be approximately 108 ft. long. This makes up a total length of 3,449 ft. for the railway section of the bridge and 2,364 ft. for the highway section. The skew bridges are connected with the south end bearing of the swing span of the main bridge by short plate girder spans. They give a clearance of 22½ ft. over the top of rail of the Canadian Pacific Railway line.

The bridge proper will carry between trusses a single railway track on the west side, and a 37½-ft. roadway between curves, including two electric car tracks on its east side. There will be an 8-ft. cantilevered footway outside of the eastern truss for the entire length of the bridge.

The foundation work will be expensive and rather difficult owing to the great depth of water and to somewhat unsatisfactory conditions of the river bed. The depth in the channel is 96½ ft. at ordinary tide stage, with a tide range of 13 ft. The north bank consists of gravel to a depth of 155 ft., overlain with about 5 ft. of silt. The south shore is composed of sandstone rock with a considerable overlay of soft mud. In mid-channel the two strata meet in a bed of gravel and boulders. In addition to the above the tide currents through the Second Narrows have a velocity of approximately 7 knots. Diving operations are rendered difficult owing to the continuation of the bottom flow for a considerable length of time after the turn of the tide.

According to the official design, there will be a clearance of 45 ft. above ordinary spring flood stages. The line of the swing span will afford a minimum depth at low water of 35 ft. under its north arm. At the swing span a clear waterway of 225 ft., measured square to the channel, is provided, as requisitioned by the Department of Railways and Canals of the Dominion government. There is a skew of 15° in the line of the bridge across the channel.

The span is to be supported by four wrought steel cylinders, filled with concrete and resting on piles. They are to be spaced 49 ft., centre to centre, both ways, and braced. The south end bearing will rest on a pair of wrought steel braced columns resting on cylinder piers 59½ ft. apart. The north end bearing will be supported by similar columns on a solid pier, full bridge width. The fender pier, in the plane of the swing span, when open will consist of six cylinder piers 24 ft. in diameter, with bracing and timber fender work between.

The operation of the span, the locking of the bridge, the opening and closing of the gates, as well as the signalling apparatus for river and land traffic, will be electrically controlled. The operating cabin is located above and at the centre of the span.

Delays in Proceeding.—The above plans, prepared by the English firm, provide a design estimated to cost $2,500,000. The Burrard Inlet Tunnel and Bridge Co., finding difficulty in the financing of such a large undertaking, appealed to the Provincial Government to take over the entire project. The latter declined, however, and announced that it was not prepared at that time to subsidize the enterprise to a greater extent than $400,000, previously arranged, and advised the company to build a less expensive structure.

Subsequently, Mr. C. P. Moss, local representative for the Strauss Bascule Bridge Co., submitted plans for a bridge of the Bascule type to the government, which, in turn, recommended them to the company as they involved a cost of approximately $1,500,000. This design had spans of 44 ft., centre to centre of trusses, and provided for two electric railway tracks in addition to the steam railway line, and a 16-ft. roadway. Outside of the truss line an 8-ft. sidewalk was provided on brackets for pedestrian traffic. The required width of 225 ft. in the channel, overhead clearance of 45 ft. between water at high level and under side of the spans over the navigable channel, and a clearance of 22½ ft. over the rails of the Canadian Pacific Railway were all provided for. The design suggested a movable span of the Heel trunnion type, with concrete counterweights. Electrical operation by two 90 h.p. motors, in addition to a 5 h.p. motor to operate locking mechanism, was called for. The time of opening or closing under normal conditions was stated to be 1½ minutes.

Acting upon the advice of the Provincial Government the company called for tenders for a cheaper structure, and a number of plans and specifications were submitted accordingly. Chief of these were the tenders of the Dominion Bridge Co., associated with Armstrong, Morrison & Co.; the Canadian Bridge Co.; and C. A. P. Turner, associated with the Western Foundation Co. These three designs were submitted to Messrs. Cleveland & Cameron, the consulting engineers to the company, for a report. The following is a summary of their findings and conclusions, many points of interest arising therein:—

Tender No. 1.—The design submitted follows the official design as to general outline.

The length of the plate girder spans for the north approach are slightly increased.

The two fixed truss spans are the same length and occupy the same positions.

The clear opening provided by the swing span is the same, but the length between end bearings has been reduced from 581 ft. 6 ins. to 578 ft. 0 ins.

Truss spans have been used for the south approach over the tracks of the Canadian Pacific Railway.

The substructure designs for the north approach substitute pedestals on pile foundations for the cylinder piers of the official design.

The pedestals are carried down to 10 ft. below the ground line for the first three bents, 8 ft. for the following three, and 6 ft. for the remaining bents; they are all carried on piles having a maximum load of about 16 tons per pile, which is good, conservative practice.

The design of the pivot pier differs from that of the official design in consisting of a single 56-ft. diameter cylinder in place of four 24-ft. diameter cylinders, spread at the base to 28 ft. The bearing pressure is about 6 tons per square foot.

The north rest pier, on Pier No. 4, consists of two shafts in place of the solid pier called for in the official design. Sufficient bearing area is provided, but the pier is not so well able to withstand the blow from a heavy vessel. With this exception, we consider the design for the substructure an excellent one.

Wooden caissons are used in place of steel for all piers, and the piers are carried to the maximum height and the steel bents under trusses eliminated.

The superstructure has been designed for the Dominion Government especial heavy loading on the steam railway track, two 40-ton electric cars on each tramway track, and the balance of the floor has been figured for 100 pounds per square foot for the floor system and 60 pounds per square foot for the trusses.

The floor system has not been designed for a concentrated load similar to the heavy motor trucks which it will have to carry.

A unit stress of 18,000 pounds per square inch has been used in the design of the west or railway side truss, and 20,000 pounds per square inch for the east truss. We are of the opinion that since this structure carries railway traffic as well as electric railway these stresses

are too high. The Dominion specifications allow 16,000 pounds per square inch for railway bridges.

The centre chord members of both trusses of the swing span, which receive their maximum stresses while the bridge is swinging, are designed for a unit stress of 20,000 pounds per square inch, due allowance being made for impact as per Clause 186 of the Dominion Government specifications.

The centre girders of the draw are designed for 18,000 pounds per square inch.

The arrangement of the centre and radial girders of the swing span is such as to load the drum at thirty-two points, but these points are not uniformly spaced, thirty of the spaces being about 4 ft. 3 ins., and two of them 15 ft. 0 ins., centre to centre. This gives uneven distribution of the load to the rollers. A portion of the load is carried to the centre pivot and the rollers and the lower track are securely tied to the pivot as required by good practice in draw-bridge designs.

In other particulars the bridge follows the lines of good practice in bridge design.

Tender No. 2.—The design submitted is similar to that of Tender No. 1, except that the swing span is the same length as on the official plans, but the pier design

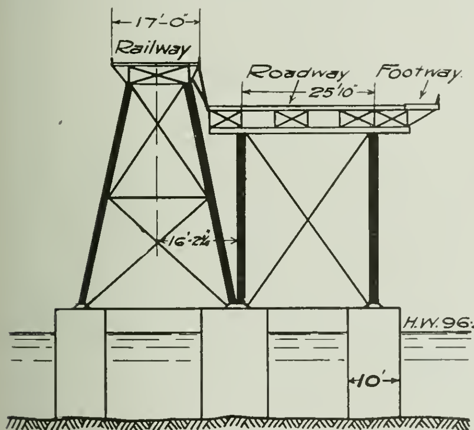

Fig. 2.—Typical Cross-Section of North Approach.

is such as to allow of this length being decreased, still maintaining the same clear opening.

Through plate girders are used in place of trusses for the highway approach over the Canadian Pacific Railway tracks.

The substructure has been designed for Dominion Government heavy loading on the railway track and two 40-ton electric cars on the tramway tracks, the balance of the floor has been figured for 100 pounds per square foot, or a 20-ton traction engine for the floor system, and 60 pounds per square foot for the trusses.

The 20-ton traction engine is practically equivalent to a modern heavy motor truck.

In proportion, the floor beams and truss members, the stresses due to dead load and railway loading have been provided for a unit stress of 16,000 pounds per square inch, tramway loading at 18,000 pounds per square inch, and highway loading at 20,000 pounds per square inch.

The centre chord members of the swing span which receive their maximum stress while the bridge is swinging are designed for a unit stress of 16,000 pounds per square inch. This unit stress has also been used in the design of the centre girders. Due allowance has been made for impact in all cases.

The drum is 42 feet diameter, which is smaller than used on other designs submitted, but the arrangement of the centre and radial girders is such that the rollers are evenly loaded and not overstressed. In this design, as in the design of Tender No. 1, a portion of the load is carried to the centre pivot, which is a desirable condition.

Two 200 horse-power motors are to be supplied for swinging the bridge. This is sufficient for rapid operation, with ample power in case one motor is under repair.

The design follows the lines of accepted good practice in modern bridge construction.

Tender No. 3.—The design follows the lines of accepted good practice in design for the channel crossing from low water to low water. It consists of one 60-ft. and one 80-ft. plate girder span, one 345-ft. truss span and the 586-ft. swing span.

The substitution of the three fixed spans for two, as on the official design, would necessitate a change in the Crown grant already obtained of portions of the bed of the Narrows.

The clearance above high water is not as great under the plate girder spans as for the same location on the official design.

The south approach consists of plate girder spans up to and over the tracks of the Canadian Pacific Railway.

The length of bridge shown on the plans for the south railway approach is about thirty feet short.

The north railway approach consists of a series of deck plate girder spans on reinforced concrete towers without longitudinal bracing. This portion of the approach is 39 ft. shorter, and the top of rail at abutment is 2 ft. 3 ins. higher than called for on the official plan.

Two designs have been submitted for the north highway approach. One of these consists of the mushroom system, or flat slab construction; the other consists of plate girder spans on concrete columns.

The alternative design submitted for the north highway approach consists of a flat, reinforced concrete, continuous slab on reinforced concrete columns on a pile foundation.

We do not consider that this is a good type of construction for this location. The strength of the structure depends upon a total absence of settlement of the supports, which it is practically impossible to get in this location with the details shown. Some of the supporting piles have a load of about 45 tons, or about 20 tons per pile overload.

The length of spans of the mushroom approach and the adjoining railway approach being different, the two lines of piers, about 9 ft. apart, obstruct about 33 per cent. of the waterway.

The plate girder spans of the north railway approach follow the lines of usual practice, but the end stiffener angles of the 60-ft. spans are too light to properly transfer the end shear from the webs to the angles and bearing plates.

No lateral bracing is shown or called for on the drawings, between the bottom flanges of the 60-ft. and 80-ft. deck plate girder spans; these are required by the Dominion specifications.

No longitudinal bracing is provided between the towers to take care of the forces due to traction or suddenly stopping a train. In the drawing presented these forces cause bending in the columns and the pedestals supporting the tower, which gives tension on the one side and excessive load on the piles under the opposite side of the pedestal. These piles, without the load due

to this lateral force, are loaded with over 35 tons each.

Piers No. 0 and No. 1 are not carried as deep as the similar piers of the other two designs, resulting in a large difference in value between the different structures.

Pier No. 2 (north rest pier) consists of two shafts joined by braced side webs. The bid suggests filling the space between these webs with a lean concrete at an extra cost of $7,000. This would enable the pier to withstand a heavier blow from a colliding vessel.

The pivot pier consists of a reinforced concrete cap supported by four cylinders, each 22 ft. in diameter. The bearing area is considerably less than provided by the other designs and the pressure on the foundation much greater.

Reinforced concrete shells of 1:1 1-2:3 concrete are used for piers 1 to 3 inclusive, but for all massive work, with the exception of Pier No. 5, a leaner concrete is used composed of 1:3:5 with the addition of two parts of coarser aggregate.

The superstructure has been designed for Dominion Government heavy loading on the railway track, 40-ton electric cars on the tramway, and 60 pounds per square foot on the balance of the roadway and the sidewalk.

The floor system has been designed for traction engine or motor truck similar to that assumed in Tender No. 2.

The fixed span is of the Warren type, and is 340 ft. to centre of bearings. The maximum unit stress in the bottom chord is 18,000 pounds per square inch for the west or railway truss, and 20,000 pounds per square inch for the east or highway truss. Full allowance has not been made for impact in the centre diagonals as required by the Dominion specifications, and as allowed by the other competitors. With this allowance added, unit stresses of 24,000 pounds per square inch exist in the railway truss.

Short redundant members are used to reduce the unsupported length of the vertical posts and hangers. This is not good practice, as they introduce secondary stresses in the members.

Sway frames between the trusses are not provided at all panel points as required by the Dominion specifications.

In the design submitted the swing span has sufficient lift of the ends to make the trusses non-continuous, so that they form two separate simple spans when the bridge is closed. This is a desirable arrangement if the boat traffic is so light as to require but few openings and the bridge is used almost entirely as a fixed span.

The heaviest structure of this type which has been built is the Charlestown bridge at Boston, the weight of which is about one-third that of the span under consideration. When swinging to its closed position the ends are lifted by hydraulic jacks, requiring about eight times as much work as when the ends are only lifted enough to prevent all tendency to hammer under the rolling load. The time required for operation is also greater.

To lift the ends by the centre top chord bars as is done in the design under consideration is not economical, as it requires about four and a half times the power that is required to do the lifting at the ends. The designer may claim that the toggle arrangement reduces this, but a toggle or similar arrangement can be used in either case. It is the ends that have to be lifted; and the more direct the application of power, the less is required.

A noted authority on swing bridges in a paper presented at a meeting of the American Society of Civil Engineers on April 3rd, 1907, says: "A few bridges have been built with a lifting apparatus applied at the top chord of the centre panel. This arrangement has the additional disadvantage of using a part of the structure which carries the strain while the bridge is swinging, also as a part of the lifting mechanism, which is not good practice. If the machinery parts get out of order the structure should not be affected thereby. The writer's experience with a bridge of this kind prompts him to advise its use."

In the swing as in the fixed span redundant members have been inserted between the diagonals, and sway frames omitted at four panel points where required by the Dominion specifications and good practice.

Full allowance has not been made for impact in the diagonals, and the stresses in the diagonals and chords are high.

The centre chord eyebars are stressed by direct stress and impact to 21,000 pounds per square inch. Tender No. 1 has 20,000, and Tender No. 2 16,000 pounds per square inch for the same members under the same conditions. In this design the centre eyebars have to resist the bending due to the friction at the pins or trunnions when raising or lowering the ends of the span. As the pressure between the bushing and pin is about 8,000 pounds per square inch, the friction should not be assumed as less than 20 per cent., which gives a unit stress from bending of 7,500 pounds. This, added to the direct stress and the proper allowance made for impact gives a total stress of more than 31,000 pounds per square inch, or about the elastic limit of the material.

The pressure between the nickel steel bushing and the trunnions at the centre is over 8,000 pounds per square inch. This bearing has to perform a similar service to the trunnions of a bascule bridge, although the movement is not so great. The specifications of Sir William Arrol and others allow a pressure of 2,500 pounds per square inch, and Unwin allows a pressure of 3,000 pounds per square inch on such bearings.

The centre lifting screw has a pressure of about 1,470 pounds per square inch on the thread. The specifications of B. R. Leffler, engineer of bridges of one of the large American railway companies, published in the transactions of the American Society of Civil Engineers, allow a pressure of 200 pounds per square inch on screws which transmit motion.

In this design the total weight of the bridge while swinging is carried by the drum, which is connected to a light centre casting by radial struts. We are of the opinion that this cast-iron centre has not sufficient strength to centre the bridge when closing or to prevent its being knocked out of position. It is an advantage to carry a portion of the total weight on the centre pivot, as is done in the other designs, for it assists in resisting any tendency toward lateral movement on the part of the live ring.

The drum is loaded at sixteen points, but these points are not evenly distributed, some of the spaces being about 7 feet, while others are about 26 feet. This is most unsatisfactory arrangement, as unequal distribution, on account of the deflection of the drum between points of loading, gives unequal load on the rollers; this, besides giving excessive pressure, distorts the live ring and causes the bridge to turn hard, with unnecessary wear and tear on the rollers, track and spider.

If the load is evenly distributed the pressure on the rollers would be about 14 per cent. greater than allowed by the Dominion specifications. With the uneven distribution the load would probably be about 40 per cent. greater.

The centre pivot in this design is entirely independent of the lower track and rack. They should be con-

nected by radial struts so that they can be erected and centred accurately in the shop, and when later put in position will occupy the same relative position.

In this design the live ring is connected to the centre pivot by radial rods, which are connected on the outside of the wheels by a flexible ring and on the inside by an angle. With this construction the centre ring around the pivot does not start to turn as soon as the wheels, but drags, and the rods through the rollers are thrown out of radial lines, so that the rollers do not run concentric with the top and bottom treads.

This is the reason for a large percentage of the broken wheels of old swing spans, and it also increases the power required for turning.

With reference to the drum wheels and spider, Tenderer No. 3 states: "It approaches very nearly that of the great swing span over the Thames River at New London, Conn., which it follows very closely in general design." This bridge was built more than twenty-four years ago, and, although the span is nearly 500 feet, the construction is light.

The specifications of Sir William Arrol say: "All radial bars and the roller frame of the live ring shall be formed of rigid members with suitable tangential bars to maintain the relative motion of the parts of the frame."

One of the Past Presidents of the American Society of Civil Engineers, in a paper on "Movable Bridges," presented before the Society on April 3rd, 1907, describing this type of construction, says: "The live ring arrangement for separating and holding the rollers which was formerly popular, consisting of adjustable radial rods, one end of each rod carrying a roller, the other end being connected to a ring devolving round the centre pivot, is, to say the least, an unmechanical contrivance. Good practice requires a more substantial construction. The rollers should run between two concentric circular girders firmly connected to each other; this ring should be connected to the revolving part of the pivot by rigid struts."

The design of the end shoes does not meet the requirements of good, modern practice, which requires supports for the ends of a swing span of solid, substantial construction similar to the end shoes of a fixed span. In this design the bearing pressure of the roller on the cast steel base is excessive and the base is too shallow to distribute the reaction over its full area.

It is stated that the ⅞-inch cup at the centre of the casting is for lock and centring device when closing. Tenderer No. 3 says: "These shoes are likewise of simple but massive construction. Cast steel bearing plates having an inclined approach and a hollow provided for the seat of the 16-inch solid steel roller bearing supporting the draw-arm. These rollers are to have a 9-inch pin and bearing at each end. This roller bearing is designed to form an automatic locking device and centreing device in addition to the rail lock for the bridge when it is closed, the roller, by gravity, rolling into the cup or seat provided."

In order to have the roller and the base casting centre the bridge when closing, the ends of the span must be lowered by lowering the ends of the centre eyebars through a percentage of their travel before the span has been turned to its final position. If the lowering has been excessive the momentum of the span will not be sufficient to carry the ends up the inclined path on the base casting, while if the ends have not been sufficiently lowered the momentum will carry the span past the ⅞-inch drop provided for the centreing. The momentum of the span must be sufficient to lift the ends up an inclined plane until a point 8 inches from the centre is reached and to carry the span on a horizontal plane for a distance of about 4 inches, but it must not be so much as to carry the ends 4 inches past the centre, or the device fails to act. As the deflections of the two trusses are different and vary with the temperature, the chances of successful operation are very small.

Suddenly dropping the ends of the bridge ⅞ of an inch will produce a hammer action on the cast steel base and a racking strain all through the structure.

Summarizing, we would say that the pressure on the foundation for the pivot pier is much higher in the 3rd design than in the other designs submitted.

The piles for the north approach foundations are loaded more than twice as high in the 3rd as in the other designs.

Maximum unit stress in the chord members of the trusses are 32 per cent. higher in the 3rd and 25 per cent. higher in the 1st design than in the 2nd.

The 1st and 2nd designs follow the lines of accepted good practice in modern swing bridge construction. The 3rd design is a distinct departure, and the largest structure operated in a similar manner, of which we can find any record is a double-track swing bridge, 228 ft. long, at Hammond, Indiana. In this structure the ends of the bridge are raised by means of double toggles in place of the single toggles.

The recommendation of the consulting engineers, however, was at variance with that of the British Columbia Manufacturers' Association, the Board of Trade, and other public organizations.

Despite the fact that the Provincial Government is exceedingly desirous that the company proceed without delay in the construction of the bridge in order to have the structure completed by the time the Pacific Great Eastern Railway connects North Vancouver with Fort George, little progress can be announced. The directors of the company appealed to the Government in the matter of awarding a tender. The Government, however, expressed itself as indisposed to take the responsibility of making an award and referred the question back to the Board of Directors. Numerous alterations to tenders were permitted, all three undergoing various changes. Then the Board decided to place the whole question before a disinterested engineer, fully capable of recommending the best award. Mr. Ralph Modjeski, of Chicago, was accordingly retained on July 10th, 1914. His report is expected in a few weeks, whereupon an award will probably be made.

INTERNATIONAL IRRIGATION CONGRESS.

There will be no postponement of the session of the International Irrigation Congress, which is scheduled for October 5th to 9th. On account of the war and the fact that European countries would not be in a position to participate in the Congress, some question arose as to the advisability of holding a session this year. It has, however, been decided to go ahead as previously planned confining the work to the United States and Canada. The Dominion and provincial governments which are really most interested in the success of the gathering, have concluded that it will be better to proceed than to postpone.

In the fear that the United States government may make the coal product contraband of war, all the Rochester and Pittsburg coal company mines in Indiana county have received word to start all mines full time, give all miners employment, and get out all the coal possible. The Canadian railroads have placed big orders and want the coal shipped to Canada at once.

REINFORCED CONCRETE DOCK CONSTRUCTION.

THE study of reinforced concrete docks involves so many phases of the problem that they are difficult to cover with any degree of completeness in a single article. There are many in successful operation in Europe, the most extensive development being in England, where they have, to a certain extent, proven their practicability and commercial economy. But in America they are more or less of a novelty, and can hardly be said to have, as yet, proven themselves. For this reason there is much of interest in a review of the art of reinforced concrete dock construction given by Harrison S. Taft in a paper on May 20, 1914, before the American Society of Civil Engineers—particularly in that portion of the paper outlining the practice in the old world and examining the work in each country. Their successful use for about 50 years in Europe for structures exposed to the action of salt water leads one to the conclusion that what has been done there, and in other parts of the world, will bear investigation. We extract the following pertaining exclusively to English practice, from Mr. Taft's paper:

In building reinforced concrete docks and other concrete structures in sea or fresh water, it is only natural that a forested country should be the last to take up the development of such a material. Consequently, America has been far in the rear in regard to this question, as compared with what other and older countries have accomplished. In England, France, Germany, Italy, and other European countries, in Australia, and in Asia, as well as in certain South American countries, concrete seawalls, breakwaters, dry docks, piers, trestles, coaling stations, etc., in salt water, have been in existence for years.

Southampton, Eng.—One of the most noted developments in reinforced concrete construction, as applied to harbor and dock development, is that of the London and Southwestern Railway Terminals at Southampton. The first and most prominent reinforced concrete structure in connection with this terminal was a coal barge jetty, 300 ft. long and 20 ft. wide, built in 1904, on the Hennebique system of driven concrete piles. The piles are about 44 ft. long, standing in 29 ft. of water at high tide, the rise and fall of the tide being about 13 ft. Each pile carries a maximum load of 17 tons.

This structure carries a very heavy traveling coal-hoisting apparatus for unloading coal from large vessels docked on one side, into harbor barges or scows which lie on the other side. Thus the jetty is subjected to constant blows from both sides, in addition to the heavy vibration due to the traveling machinery it supports.

In speaking of this jetty, Mr. Francis Wentworth-Shields, Dock Engineer for the London and Southwestern Railroad, says:

"Though the impacts from the vessels and scows cause this whole jetty to sway, there seem to have been no signs at the end of the first 2½ years of its existence of any of the concrete peeling off."

During recent years this dock or jetty is said to have shown some signs of deterioration, due to the vibration of the heavy machinery traveling along it, the supposition being that it was built too light in the first place to absorb the heavy vibrations to which it has been subjected. Still, the dock is said to have considerable elasticity. In one instance it was in heavy collision with a steamer, two piles and the beams they carried being broken. The dock was effectively repaired, but perhaps with some difficulty, though it is claimed that the repairs were easily accomplished.

The same railroad company has built several other reinforced concrete pile docks at Southampton, designed to carry the same heavy deck loads as the coaling jetty, but without the heavy vibration to which this jetty is subjected. Though built on the same system of construction as the coal jetty, the latter docks have shown no signs of wear or deterioration. It is said, on the best of authority, that they have cost nothing to date for maintenance.

The largest of these is the extension, on the Itchen Front, of "The Empress Dock," a widening of the so-called "Old Extension Quay" by a reinforced concrete pile structure, 50 ft. wide and about 1,300 ft. long, parallel to and securely dovetailed into the old quay wall. This widening dock is built of complete concrete bents, along the tops of which are steel deck-beams or stringers, which in turn are covered with 4 in. of wood, a wooden block pavement being used for the wearing surface. The depth of water at low tide at the face of this structure is 35 ft., which, with a 13-ft. rise and fall of the tide, gives a depth of 48 ft. at high tide.

One of the finest cold storage and cattle stations in existence was built at Southampton in 1905 to accommodate the foreign cattle trade. The landing stage or jetty of this station is a reinforced concrete structure, 200 ft. long and 38 ft. wide, connected with the main land by two runways, 142 ft. long and 15 ft. wide.

On the opposite side of Southampton Harbor, at Woolston, on the Itchen, there is a reinforced concrete landing dock, 136 ft. long and 100 ft. wide, built in 1899 on the Hennebique system. This was the pioneer of reinforced concrete dock construction in Southampton waters. Up to date, this dock has cost practically nothing for repairs, except for damages due to the fact that it was rammed or otherwise damaged by a large steamer; it is in excellent condition at present. The cost of making the repairs is said to have been very small.

Up to the present time, it appears that at least six reinforced concrete docks, jetties, or quays, have been built in Southampton waters.

In building one of the Southampton docks, it is stated that some of the concrete piles were sprung out of line in drying them. A prominent American engineer reports that he saw a number of piles from 1 to 2 ft. out of line, but that they showed no signs of cracks. It has been stated that, in handling Chenoweth concrete piles, up to a length of 61 ft., and 13 in. in diameter, they were rolled about like wooden piles, at times having quite a spring in them. Under this treatment they showed a remarkable degree of elasticity and no signs of cracking.

Bending of Piles.—In discussing the bending of concrete piles, it is of interest to note a series of tests made on a hollow telephone pole in Fulham, London, England, in 1911. The pole was 44½ ft. long, 17 by 17 in. at its base (outside dimensions), tapering to 8 by 8 in. at its head. The thickness of the shell was 2 in., making the inside dimensions of the pole 13 by 13 in. at the base and 4 by 4 in. at the top. The vertical reinforcement consisted of 248 3/16-in. rods of high-tension steel, the ultimate tensional stress being from 80,000 to 85,000 lb.; 56 rods were grouped at each corner, 6 rods being spaced evenly on each of the four sides of the pole. The area of the concrete at the base was 106 sq. in., and the area of the steel 6.85 sq. in., a ratio of 0.0445. In making the test, the pole was set in 5½ ft. of massed concrete, with the pulling rope attached to its upper end.

In Table I. is recorded the pull, in pounds, the deflection, and the permanent set after the loads had been released.

After applying the 6,000 lb., the test was discontinued for 3 days, and then the load was slowly increased to 9,200 lb., which gave a deflection of 66 in. and a permanent set of 21 in., with "cracks on tension side and permanent cracks more numerous and pronounced." There was no sign of failure on the compression side of the pole.

Table I.—Test of a Hollow Concrete Pole at Fulham, England.

Loads, in pounds.	Deflection, in inches.	Permanent set, in inches.
300	¾	None that could be observed
500	2	
1,000	4¼	
1,250	5	
1,500	6¼	
1,750	8	
2,000	9	
2,250	10½	
2,500	12	¼
2,750	14	½
3,000	14¾	⅝
3,550	19½	¾
3,100	16½	½
3,500	18¾	⅝
4,000	22	¾
4,500	25½	1⅛
5,000	29	1¾
Load gradually increased to 5,750	34	Pulling wire broke. Pole flew back, vibrated short time and came to rest in vertical position with no permanent set.
Load gradually worked up to 6,000	37½	2 in. immediately after release of load. After interval of 1½ hours, set was reduced to 11/16 in.

Add to the above loads 100 lb. for weight of wire and recording apparatus, etc.

Notes on Behavior of Pile.—At 3,350 lb., slight hair cracks appeared on tension side at about 5 ft. 6 in. above foundation.

At 3,600 lb., slight hair cracks appeared at regular intervals about 6 to 9 in. apart.

At 4,100 lb., slight shear cracks appeared, starting at 33 in. above foundation and extending vertically, at a distance of 2 in. from tension side, for some 3½ ft. in length.

At 4,600 lb., hair cracks occurred regularly, 3 or 4 in. apart on tension side.

At 5,100 lb., cracks on tension side were noticed to be traveling across the sides of the pole to within 6 in. of compression surface.

At 6,100 lb., the shear cracks were more pronounced. The hair cracks on tension side were about 1 in. apart, but no signs of failure appeared on compression side.

The load was again applied. When a deflection of 73 in. was obtained, signs of failure appeared for the first time on the compression side, and the pole failed, but no record of the amount of the pull was obtained. The final examination showed that the pile failed equally for its entire length on the shear and tension sides, but without any local weakness. The compression side failed from the base up for a distance of about 2 ft. The bending moment at the base of the pile was reported to be 4,863,936 in.-lb., a most remarkable test, which seems to substantiate the experience quoted above.

Liverpool.—The Mersey Docks and Harbor Board appears to have made a very limited use of reinforced concrete in its latest port developments, in spite of the extensive tidal and graving docks of concrete constructed at Liverpool. As a matter of fact, most of its first so-called reinforced concrete docks were in reality semi-concrete structures, that is, wooden piles carrying a concrete deck system. The oldest of these structures, the Cattle Wharf, Prince's Stage, was built in 1899-1901 on greenheart piles, with the usual Hennebique system of concrete deck-beams and slab. In addition to the Cattle Wharf, there are two other dock-quays in Liverpool, built on the same system, designed for a load of 3 tons per sq. yd., with a test load of 4½ tons.

Another of Liverpool's reinforced concrete docks is the Prince's Dock, West Quay, completed in 1905. This structure was designed to carry a super-load of 3 tons per sq. yd., or about 66 tons per pile. The piles are of concrete, 16 in. square, spaced 15 ft. 9 in. from centre to centre, across the dock, and 12 ft. 6 in. from centre to centre, longitudinally, and resting on rock.

At the west end of Liverpool's dock system is the so-called Brocklebank Dock, 226 ft. long and 64 ft. wide, a reinforced structure built in 1908 on the Hennebique system, and designed to carry the same loading as the Prince's Dock. The test load applied was 9 tons per sq. yd. The piles of this dock are 20 in. square, and had to sustain a load of about 95 tons each, when the test load was applied.

During the first year of its existence there was considerable trouble with the Cattle Wharf and other semi-concrete structures, due to the permeability of the deck-slab part of the structure. The dampness from the salt water entered the permeable concrete and attacked the steel reinforcement on the under side of the slab, causing pieces of concrete to fall off. The defect was overcome by applying a heavy coating of cement to the under side. The upper side of the deck-slab, which is washed daily, shows no signs of deterioration. This emphasizes the fact that great care must be taken in placing concrete in structures standing over or in salt water; there must be the closest inspection during their construction. As a result of this trouble, it appears that the steel reinforcement must be kept farther from the surface of the concrete in salt water concrete structures than in ordinary work. Whereas, at first a minimum of 1½ in. was supposed to be sufficient, the engineers of the London and Southwestern Railway have found this to be insufficient, and are now specifying a minimum of 2 in. for their new structures. Another difficulty encountered was the numerous joints in the Liverpool system of dock construction. This appears to have been overcome by cleaning out the joints and filling them with a rich cement grout, with such success that the docks are reported to be in very satisfactory condition at the present time.

Thames River, Etc.—Within the bounds of the "Port of London Authority," and at other places on the Thames, many reinforced concrete docks or quays have been constructed. One of the most prominent of these is the Thames Haven Jetty Head, near the mouth of the river. This structure was built in 1908, for the berthing of large vessels, and is 136 ft. long and 32 ft. wide. It is supported by 19 columns or piers, 5 ft. in diameter up to low-water mark but of oval shape, 5 by 2½ ft. above. Each column rests on two 15-in. concrete piles of octagonal

section, 45 ft. long, with a penetration of from 18 to 20 ft. After these concrete piles had been driven to refusal, a temporary iron caisson was put down over them. The reinforcing hoops were then lowered into place around the two piles and the caisson was filled with concrete. The caisson was afterward removed, being built in half sections.

Farther up the Thames, 20 miles from its mouth, is the Purfleet coaling jetty, built in 1904, a reinforced concrete structure, 250 ft. long and 34 ft. wide, carrying two heavy traveling cranes. The concrete piles are 14 in. square, from 40 to 50 ft. long, with from 15 to 18 ft. of penetration. The deck-slab is 5 in. thick. The jetty is connected with the mainland by a reinforced concrete approach, over which cars are run to the jetty itself. On one occasion this jetty was rammed by an 8,000-ton steamer, eight piles and 20 ft. of the decking being damaged. That the damage was not more extensive is said to have been due to the firmness of the horizontal decking. In repairing the dock it was necessary to withdraw the eight broken piles and drive new ones. In conducting this repair work, it was especially noticed that the steel reinforcing bars of the original structure showed no signs of rust, though it is well to note that the water at this point of the Thames may be brackish, and not real sea water. The repairs were efficiently made, and the quay is still doing duty.

Another interesting reinforced concrete coaling dock is at Dagenham-Essex-on-the-Thames, 10 miles below London, built in 1901. It is 780 ft. long and 35 ft. wide, and carries eight heavy traveling cranes, weighing 60 tons each, besides a railroad track. Each supporting column consists of three concrete piles encased in a concrete cylinder filled with concrete. Though it may seem a trifle odd, a careful study of photographs of this structure indicates that the tops of the columns are made with "capitals"—a well-proportioned and artistic structure as regards concrete dock work. A similar structure, known as the Prince of Wales Pier, was built in 1903 at Falmouth.

The Thames Iron Works and Shipbuilding Company has constructed at Dagenham a very substantial reinforced concrete dock, designed to carry a concentrated load of 60 tons, for the berthing and fitting out of dreadnought battleships. In the construction of this dock, the Williams type of concrete piles was used for the first time. This type consists of an I-beam surrounded with 3/16-in. wire, 12 in. from centre to centre, the whole being encased in concrete, with special provision at each end to take up the reaction of the driving.

In the same vicinity is the Hornchunk Dock and approaches, built in 1906. The main structure is 400 ft. long and 24 ft. wide, the approach being 280 ft. long and 16 ft. wide; both were built on the Hennebique system. The concrete pile bents are 14 ft. from centre to centre, braced diagonally and support a concrete beam and deck-slab system. Along the water-front side of this dock and its approach, a concrete curtain-wall was built between the piles. This curtain-wall in turn is protected by a wooden fender system. The plans seem to indicate that this structure was designed to carry a 27-ton crane in addition to a 27-ton locomotive.

A reinforced concrete coal dock was built in 1906 at Rochester, on "The Medway," a river flowing into the estuary of the Thames. This dock consists of a main water-front section, 32½ ft. wide and 340 ft. long, connected with the land by two concrete approaches, 100 ft. and 180 ft. in length, respectively. It was built on the Hennebique system, and carries a heavy traveling crane in addition to two railroad tracks. This was one of the first large undertakings in reinforced concrete dock construction on the Thames or its tributaries. At the time it was built it was looked on as the most important structure of its kind in England.

Though the exact number of reinforced concrete docks now in existence on the Thames or its tributaries is perhaps unattainable, it appears that they are more numerous in those waters than in any other part of England.

General.—Perhaps the largest reinforced concrete dock constructed up to date in England is at Swansea, on the southwest coast of Wales. It is a Hennebique design, almost 2,000 ft. long, completed in 1908, the whole structure being built in the dry. Some of its columns are 3½ ft. square. As this structure is used as a coal loading quay, and stands in 40 ft. of water, it is subjected to heavy loads and severe lateral shocks.

At the naval dock yard at Rosyth, Firth of Forth, Scotland, is found one of the most unique and interesting reinforced concrete docks or piers in existence. It is triangular in shape, 620 ft. long, has been finished recently, and forms the entrance pier to a tidal basin. The outer end consists of seven concrete monoliths with a mass concrete fill in the centre, making a solid concrete head, 127 ft. long and 65 ft. wide, covering an area of some 8,300 sq. ft. The rest of the pier consists of twenty concrete monoliths, 25 by 30 ft., supporting a reinforced concrete structure consisting of girders, columns, arches, braces, and deck-beams. The upper decking consists of 3 by 10-in. creosoted wooden joists covered with a creosoted planking arranged so as to prevent any water from collecting thereon. It is a most massive and homogeneous structure, well capable of absorbing any heavy stresses it may receive from warships lying alongside.

In the Bay of Bristol, at Clevedon, where the tide has a rise and fall of some 49 ft., there is another interesting reinforced concrete structure, in the nature of a landing stage. It is 95 ft. long and rests on 22 reinforced concrete piles. The piles, extending up to low-water mark only, were driven through the marl until they reached hard rock. On top of these piles the reinforced concrete landing stage was erected, a structure consisting of columns, beams, bracing, and four different decks or landings.

A reinforced concrete dock of magnitude was recently constructed at Port Talbot. Being designed for coaling operations, it is subjected to heavy loads. The designed load was 850 lb. per sq. ft., the test load being 1,390 lb. per sq. ft., covering an area of 720 sq. ft. The outer row of piling consists of two 14-in. square piles encased in a concrete cylinder, 4 in. thick, and 4 ft. 6 in. in diameter. There are six such columns at the face of the dock. Each of the other two rows consists of eight 14-in. square piles. At this port there are also a number of similar structures, the first having been built in 1907.

It is of interest to note that one of the reasons which influenced the engineers in adopting reinforced concrete for the coaling jetties and wharves at Port Talbot Docks was an extensive fire in one of the docks, due to fuel oil which had escaped from one of the vessels. The oil was ignited through carelessness, and caused a very intense blaze over an area of about 250 by 50 ft. though, fortunately, the oil did not spread out under the wooden structures. With the world-wide use of oil as a fuel for the merchant marine, it is well to consider this danger in American wooden dock structures.

Although the Port Talbot Railroad and Dock Company was among the first to adopt reinforced concrete for wharf construction in England, and so was adversely

criticized "for using an alleged untried material in such types of work," the results obtained have fully justified this radical departure from what was at that time the prevailing practice the world over.

Scattered all through other English ports are reinforced concrete docks of various sizes.

At Fleetwood, from 35 to 40 miles north of Liverpool, a reinforced concrete fish and coaling dock of considerable magnitude was completed in 1911. The fish shed section is 1,330 ft. long and 26 ft. wide, that is, the reinforced concrete quay part; the filled-in land behind the quay makes the shed sections some 70 ft. wide in all. The coaling section, of similar construction and carrying a coal-loading traveling crane, is 680 ft. long and 26 ft wide.

At Harwich, 40 miles northeast of the Lower Thames, is the Parkeston Quay, a reinforced concrete dock structure more than 1,000 ft. long and 51 ft. wide.

On the northeast coast of England, at Newcastle-on-Tyne, a reinforced concrete jetty wharf of extensive size lies along the water-front of a large turret shop.

The port authorities at Dundee and Aberdeen, Scotland, are gradually replacing their worn-out wooden dock structure with reinforced concrete.

On the north coast of Scotland, at Ackergill, stands a life-boat slipway, 194 ft. long, built of reinforced concrete, extending out from the rocky shore into the wide open sea. There are several similar structures in other parts of Great Britain.

A reinforced concrete dock was built in the Shetland Islands in 1910. The head of this dock is 80 by 24 ft., and is reached by a concrete approach, 113 ft. long.

In Cork Harbor and other Irish ports reinforced concrete docks of considerable size have been and are being built.

At Portsmouth, Plymouth, and Cardiff are found the first reinforced concrete docks constructed in England, having been built previous to 1906. They are small, and are used mostly for coaling purposes. Quite extensive reinforced concrete docks, constructed during the last year or two, are found at Newport (Mon.), Swancombe, Gravesend, Portencross, South Bank, Ipswich, Newlyn, and numerous other places.

A number of small reinforced concrete docks or pierheads, other than those just mentioned, exist in England in connecton with shipyards, etc. Such docks are found at Dumbarton Shipyard, on the Clyde, and at several similar establishments.

At first the Hennebique system prevailed in all English reinforced concrete dock construction, but, of late, several other systems have been introduced, the most pronounced of these being the Considère spirally armored concrete piling. Though different types of piles are used in English reinforced concrete dock work, there is a most thorough system of diagonal bracing with each type.

In using the Hennebique or other systems of dock construction, where lateral and diagonal braces of reinforced concrete are put in the structure, it appears that trouble has arisen, and might again arise, from the joints in the bracing system. As the foreign docks built on the Hennebique and similar systems seem to have been a success, it does not perhaps cause as much trouble as it did at first, or would appear to cause. In a concrete structure, of whatever design, built in the water, there is always the danger of cracks below the water line, and these cannot be seen and properly attended to.

In a recent address, Mr. Robert Porter, of "The London Times," stated that "England is one big port." From the vast number of reinforced concrete docks at present in her harbors, it does not seem amiss to say that some day soon the ports of England will be, figuratively speaking, one big reinforced concrete dock, and it will be impossible to enter that country without passing over a structure of this type. In fact, current English technical publications plainly indicate that there is hardly a port of any prominence along her coast where reinforced concrete construction is not now being carried on extensively, to the extent of five heavy coal tip docks in one harbor alone, due to the great economy of such structures over their old wooden predecessors, in the way of maintenance expenses.

In a recent rebuilding of the old wooden docks or wharves at Plymouth, constructed 30 years ago, the engineers of the Great Western Railroad have stated that concrete construction was adopted because "the cost would be about two-thirds of the cost of rebuilding in timber." These new concrete docks rest on Considère piles, and were designed for a live load of 400 lb. per sq. ft.

In closing this description of English reinforced concrete dock construction, it is well to take note of a few points in favor of this type, as set forth by an English engineer from his experience in that field: (1) Easy to build; (2) indestructibility; (3) small cost of annual maintenance; and (4) easy to repair.

QUAY WALL AT VICTORIA, B.C.

The contract will shortly be let by the Department of Public Works at Ottawa for the construction of a quay wall and for a large amount of excavation work in Victoria harbor. Tenders were called on June 4th and closed on June 27th. According to the plans, a sea-wall about 1,000 ft. in length is to be built in the inner harbor at Victoria, it being part of the large revetment scheme of the Dominion Government. It will extend from Songhees Point to the abutment of the Johnson Street bridge, and will facilitate the filling in of an area of over 13 acres that lie between it and the natural shore line. The foundation for the wall is to extend to a depth of 20 ft. below low tide, and will entail the removal of over 65,000 cu. yds. of excavation work. The foundation will consist of a lower layer of rubble about 3 ft. in thickness, over which will be placed broken stone in a layer about 1 ft. thick, which will be carefully levelled to provide a base for reinforced concrete cribs. These cribs will be constructed on a dry dock and will be towed to the site and sunk into position. This is the usual practice in work of this nature on the Pacific coast, and several references have been made to it in these columns of late in connection with other harbor and dock developments. The cribs will vary in length from 80 ft. to 100 ft., and will be 25 ft. wide by 30 ft. in height. The reinforced concrete walls and bottom of each will be 15 in. thick. The interior will be divided into sections by partitions 10 in. thick, and will, when placed, be filled with rubble. The cribs, when in position, will extend in a straight line for the full length of the wall.

With these cribs as a substructure the quay wall will be built in sections about 30 ft. in length and with an average height of 37 ft. above the foundation. Its top will project approximately 7 ft. above high water, and the fluctuation in water level is about 10 ft. at this point. Protection on the face of the quay will consist of 12 in. x 12 in. creosoted fender timbers wedge-bolted into the concrete on 10 ft. centers, spaced by three lines of walings, 10 in. x 12 in.

FOURTH AMERICAN ROAD CONGRESS, NOVEMBER, 1914.

THE mayor of Toronto has been requested by the Hon. A. B. Fletcher, president of the Fourth American Road Congress, and state highway engineer of California, to name three delegates to attend the sessions of the Congress at Atlanta, Georgia, during the week of November 9th.

Forty-seven organizations are taking part in the Congress under the leadership of the American Highway Association and the American Automobile Association. In his letter to the mayor, President Fletcher calls attention to the fact that practically every state highway commissioner will be present and take part in discussing the important problems of road construction and maintenance, and that some of the foremost men in public life will devote their attention to the great question of federal aid to road improvement, in an endeavor to work out a policy which may be submitted to the Congress of the United States with the support of the organized road movement of America. An important move bearing upon state legislation will be made at the session to be held under the auspices of the American Bar Association, at which a joint committee, appointed at the 1913 Congress, will report progress in compilation and suggested revision of state road laws. The creation of a commission participated in by each state to work out a revision of the road laws will be urged. The National Civil Service Reform League will hold an exceedingly important session on the merit system in road administration.

President Fletcher calls attention to the exhibits to be made by the United States Government, the States, and more than a hundred of the leading manufacturers at the Congress, which will illustrate every known method, material and equipment for road construction and maintenance. He urges that the city and county be officially represented, as the Congress is in reality a training school where a very great amount of useful information can be obtained through attendance at lectures with leading specialists in road and street work, and the collecting of the many instructive bulletins which will be available for distribution.

The following is a partial list of papers and addresses to be presented:

General Addresses.—Fairfax Harrison, President Southern Railway; Logan Waller Page, Director U.S. Office of Public Roads; Col. E. A. Stevens, State Highway Commissioner of New Jersey; Brig. Gen. Wm. T. Rossell, U.S.A., retired; James R. Marker, State Highway Commissioner of Ohio. Others to be announced.

Drainage Structures—By W. E. Atkinson, State Highway Engineer of Louisiana. Discussion opened by Frank S. Rogers, State Highway Commissioner of Michigan.

System in Road Management—By C. J. Bennett, Highway Commissioner of Connecticut. Discussion opened by Paul D. Sargent, State Highway Engineer of Maine.

Maintenance Methods and Relation to Traffic—By George W. Cooley, State Highway Engineer of Minnesota. Discussion opened by H. R. Carter, State Highway Engineer of Arkansas.

Convict Labor—By George P. Coleman, State Highway Commissioner of Virginia. Discussion opened by J. E. Maloney, State Engineer of Colorado.

Rights of Way—By Austin B. Fletcher, Highway Engineer of California.

Efficiency in Highway Organization, Centralization of Purchases, Etc.—Discussion opened by John S. Gillespie, Road Commissioner of Allegheny County, Pennsylvania.

Surfaces for Light Volume Mixed Traffic—By S. Percy Hooker, State Superintendent of Highways of New Hampshire. Discussion opened by S. D. Foster, Chief Engineer State Highway Department of Pennsylvania.

State Control of Road Work as a Policy—By A. N. Johnson, Former State Highway Engineer of Illinois. Discussion opened by T. H. Macdonald, State Highway Engineer of Iowa.

Engineering Supervision of Road Construction—By W. S. Keller, State Highway Engineer of Alabama. Discussion opened by R. C. Terrell, State Highway Commissioner of Kentucky.

Economics—By J. E. Pennybacker, Chief Division of Economics, U.S. Office of Public Roads.

Educational Field for Highway Departments—By Dr. Joseph Hyde Pratt, State Geologist of North Carolina. Discussion opened by Col. Sidney Suggs, State Highway Commissioner of Oklahoma.

Heavy Traffic Roads—By Henry G. Shirley, Chief Engineer, State Roads Commission of Maryland. Discussion opened by W. A. Hansell, Superintendent of Public Works, Fulton County, Georgia.

Grades and Excavation—By A. D. Williams, Chief Road Engineer of West Virginia. Discussion opened by William J. Roy, State Highway Commissioner of Washington.

National Legislation—Addresses by: Hon. John H. Bankhead, United States Senate; Hon. Dorsey W. Shackleford, U.S. House of Representatives; Hon. William P. Borland, U.S. House of Representatives. Others to be announced.

CANADA'S STEEL INDUSTRY

Replying to an inquiry as to how the European war would affect the Dominion Iron and Steel Company's plant, Mr. J. H. Plummer, president of the company, said:—

"We have a considerable tonnage of rail orders on our books, but they are chiefly for shipment by water. The disturbed condition which affects the sending of material by sea and the further disturbance of financial arrangements of our customers caused by the war would seem to make it inexpedient to continue rolling on these orders.

"We already have several cargoes awaiting shipment, and more or less held up by those conditions. We think it probable, therefore, that we shall have to shut down much of the plant, or rather to suspend a major part of our operations for a time until we see more clearly what conditions we have to meet.

"In time of war the general iron and steel industries are usually very active and that effect is likely at this time to be more marked in neutral markets because the great centres of industry in Europe are all directly involved. It is difficult to say how this would affect us in Canada, but if there is an active market in the United States we shall follow them to a greater or less degree.

"At the moment we are preparing to damp down two of the blast furnaces now in blast, and the open hearth furnaces. The finishing mills can and will be operated so far as orders are obtainable. We have on hand a supply of billets sufficient to keep these in full operation for some months. The demand for coal is unlikely to fall off, and unless our transportation arrangements should be seriously interfered with, this portion of our business will continue without change."

President Harris of the Nova Scotia Steel Company has announced that as a result of the financial situation created by the war it has been decided to close down a portion of the plant at Wabana Mines and the blast and open hearth furnaces at Sydney mines have been temporarily stopped.

ROAD-BUILDING AND DRAINAGE WORK IN SASKATCHEWAN.

DURING the present season the Board of Highway Commissioners of Saskatchewan is undertaking a considerable amount of drainage work, which will result in the addition of much valuable agricultural land to the municipalities in which the works are situated. Five schemes are now under way, namely, at Rouleau, Invermay, Margo, Rama and Yorkton, while others are being advertised at Kuroki and Canora.

The scheme which will render available the largest amount of land is at Rouleau, and this work is at the point of completion. The work at Invermay, Rama and Yorkton will probably be all finished by the end of August. All of the works are being done by contract under the drainage Act. The schemes in every case went through without difficulty, as there were not enough appeals against the assessments to block any of them. Under the drainage Act the expense is borne by the owners of the lands affected, and also by the rural municipalities whose roads may be benefited. The cost is in the first place met by the government, which is repaid by debentures covering a period up to twenty-five years.

Road-Building.—The carrying out of the road-building programme of the board for the year 1914 is progressing very satisfactorily. Over 100 road gangs have been actively engaged in various parts of the province, and it is considered that the standard of the work being done this year is higher than has been achieved in any former season.

The payment of direct money grants to rural municipalities for road work was found to entail many disadvantages, chief amongst which was a lack of uniformity in construction methods, and it has accordingly been almost entirely discontinued. Some eight rural municipalities, however, had entered into a three-year contract with the board, whereby they receive a grant up to $5,000 in each year on the dollar-for-dollar basis. With these exceptions the work is done almost entirely by the government gangs, although in some cases contracts have been let, where the work was of sufficient magnitude and of such nature as to permit of contracts being awarded economically. About twenty other rural municipalities were found to have well-equipped and competent road gangs, whose work during the last year was fully up to the required standard. The board retained the services of these organizations, and put them to work in the regular way under its own inspectors, and the workmen will be paid direct by the Commission off pay-sheets submitted.

Rural municipal councils have scarcely done as much as they ought in the way of maintenance of roads that have been built, but still there is a noticeable improvement in this respect. Municipalities that show themselves alive to their responsibilities as to maintenance will in future have better chances for assistance from the board. From year to year farmers see the advantages being derived from the use of the road-drag, and its educative effect, which is of the highest, is bound to make itself felt.

Road-Dragging.—At a recent meeting of the Board of Highway Commissioners the matter of maintenance was very thoroughly discussed, and it was regretted that so many rural municipalities appear to have overlooked their responsibilities in connection with maintenance of works undertaken not only by the board, but also out of their own funds. It was decided to send a general letter to all municipalities pointing out to them that it is considered waste of money to improve roads and afterwards let them fall into ill-repair.

The board started a road-drag competition with the sole object of proving the value of this simple implement as a road-maintainer, and it was hoped by the numerous examples scattered throughout the province that the practice would become general, and that every municipality would at an early date see the advantages to be derived from its use.

A great many municipalities have already inaugurated a systematic maintenance programme for their roads, and it is urgently requested that this matter be dealt with in a substantial way by every rural municipal council in the province.

Interest in this year's road-drag competition is much keener than last year, and this is due not so much to the increased prize money, but because of the splendid results achieved. The province has been divided into six districts, in each of which the same prize money be awarded, and all of them are eligible for the $400 championship prize. The list of rural municipalities entered are 68, in all, covering 209 miles of road.

NEW ELECTRIC CRANE CONTROLLERS.

The Westinghouse Electric and Manufacturing Company has recently put on the market a new line of magnet switch crane controllers. This line is complete and includes the following controllers for single motors or for the motors in series or in parallel:—

Trolley; bridge, with or without speed control; and hoist, with or without speed control and dynamic braking.

Dynamic braking is very desirable for hoist operation because it gives the operator complete control over the load. He can hoist or lower at high speed and stop instantly with no over-run, and he can "inch" the load with precision.

The controllers are characterized by reliability, durability, and simplicity. The magnet switch contacts cannot stick together. The parts are few in number and all are strong and substantial. The number of interlocks, with their multiplicity of contacts and complicated connections, is reduced to a minimum. Inspection and repair of wearing parts can be easily made so that time lost on account of controller repairs is negligible. Each switch is mounted on an individual slate base and the whole assembly is mounted in a very substantial manner on a pipe frame work.

Overload protection is provided for by means of two overload relays (one in each side of the line). After the relays have operated, they are automatically reset by bringing the master switch to the "off" position. Since these relays open both sides of the line, failure of operation due to grounded wires is made impossible.

The no-voltage release opens the control circuit on failures of the supply voltage and the motor cannot be started again until the master switch is returned to the "off" position.

In order to secure safety during inspection and repair of crane apparatus, there is a device for locking the main line switch employed. The switch is locked open when the safety key is removed and cannot be closed until the latter is replaced. Several holes are provided for padlocks, which may be inserted by men working independently on the apparatus and prevent the insertion of the safety key as long as they remain in place.

RAILWAYS IN PERU.

Very little progress has been made in the construction of railways in Peru, owing principally to the mountainous nature of the country, which makes it both difficult and costly. The only addition in recent years has been the Lima to Huacho Railway. There are in course of construction a line from Cuzco to Santa Ana and another from Lima to the small port of Chilca. No work has as yet been begun on the projected railway to navigable waters of the River Ucayali.

SURGE TANK PROBLEMS II.

CONTINUATION OF ANALYSES OF PROBLEMS ARISING FROM SUDDEN SHUT-DOWN AND SUDDEN OPENING OF OUTFLOW.

By PROF. FRANZ PRASIL

Authorized Translation by E. R. Weinmann and D. R. Cooper, Hydraulic Engineers, New York City

Special Case of Sudden Shut-Down (Continued).

(2) Graphical Demonstration.—For the graphical demonstration of the velocity, a very simple construction may be used. We may divide the equation 32 into two equations which, using $\varphi = t/T_1$, may be written:

$$B = Re^{-\frac{T_1}{2T_0}\cdot\varphi} \qquad y = B \,.\, \sin(\beta + \varphi) \qquad (47)$$

The former gives in the polar system of co-ordinates (Fig. 3) (φ in radians) with β as the vector radius a logarithmic spiral with the slope $\alpha = -T_1/2T_0$.

The second equation may be demonstrated in the rectangular system of co-ordinates, where y and therefore z is a function of φ, if we consider the axis of abscissæ in the continuation of this ray of the polar system, which is turned from the initial point with the angle β, and if we plot from an initial point in that system the values of φ projecting the points of the spiral on the ordinates which apply to the same values of φ. As $\varphi = \frac{t}{T_1}$, the time may be measured as abscissæ showing the water surface fluctuations with respect to time.

The equation 35, which determines s, has the same form as equation 32. It follows that for the graphical demonstration of s, the same method may be applied as s becomes o when $t/T_1 = \gamma - \beta$ and we see that the axis of the abscissæ for the rectangular system of co-ordinates which demonstrates s, is in the continuation of that ray of the polar system which corresponds to the maximum and minimum values of z and also of y. By projection of the points of the spiral to the corresponding ordinates, we get the z curve, whose ordinates, as may readily be seen, cannot be measured by the same scale as those of the z curve. We have to take: If (for the z curve) an ordinate of one inch equals m feet, then for the s curve an ordinate of one inch $= \frac{m}{T}$ feet per second. The demonstration of the acceleration is similar.

(3) Practical Example.—We may now compute for this case an example to which the graphical demonstration also applies. The dimensions are the following:

$L = 9{,}050$ feet $\qquad p = 32.8$ feet
$a = 80$ square feet $\qquad Q = 530$ cubic feet per second

For a flow of 530 cubic feet per second, according to the usual method of computation, a friction coefficient $K = 101{,}000$ in the formula $h = \frac{L.a}{K.p}\,.\,v^2$ and, therefore, $v_1 = 6.63$ feet per second and $h_1 = 9.6$ feet, are determined.

The surge tank section may be constant and $A = 5{,}380$ square feet. According to the theory, we assume that $h = n.v$, $n = \frac{h_1}{v_1} = 1.45$ sec. $= \frac{9.6}{6.63}$. Therefore, except for the conditions $v = o$ and $v = v_1$, the friction is greater than it would be according to the friction formula commonly used $h = \frac{L.a}{K.p}\,v^2$. If we take

$$\frac{L.a}{K.p} = n^1 \qquad h = n^1v^2 \qquad n^1 = \frac{h_1}{v_1^2} = \frac{9.6}{43.96} = .22.$$

Thus we get for equal values of v the difference $v\,(1.45 - .22\,v)$ which, for $o < v < 6.63$, is always greater than zero.

The assumption $h = n.v$ is right in so much as by the derivation of the principal equations the dampening influences of the friction and the water quantities in the surge tank were not considered.

We compute now the example assuming a complete shut-down, therefore $\epsilon = o$.

$$T = \sqrt{\frac{9050 \times 5380}{32.2 \times 80}} = 137.5 \text{ sec.}$$

$$T_0 = \frac{9050}{1.45 \times 32.2} = 194.5 \text{ sec} \qquad T_1 = 147 \text{ sec.}$$

$$R.\sin\beta = -(1-\epsilon)\,h_1 = -9.6 \text{ feet.}$$

$$R.\cos\beta = (1-\epsilon)\left(\frac{T_0}{T^2} - \frac{1}{2T_0}\right) h_1\,T_1 = 10.9 \text{ feet.}$$

$$R^2 \sin^2\beta = 92 \quad tg\beta = -\frac{9.6}{10.9} = -.881 \quad \beta = -41^\circ\,24'$$

$$R^2\cos^2\beta = 119$$

$$R^2 = 211 \qquad \text{arc}\,\beta = -.722$$

$$tg\gamma = \frac{2T_0}{T_1} = \frac{389}{147} = 2.65 \quad \gamma = 69^\circ\,18'$$

$$R = 14.54 \text{ feet} \qquad \text{arc}\,\gamma = 1.21$$

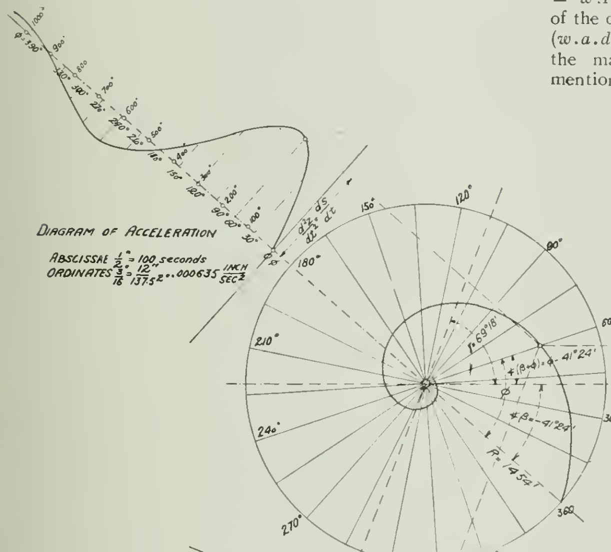
$$z = 14.54\,e^{-\frac{t}{389}} \sin\left(\frac{t}{147} - .722\right)^*$$

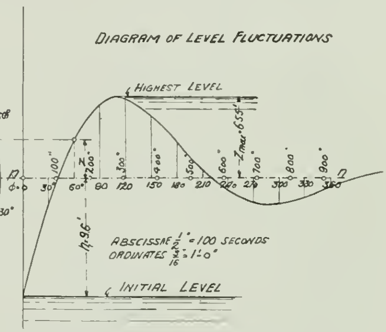
*The proportion t/T_1 is in radians, but must be changed into the usual measurements as soon as we use the trigonometric functions.

$$s = .106\, e^{-\frac{t}{389}} \sin\left(1.932 - \frac{t}{147}\right).$$

The values (in seconds) for the first occurrence of the maximum and minimum are

t_1 max $= (\gamma - \beta)\, T_1 = [1.21 - (-.720)]\ 147 = 284$ sec.
t_1 min $= (\gamma - \beta + \pi)\, T_1 = (1.93 + 3.14)\ 147 = 746$ sec.





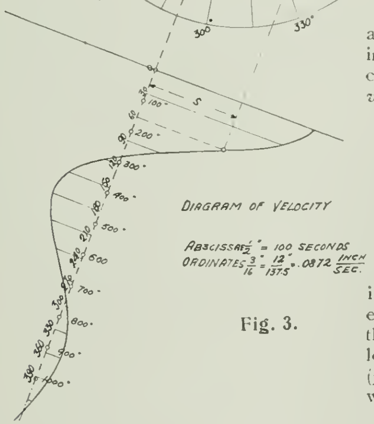


Fig. 3.

z max I. $= 6.55$ feet, $\quad z$ min II. $= -2.00$ feet,
$\delta = 2\pi T_1 = 924$ sec. $= 15$ min. 24 sec.

The graphical demonstration using these values shows very clearly the water level fluctuation in the surge tank in function of the time (Fig. 3 and Fig. 4).

(4) Work Done.—For the case of a sudden complete shut-down, it is interesting to strike a balance of the work done. The basis for such a balance may be secured by a variation of the principal equation 16, considering also the continuous equation 17. If we multiply the equation 16 by $(w.a.v\,dt)h$ we get

$$\frac{w\,a\,L}{g}\, v\,dv + (w\,a\,v.dt)\, z + (wavdt)h = o$$

$$\frac{w.a.L}{g} = M = \text{mass of the}$$

main conduit volume and for $\epsilon = o$, $w.a.v.dt$ becomes $= w\,A\,s\,dt = w.A\,dz = dG$, i.e., the increase of weight of the contents of the surge tank during the time dt. Also $(w.a.dt\,v)\ h = A^1 =$ to the amount of friction work in the main conduit during the time dt. The above-mentioned equation becomes

$$M\,\frac{dv^2}{2} + z\,d\,G + dA^1 = o$$

and the integration between the limits which refer to the initial condition and to the highest elevation for z max., considering that at the beginning $v = v_1$ and at the end $v = o$:

$$-\frac{Mv_1^2}{2} + \int_{-h_1}^{+z\max} z\,d\,G + A^1 = o \qquad (49)$$

We may place

$$\int_{-h_1}^{+z\max} z\,d\,G = G.z_1$$

if we consider G as the weight of the water that has entered the surge tank during that period and if z_1 is the distance of the centre of gravity of G above static level $n - n$. But we may as well say $z_1 = y_1 - h_1$ (50) (y_1 = distance of the centre of gravity of G from the initial water level). It follows then, that

$$\frac{Mv_1^2}{2} + G\,h_1 = G\,y_1 + A^1 \qquad (51)$$

This is the equation for the work done, which is correct also when the cross-section A is variable. As potential energy, we must introduce: (1) The kinetic force of the volume of the main conduit, and (2) The potential energy of the weight G due to the first difference of level h_1 between the elevation in front of the forebay, (i.e., the static level $n - n$) and the initial level.

As used work we must introduce:

(1) The lifting work due to the lift of the weight G through the height y_1.

(2) The friction work.

We may strike the balance in the following manner:

Useful work in foot-tons.		Used work	
15800	Kinetic Energy of the Conduit Contents		$\frac{62.5 \times 80 \times 9050}{32.2} \times \frac{6.63^2}{2}$
26600	Potential Energy of G = 2770 Tons for h_1 = 9.6 Feet		5380 (9.6 + 6.55) × 62.5 × 9.6
	Lifting Work for 2770 Tons for height of 8.07 Feet	22400	$\frac{16\ 15}{2} \cdot 2770$
	Friction work	20000	42,400 — 22,400
42400		42400	

The total friction work of 20,000 foot-tons corresponds to an average friction head corresponding to the conveyed weight of 2,770 tons.

$$h_1 \text{ (average)} = \frac{20{,}000}{2{,}770} = 7.22 \text{ feet} = .752 . h_1 \quad (52)$$

We might use this result to determine the necessary surge tank volume in a similar case, if in the equation 51 we write: A^1 is similar to:

h (average) . G which must be equivalent to $.752\ h_1 G$

A supplementary formula to determine the value h (average) follows in the final chapter.

Case B.—Sudden Opening.

Before the beginning of outflow through the penstock, the water in the main conduit and in the surge tank is quiescent. The water surface in the surge tank is at the level $n - n$ and z = zero. As soon as the opening occurs, which is considered as taking place instantaneously, the outflow begins. However, the full amount of the outflow does not occur instantaneously because of the inertia of the mass; also during the time following the opening, q will not be constant even with a constant opening, as with the variation of the water surface elevation the slope due to the outflow velocity also varies. As in case (A), where we assumed that all these influences and variations are a very small amount, we consider q as constant from the instant that the opening occurs.

The following will now happen at this juncture: Immediately after the opening the water surface in the surge tank goes down. The head, due to this difference between the water level in the main conduit and that in the surge tank, creates a movement in the main conduit, but on account of the inertia of the mass and the increasing friction, the velocity does not increase in the same proportion as the drop of the surface in the surge tank below the static level $n - n$. On this account the water surface in the surge tank goes below the level which corresponds to the normal water level for a constant flow. So that we have first a dropping down to a lowest level whereas afterwards there occurs a damped oscillation, until finally, under the influence of all resistances, a normal balanced condition is reached, where the level in the surge tank is as much under the level $n - n$ as the amount of head required to create the necessary slope.

The initial equation 23 has in this case (if we say $q = \epsilon Q_1$ for purposes of comparison) the same form as in case (A) and therefore all other equations (growing out of equation 23) also apply. The determination of the integration constant will, however, give other values for R and β since the initial condition is different. We have at the time t = zero, z = zero, and $s = s_0 = -\frac{Q_1}{A}\epsilon = -\epsilon . C_1$. For the determination of the constants R and β we get the equations:

$$R . \sin\beta = +\epsilon h_1; \quad R\cos\beta = -\epsilon\left(C_1 - \frac{h_1}{2\,T_0}\right) T_1 \quad (53)$$

The same procedure as in case (A), referring to the signs of $\sin\beta$ and $\cos\beta$, shows in this case that β lies in the second quadrant, if $\frac{A}{a} < \frac{2\,L}{n^2 g}$, and in the first quadrant when $\frac{4\,L}{n^2 g} > \frac{A}{a} > \frac{2\,L}{n^2 g}$.

We get, further,

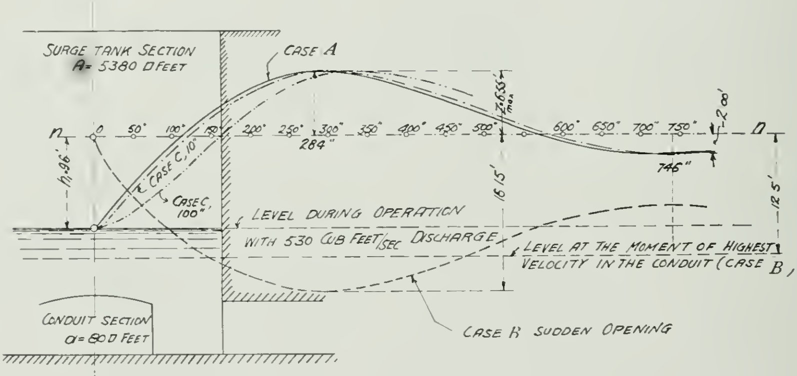

Fig. 4.

$$R = \epsilon h_1 \frac{T_1 T_0}{T^2} \quad tg\,\beta = -\frac{1}{T_0/T_1 - \frac{1}{4}\,T_1/T_0} \quad (54)$$

If we open the penstock so that the outflow has the full value $q = Q_1$ ($\epsilon = 1$) then R assumes the same value as in case (A) for a complete shut-down. β has in both cases the same form, therefore, (referring to the above-mentioned investigations) it follows that the initial radius vector in the polar co-ordinate system for the case (B) is turned through 180° from case (A). The duration of the period is the same as in case (A). The graphical demonstration may be begun also from the same spiral with the slope $tg\,\alpha = -T_1/2T_0$. The analytical results (assuming a full opening from zero to 530 cubic feet per second, that is, $\epsilon = 1$, $n = 1.45$ sec., assuming the same dimensions) are as follows:

$T = 137.5$ sec. $T_0 = 194.5$ sec. $T_1 = 147$ sec.
$R = 14.54$ feet $\beta = 180 + (-41^\circ\,24') = 138^\circ\,36'$
arc $\beta = +2.420$

$$z = -9.6 + 14.54\,e^{-t/389} \sin(2.42 + t/147)$$

$\gamma = 69^\circ\,18'$ arc $\gamma = 1.210$

$$s = .106\,e^{-t/389} \sin(-1.21 - t/147)$$
$$= -.106\,e^{-t/389} \sin(1.932 - t/147)$$

Therefrom we determine the time for the first minimum of z

t_1 min $= 1.932 \,.\, 147 = 284$ sec.

and for the first maximum:

t_1 max $= (1.932 + 3.142)\;147 = 746$ sec.

These are the same values as were reached before for the occurrences of the first maximum and minimum. Finally follows

$z^1_{min} = -9.6 - 6.55 = -16.15$ feet;
$z^1_{max} = -7.6$ feet.

As z^1 max is negative, we see that with the assumed dimensions and for full opening to 530 cubic feet-seconds, the water surface does not rise any more above the level $n - n$ after the first dip. (Fig. 4.)

The velocity in the main conduit at the time of the greatest drop becomes $v_1 = Q_1/a$ but the velocity increases continuously thereafter, as in the following period of rise of the water surface, besides the outflowing quantity Q, also that water from the main conduit which is necessary for the refilling of the surge tank has to flow in. And the increase lasts until v becomes a maximum. Because $v.a = s\,A + Q_1$ the velocity v becomes a maximum if s is a maximum and we get:

$$s \text{ max} = \frac{R}{T}\,e^{-\frac{\pi T_1}{2\,T_0}} .\sin\gamma = .03 \text{ feet per second.} \quad (55)$$

$$v \text{ max} = \frac{A}{a} \,.\, s \text{ max} + v_1 = 8.65 \text{ feet per second.}$$

The conclusion of practical value is that the greatest drop below the static level $n - n$, resulting from a sudden full opening, reaches the same value as the greatest rise from the initial level for a sudden full shut-down.

(To be continued.)

DESIGN OF INTERCEPTERS FOR A LARGE SEWERAGE SYSTEM.

THE recently issued progress report on the plan of sewerage for the City of Cincinnati contains a number of important solutions to problems typical of those to be found in large sewerage systems. The report, to which we have previously called the attention of our readers, is most complete in that it contains all data used in connection with the development of the system and the projected improvements.

One of the outstanding sections is that descriptive of the design of the new intercepting sewers. This section was prepared by Mr. E. J. Miner. The designs were worked out under Mr. Victor T. Price, Director of Public Service, and Mr. Henry M. Waite, chief engineer. Mr. H. S. Morse was engineer in charge of all sewerage investigations and Mr. H. P. Eddy was consulting engineer.

The following study of the Cincinnati requirements

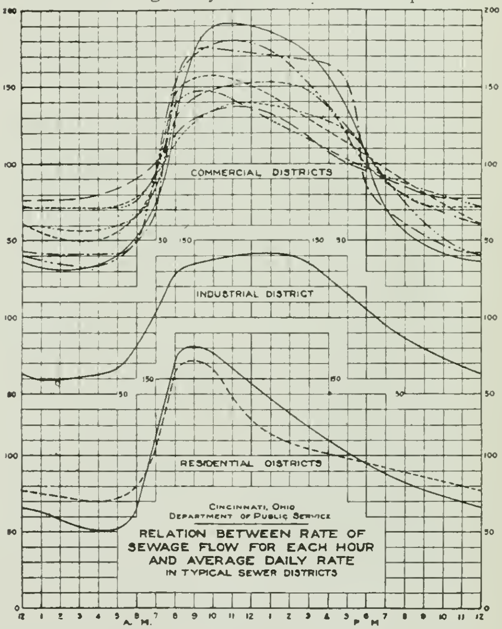

Fig. 1.

and of the resulting design will undoubtedly be found of considerable service.

General Problem.—The present sewerage system consists of a large number of disconnected sewers, each serving a limited district. In some cases these districts are very small; in others, very large. Each sewer has been constructed to discharge into the nearest water course thought adequate to take away the sewage. Nearly all of the existing sewers are built on the combined system, during dry weather the sewers discharging domestic sewage into the streams and during storms, street washings and roof water, combined with the sewage.

In the case of districts adjoining the Ohio River this method of discharge has not in general proved objectionable. As a rule, the trunk sewers empty into the river below the water level, so that, except in the immediate vicinity of the outlet, the fact that sewage is being discharged into the river is hardly noticeable. In the case

of the small streams flowing through the city, however, conditions are very different. During dry weather these streams carry very little water, and the result is that the sewage flow constitutes a sufficient percentage of the water flowing in the streams to be noticeable and offensive. Stagnant pools of putrifying sewage are not uncommon, and during the dry months these streams are a menace to the health of the community. At times of storm the accumulated sewage is flushed out and carried to the Ohio River.

With the exception of the sewers discharging into the Ohio River, practically all of the sewage of the city is discharged into Mill Creek and its tributaries and Duck Creek. These two streams receive at least 65 per cent. of the sewage of the city, and are accordingly in very bad condition.

It is necessary to provide intercepting sewers to receive the sewage from the trunk sewers and to convey it to a suitable point of disposal. These intercepters were designed not only to receive sewage from the existing and future sewers, but to convey it to a point where it may be discharged without offense, or treated in such a way that the resulting effluent may be discharged into the streams.

There are at present a few sewers which are called intercepters and which serve to some extent as intercepting sewers. They receive the dry weather discharge of one or more sewer districts and convey it to a point where the stream flow is assumed to be greater, so that the dilution of the sewage is more thorough. These sewers will serve as branches to the main intercepters which will be required in any comprehensive scheme.

Disposal by dilution will be sufficient for the present. It may be, however, that ultimately the discharge of untreated sewage into rivers and streams will be prohibited by law, and to fulfil sanitary requirements it will be necessary to treat all sewage before its discharge into streams. Accordingly, the intercepters have been designed with a view to the ultimate collection of the sewage at suitable sites for such treatment as it may require.

Collection of Sewage.—Intercepting sewers following in a general way the course of the streams into which the trunk sewers now discharge will be necessary to collect the sewage from the several sewer districts. It is obvious that three main intercepters or systems of intercepters will be required: one in Mill Creek Valley, one in Duck Creek Valley and one following the bank of the Ohio River.

In such a case as the Mill Creek Valley it is sometimes practicable or desirable to construct two or even three intercepters. For instance, conditions might make it desirable to build high level intercepters at the edge of the high land on both sides of the stream, each of which would intercept the greater part of the sewage tributary to the stream from its side. The third intercepter, which might not be needed if the valley below the high land were not developed, would closely adjoin the stream and would receive the sewage from the districts lying below the high level intercepters. Such a project is particularly desirable where pumping the sewage is necessary, in order to collect as much of the sewage as possible at a high level and thus reduce the amount to be lifted or the height to which it must be pumped. This method was not found practicable for Cincinnati, and it is planned to construct a single main intercepter closely adjoining Mill Creek, a similar one near Duck Creek and a third along the bank of the Ohio River.

Economic Period of Design.—In designing intercepting sewers it is obviously necessary to make provision for a reasonable amount of growth in order that they may not be soon outgrown. It is also necessary, first, that engineering works should not be constructed on too large a scale, so that they cannot operate efficiently under present conditions, and, second, that expense of construction for future requirements should not be so great that the burden of debt imposed at present becomes unreasonable. It may readily be seen that in some cases the saving of expense resulting from providing works sufficient for the present may be sufficient amply to provide for the additional construction that may be made necessary when larger works are needed.

The economic period for which provision should be made in the design of intercepting sewers depends on various conditions, among which the rate of growth of

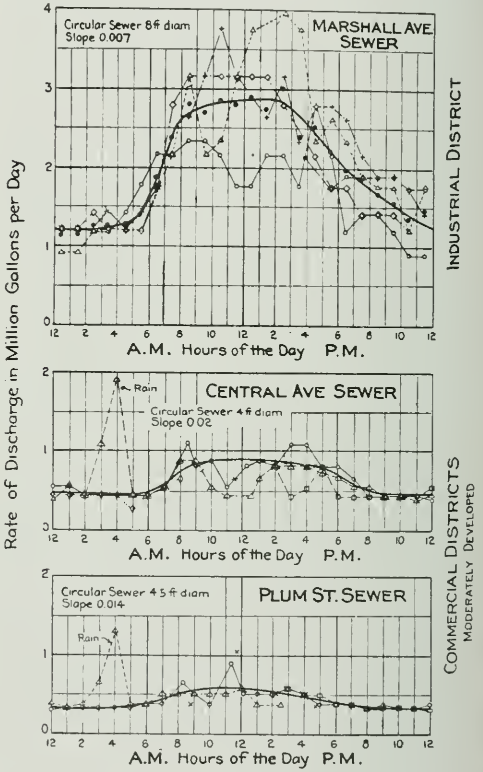

Fig. 2.—Hourly Variation in Rate of Sewage Flow in Commercial and Industrial Districts.

the city is one of the most important, and is a condition which cannot be absolutely fixed. In general, it is desirable to provide for a period ranging from 30 to 50 years from the date of design. In the present study it has been concluded that approximately 40 years is a suitable period for which to make provision and, rounding off the figures, designs have been made on the basis of the requirements of the year 1950.

Area.—From 1802 to 1848 the area of Cincinnati was three square miles. Various small areas were annexed from time to time until, in 1910, the total area was approximately 50 square miles. During 1911 an area of over 16 square miles was annexed to the city and in 1912 the

area annexed was about 3.5 square miles, bringing the total area of the city up to about 70 square miles.

After due consideration it has been decided to base the design of the comprehensive system of sewers upon an estimated future area of about 140 square miles.

Population.—Cincinnati has had an exceptionally slow rate of growth, but the natural advantages, its location and the enterprise of its citizens would seem to warrant the opinion that a more rapid growth will occur in the future. Careful consideration of the data which has been accumulated in connection with this study, and of the local conditions, leads to the conclusion that a comprehensive system of sewers designed at the present time for a period of about 40 years in the future should be based upon a future population of about 720,000 persons and a rate of growth averaging from 20 per cent. per decade in the immediate future to 17 per cent. per decade 40 years hence. The population of the city at the end of each decade, should this estimate prove correct, will be: 1920, 440,000; 1930, 520,000; 1940, 615,000; 1950, 720,000.

By basing the designs for a sewerage system upon these estimates provision is made for a future population approximately twice as great as that of Cincinnati at the present time.

As a basis for computing the quantity of sewage to be provided for by the intercepting sewers, the estimated future population was distributed among the several sewer districts.

The boundaries of each voting precinct and of the several sewer districts were plotted upon a map, scale of 1,000 ft. to 1 in. By combining the populations in the several precincts and parts of precincts within a given sewer district the total population now residing in each sewer district was determined. In determining the density of population in the various districts allowance was made for unpopulated areas, as parks, cemeteries and railroad yards, by deducting these areas from the area of the district.

Table I.—Density of Population, City of Cincinnati, 1850-1950.

Year.	Population.	Area, sq. miles.	Density, persons per acre.
1850	115,435	6.16	29.3
1860	161,044	6.93	36.3
1870	216,239	19.05	17.7
1880	255,139	23.53	16.9
1890	296,908	23.73	19.6
1900	325,902	35.27	14.5
1910	364,463	50.26	11.3
1912	380,305	69.85	8.5
1920	440,000	82.45	8.3
1930	520,000	99.30	8.2
1940	615,000	119.35	8.1
1950	720,000	141.50	8.0

The areas of the sewer districts vary greatly, the small districts for the most part being those which are directly tributary to the Ohio River and in the older portion of the city. The area of the smallest district is 10.5 acres, while that of the largest well-sewered district is 4,068.7 acres. The present density of population varies from 0.2 person per acre to 104 persons per acre. The estimated future density of population varies from 0.4 person per acre to 110 persons per acre. This is considered to be a liberal basis for the design of the intercepting sewers, as the deficiencies of some districts will offset the excesses of others; but where individual sewer systems are to be designed a more liberal allowance for future growth should be made, because no such compensating conditions can be relied upon for the relatively small sewer districts.

Main Drainage Districts.—The city may be naturally divided into three main drainage districts, that served by Mill Creek, that draining directly into the Ohio River, and that served by Duck Creek; to which should be added two small areas within the estimated future city limits, one of which is naturally drained by Rapid Run and Muddy Creek, and the other by Sycamore Creek. It appears that provision has been made for an estimated future population of over 300,000 persons in Mill Creek Valley and approximately an equal number in the Ohio River District, and that the estimated future population in the Duck Creek Valley is nearly 100,000 persons.

Classification of Future Area of City.—The quantity of sewage contributed from residential areas is much less than that from industrial and commercial areas. To arrive at a reasonable basis of design, a study was made to determine the proportions of the city which in the future will be devoted to residential, industrial and commercial purposes, and to parks and cemeteries. From the last two the quantity of sewage for which provision should be made is very small, being made up chiefly of ground water. As hereinbefore stated, it has been assumed that the area of the city in 1950 will be approximately 140 square miles. With the aid of the opinions expressed by representatives of local real estate firms an estimate has been made of the probable limits of the industrial and commercial areas. The distribution of the area within the assumed limits of Cincinnati as of 1950 is as follows:

Area.	Square miles.	Percentage.
Industrial	12.79	9.04
Commercial	1.13	0.80
Residential	123.30	87.11
Cemetery and park	4.02	2.83
Railroad yards	0.31	0.22
Total	141.55	100.00

Quantity of Sewage to be Handled by the Intercepting Sewers.—The system of intercepting sewers was designed to receive and convey to a point of discharge all of the sewage contributed in 1950 by the several district sewers with which they connect, at times when storm water is not actually running into the city sewers. It is therefore important that the intercepters be large enough to carry the maximum quantity of sewage collected by the trunk sewers. This quantity will vary from hour to hour, from day to day and from season to season. In the spring, when the ground water is high and relatively large quantities of it seep into the sewers, the quantity collected will be large and the intercepters should have sufficient capacity to convey it to the point of discharge. It is not intended, however, to provide capacity in the intercepters for any substantial quantity of actual storm water, the plan being to provide overflows from the trunk sewers, so that when the capacity of the intercepters is reached the excess flow may discharge directly into the neighboring water-courses.

When first constructed the intercepters will have a surplus capacity, intended to provide for the expected increase in area and population of the city, which may be utilized to carry small quantities of storm water so that overflow from the trunk sewers will not take place quite as frequently as in later years, when the normal flow of sewage has reached approximately that for which the in-

tercepters have been designed. The quantity of sewage collected varies greatly from hour to hour, as the report shows by numerous curves of hourly variation in rate of sewage flow in the various districts. It also varies materially from day to day during the week, the smallest quantity usually being produced on Sundays and holidays and the maximum quantity as a rule on Mondays. The quantity of sewage from commercial districts is greatest during business hours, as indicated, Fig. 1.

The quantity of industrial waste fluctuates, depending upon the character of the industry, the condition of business and the hours of work. Paper mills are usually operated throughout the 24 hours, so that the rate of discharge of their wastes is generally fairly uniform from hour to hour. Packing houses, tanneries and woollen mills, on the other hand, are usually operated from 7 a.m. to 6 p.m., except for one hour at noon, and the discharge from such plants is therefore largely confined to those hours. In some industries, however, the processes employed are such that the wastes are discharged by the emptying of vats or otherwise, so that the discharge takes place intermittently, with corresponding fluctuations in the rate of flow.

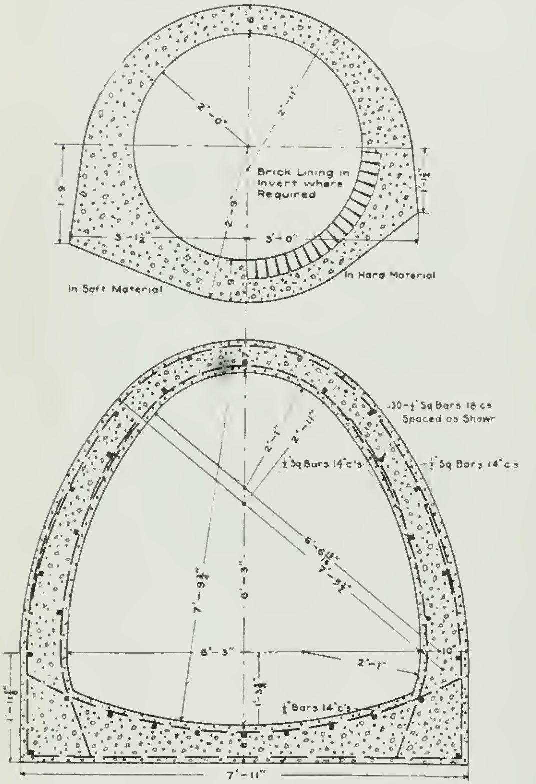

Fig. 3.—Typical Circular and Semi-Elliptical Sections.

The quantity of ground water which finds its way into the sewers varies in a general way with the variations in rainfall. Usually a hard and long-continued rain is followed by a material increase in the flow of sewage, due to infiltration of ground water. In the spring when the frost is coming out of the ground, leaving it more porous than at other seasons of the year, considerable surface water finds its way into the earth, so that the rate of infiltration into the sewer system is then usually much higher than during other seasons. The least quantity of ground water seeps into the sewers during seasons of extreme drought, or during the winter when the ground is securely sealed by frost.

In order that the intercepting sewers may perform their functions it is necessary that they shall have sufficient capacity to carry the sewage, not only on the day and at the hour when the normal flow of sewage is greatest, but also at times when the discharge of wastes from the commercial districts is highest, when the discharge from the industrial districts is a maximum, and also in the spring of the year when the infiltration of ground water is greatest. These maximum quantities may all occur at the same time, so that they must all be taken into consideration in determining the size of the sewers. At the same time it is important not to lose sight of the fact that the maximum rate of flow in the intercepter at any point is not the sum of the maximum rates of discharge of all the contributing trunk sewers.

Ordinarily the maximum discharge from trunk sewers occurs between the hours of 10 a.m. and 2 p.m. If the intercepter is so long that several hours are required for sewage discharged into it at its upper end to reach the point of discharge of the last trunk sewer, near its lower end, the maximum discharge from the lower sewer will have left the intercepter before the maximum discharge from the upper sewer has reached the lower point. In other words, there is a tendency for the peak flows in the several contributing trunk sewers to compensate each other, and on this account the rate of flow in an intercepting sewer is always more uniform than the rates of flow in the contributing trunk sewers. For example, the maximum rate of flow in one Vine Street sewer on a certain date, was 179 per cent. of the average for the 24 hours, whereas it is to be expected that the maximum rate of flow in the Ohio River intercepter, into which that sewer will discharge, will not ordinarily exceed 135 per cent. of the average flow for 24 hours.

Quantity of Sewage from Residential Areas.—The quantity of sewage collected by a system of sewers serving a strictly residential district depends upon the quantity of water used and discharged into the sewers and upon the amount of ground water seeping into them. It is therefore important to take into consideration the consumption of water, as well as to measure the flow of sewage in trunk sewers serving large residential areas in which there are no manufacturing and substantially no commercial districts.

The flow in two such trunk sewers has been measured. It was not practicable to place weirs in either of them, and it was therefore necessary to make measurements of the depth at frequent intervals of time and to compute the quantity from these measurements. These computations have been made by Kutter's formula with $n = 0.015$.

All of the measurements were tabulated and for each sewer the several observations made at the same hour of each day were averaged and smooth curves were drawn to represent these averages. It is believed that these conventional curves represent with reasonable accuracy the rates of flow which may be expected at any hour of the day, between Monday noon and Saturday night, of any week during which the ground water is low and no storm water is reaching the sewers. Similar diagrams in which the rates of flow are shown in terms of per cent. of the

average rate for the twenty-four hours were made from the conventional curves, and are included in Fig. 4.

The measurements of the quantity of sewage produced by the two residential areas showed averages of 92 and 80 gals. per capita per day, respectively, while the maximum rates were 157 and 128 gals. per capita, respectively.

Water Supply.—Very complete records of the quantity of water consumed have been kept by the Water Department. A table was prepared showing the total quantity of water consumed, the quantity of water per capita, the number of services, the number of meters in use and the per cent. of services metered, together with the census, or estimated population served for the years specified. In 1912 47.6 per cent. of the water services were metered.

From the data so compiled it appears that in the last 23 years the minimum daily rate of water consumption was 114.5 gals. per capita in 1890, that the maximum rate was 154.01 gals. per capita in 1895; and the average daily rate for the last 23 years was 130.6 gals. per capita.

During recent years an effort has been made to increase the proportion of services metered so as to check the waste of water, the experience of other cities proving that by the use of meters the quantity of water consumed can be held down to reasonable figures. In Cincinnati the consumption has been considerably higher than in a number of other large cities, but while the tendency of the times is toward a greater per capita consumption, it is expected that if a large proportion of the services are metered the daily rate of consumption will not materially exceed that of the present time, which may be fairly taken to be 125 gals. per capita. It is possible that this rate might be somewhat reduced, possibly to as low a rate as 100 gals. per capita daily. Taking into consideration, however, the tendency towards greater consumption, it does not seem wise to plan for a period of 40 years in the future without allowing for some increase. In these studies it has therefore been assumed that the daily consumption will ultimately, and within the period for which the intercepting sewers are designed, reach 150 gals. per capita.

It is commonly thought that practically all of the water supply eventually reaches the sewers. This, however, is a fallacy, for a very considerable part, probably not less than 40 per cent., is disposed of in other ways. It is evident that the water used for steam purposes, much of that used for manufacturing and mechanical purposes, that used by street and lawn sprinklers and the leakage from mains and services, as well as that used by water consumers not connected to the sewers, fails to reach the sewers.

An estimate of the quantity of water used for these several purposes in Milwaukee was made by the Milwaukee Sewage Disposal Commission in 1911 as follows:

Purposes.	Gals. per capita per day.	Per cent. of total consumption.
Steam railroads	5	4.76
Manufacturing and mechanical	5	4.76
Street sprinklers	5	4.76
Lawn sprinklers	2½	2.38
Consumers not connected to sewers	7½	7.14
Leakage from mains and services	15	14.28
Totals	40	38.08

The percentage of the water used for these purposes in Milwaukee was based upon a total average daily consumption of 105 gals. per capita. Applying the same percentage in Cincinnati, it would appear that the quantities of water given in Table II. would be used for the several purposes indicated in the years 1912 and 1950, respectively.

With an assumed daily use of water of about 150 gals. per capita, 56 gals. of which do not reach the sewers, it has seemed reasonable to take the average quantity of domestic sewage exclusive of ground water, at 90 gals. per capita per day and the maximum rate at which it will reach the intercepter at 135 gals. per capita per day. These estimates seem to be justified by the determinations of the daily flow of sewage in the Mitchell Avenue and Ross Run sewers, which were 80 and 92 gals., respectively, with maximum rates of 128 and 157 gals., respectively, per capita.

Quantity of Sewage from Commercial Districts.—The commercial district in Cincinnati is unusually well defined, and it is served by a number of parallel sewers, each draining a relatively small district, it was deemed wise to make measurements of the flow so that an intelligent estimate might be made of the quantity of sewage which will have to be taken into the intercepting sewers.

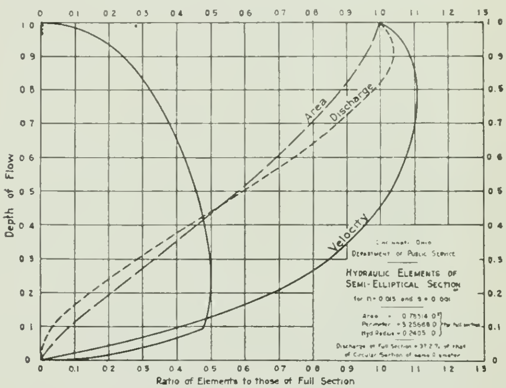

Fig. 4.—Hydraulic Elements of Semi-Elliptical Section (Fig. 3).

Accordingly, measurements were made of the flow in some of the sewers, each of which is between 3,000 and 3,500 ft. in length and serves an area of approximately 35 acres. Several of them, although in the commercial district, have large resident populations. The measurements of the rate of flow of the sewers serving commercial districts were made during the extremely dry season, and it has been assumed that the infiltration of ground water at the time the measurements were made was negligible.

Of the total area of 227.2 acres in the commercial sewer districts gauged, certain districts, with a combined area of 169.3 acres may be considered as highly developed. In these districts will be found hotels, high-class office buildings, department stores and public buildings, with relatively few apartment houses. The streets are paved with asphalt and granite blocks. Other districts, comprising an area of 57.9 acres, may be classed as moderately developed. In these districts will be found smaller hotels, smaller stores, wholesale houses and second-class business blocks, with a considerable proportion of tenement houses. A further area of 133 acres is considered as a semi-commercial area lying around that moderately developed.

The estimation of maximum rate of sewage flow from commercial areas (in addition to sewage contributed by

the resident population, and not including ground water) has been made as follows:

The average of the maximum rate of flow for the six "highly developed" districts above mentioned is 81,508 gals. per acre daily (maximum points taken from conventional curves), which may be taken to fairly represent the maximum flow of sewage per acre from these districts if combined. The area is 169.3 acres, so that the maximum rate of discharge would be 13,800,000 gals. per day. The resident population is 4,744, and the maximum rate of flow of domestic sewage corresponding to this population at 135 gals. per day per capita would be 640,000 gals. per day. The difference, 13,160,000 gals. per day, is taken to represent the maximum rate of sewage flow due solely to the commercial development of the district, equivalent to 77,700 gals. per acre daily.

Table II.—Estimated Quantities of Water Used, But Which Do Not Reach Sewers.

Purposes.	Gals. per capita per day based on total consumption of 125 gals., 1912	Gals. per capita per day based on total consumption of 150 gals., 1950	Per cent. of total consumption
Steam railroads	6	7	4.76
Manufacturing and mechanical	6	7	4.76
Street sprinklers	6	7	4.76
Lawn sprinklers	3	3½	2.38
Consumers not connected to sewers	9	10½	7.14
Leakage from mains and services	18	21	14.28
Totals	48	56	38.08

In the same way the average of the maximum rates of flow for the two moderately developed districts is found to be 26,025 gals. per acre daily, equivalent to a maximum rate of flow of 1,510,000 gals. per day from 57.9 acres. Domestic sewage at a maximum rate of 135 gals. per capita per day for a population of 2,810 corresponds to a maximum rate of 380,000 gals. per day, leaving 1,130,000 gals. per day as the maximum rate of flow from the purely commercial district. This corresponds to 19,500 gals. per acre daily.

No data exist to indicate the commercial sewage which may be contributed from the 133.3 acres of commercial area which is as yet largely undeveloped. It has been assumed that the maximum rate of flow of commercial sewage from this area may be taken as 12,000 gals. per acre per day.

Assuming that the relative proportions of highly developed, moderately developed and substantially undeveloped area will remain practically unchanged, the average maximum rate of sewage discharge from commercial area, due solely to their use for commercial purposes, has been estimated as equivalent to 44,000 gals. per acre daily; or, in round figures, 40,000 gals. per acre daily in addition to domestic sewage from the resident population and ground water.

From the estimated future commercial area of 721 acres the maximum rate of flow has been computed on the basis of 40,000 gals. per acre per day for commercial sewage; 750 gals. per acre per day for ground water, as hereinafter explained, and 135 gals. per capita per day for domestic sewage.

Quantity of Sewage from Industrial Areas.—As certain portions of the city are and will continue to be devoted to industrial enterprises from which large quantities of liquid wastes will be discharged into the sewers, an effort has been made to secure data which might aid in forming an estimate of the quantity for which provision should be made in the intercepting sewers.

It should be noted that there is always a tendency for certain classes of industrial planks, such as packing houses, dairies and the like, to discharge into the sewers large quantities of solid or heavy semi-fluid wastes. Precautions must be taken to prevent the entrance of such matter into the intercepting sewers, if necessary, by requiring all such plants to maintain settling tanks upon their branch sewers.

It is extremely difficult to determine the quantity of wastes which will be discharged from an area devoted to industrial purposes, as the amounts produced by manufacturing establishments vary enormously and because such an area is also developed for residential purposes to a considerable extent. Actual measurements were desired and were made for four districts which were selected for that purpose.

The Marshall Avenue District is probably more nearly a typical industrial area than any of the others, although the quantity of wastes per acre discharging into the sewers is probably greater than is to be expected from the industrial areas of the city as a whole. The conventional curve and other data for the district are shown in Fig. 2.

The effect of the industrial wastes in increasing the per capita rate of flow in this district is clearly shown by comparing the average rate of 363 gals. per day with that obtained in the residential district, where the average quantity of sewage was found to be 80 and 92 gals. per capita per day respectively.

Quantities of Industrial Wastes.—In connection with the studies of the purification of sewage, a careful census of the industrial establishments of the city and of those lying north of the city in Mill Creek Valley has been taken. The quantity of water used in the several industries obtained from the canal, wells and other sources, and the quantity obtained from the municipal water supply, together with the estimated quantities of liquid wastes, were tabulated.

Nearly all the industrial plants are located in Mill Creek Valley and the McLean Avenue Sewer districts. The industrial water consumption in this region amounts to about 17,000,000 gals. per day. Not all the water so used is discharged in the form of wastes. The total amount of these wastes is estimated at 16,000,000 gals. per day, which is equivalent to 5,500 gals. per acre daily, the area under discussion being approximately 2,900 acres.

In view of the fact that nearly all of the plants run but 10 hours per day, the maximum rate of discharge of industrial wastes has been estimated on the assumption that 75 per cent. of these wastes are discharged at a uniform rate during these 10 hours. The corresponding maximum rate of flow is 9,900 gals. per acre daily.

Similar estimates of the quantities of industrial wastes from smaller manufacturing districts tributary to the Ohio River show quantities equivalent to 6,000, 1,100 and 2,350 gals. per acre per day, the corresponding maximum rates of discharge being 10,800, 2,000 and 4,200 gals. per acre per day, respectively.

Giving due weight to the extent and the character of the development of the several districts, it is believed that a fair estimate of the maximum rate of discharge of industrial wastes into the intercepters is 9,000 gals. per acre per day. This quantity is assumed to be in addition to the domestic sewage from the resident population and the ground water.

Ground Water.—The quantity of ground water which reaches the sewers depends on the rainfall, the character of the soil and upon whether the sewers and their connecting drains are well or poorly built. Many of the older sewers were laid without precaution to prevent the infiltration of ground water, which even under the best conditions cannot be entirely avoided. The quantity of ground water thus entering the sewers, as previously explained, varies greatly from time to time and is usually highest after rains in the spring of the year.

It has been assumed, as previously explained, that a great increase in the area of the city will take place during the next 40 years. The estimated density of population over this large area is relatively small, being but eight persons per acre, whereas the density of population in a number of other large cities of this country is found to be from 15 to 25 persons per acre. The small number of persons per acre makes it evident that the number of miles of sewers per square mile of area is likely to be relatively small.

The report of the United States Census Bureau upon Statistics of Cities for 1907 contains data from which the number of miles of sewers per thousand inhabitants in cities having populations of more than 30,000 can be derived. From this information it appears that a well-sewered city of 720,000 persons should have about 900 miles of sewers, and it has therefore been assumed, in estimating the quantity of ground water to be provided for, that there will ultimately be that length of sewers contributing to the intercepters. Numerous measurements and estimates of the infiltration of ground water into sewerage systems indicate that 75,000 gals. per mile of sewer is a reasonable daily maximum. It has therefore been assumed that the total quantity of ground water which will eventually reach the intercepting sewers will be 67,500,000 gals. per day, from an area of 140 square miles, equivalent to 750 gals. per acre per day. This unit has been used in computing the quantity of sewage likely to reach the intercepters from each of the several sewer districts.

Storm Water.—It will be noted that in the foregoing discussion of quantity of sewage there is no allowance for storm water. In other words, when the city shall have attained the degree of development herein estimated as probable in 1950, if the quantities of domestic, commercial and industrial sewage and ground water correspond to the estimates, the intercepting sewers designed to take those volumes of sewage will flow full at the time of maximum sewage flow, and there will be no surplus capacity for storm water at that time.

Even then the flow of sewage would not fill the intercepters except during hours of maximum flow, so that during perhaps half of the day there would be a small surplus capacity. The first, and therefore the foulest, run-off from storms occurring at such times could therefore be taken into the intercepters.

The maximum rate of sewage flow estimated for the present time is but little more than half that to be expected in 1950, and after adding the ground water there would still be available at the present time about one-third the capacity of the intercepter at times of maximum average flow. That is to say, storm water could be received up to a quantity approximately equivalent to one-half the maximum rate of flow of sewage and ground water. Thus the first storm water flowing off from the streets and roofs would be conveyed with the sewage to the point of ultimate disposal.

As the years go on the surplus capacity available for storm water would grow less, until ultimately the maximum sewage and ground water flow would fill the intercepters, as stated above.

At the points where the combined sewers discharge into the intercepters adequate storm water overflows must be provided to convey to the nearest watercourse the excess storm water beyond the quantities which the intercepting sewers may be able to receive. The subject of storm water overflows and sewage flow regulators will be discussed in a subsequent article.

Specific Data on Adopted Designs.—Sections—Two forms of cross-section will be employed on the new intercepters, namely, circular and semi-elliptical. The circular type will be used for sections 5 ft. in diameter and less. On all larger sections the semi-elliptical section will be used. In the larger sewers this latter section has the advantage of economy, since the quantity of concrete and excavation are both somewhat less than for a circular section of the same capacity. This type of section is more satisfactory structurally, also, since the flatter invert is more easily built than a large circular invert, and the reinforcing steel is more easily placed. Typical sections of both types are shown in Fig. 3 and the relations of the several hydraulic elements involved in the calculation of flow in the semi-elliptical section are shown in Fig. 4.

Profiles.—The elevations of the several trunk and branch sewers which must discharge into the intercepter govern its elevation and slope, at least within somewhat narrow limits. The design for the Mill Creek intercepter has been made with the requirement that there shall be a scouring velocity of not less than 3½ ft. per second when the sewer is flowing full, and when the discharge is not retarded by high water at the outlet.

Conditions are complicated in the case of Mill Creek intercepter by the frequent high-water stages of the Ohio River. Whenever the river reaches or passes the 20-ft. stage on the Broadway gauge the effect of back water will begin to be felt in the intercepter, and when the river reaches the 30-ft. stage, if not before, the lower portion of the intercepter will be entirely submerged, and much, if not all, of the sewage will then be discharged through the storm overflows into Mill Creek.

When the velocity of flow is checked by the rise of the river deposition of silt will occur in the intercepter. It is desirable that when the river falls again as high velocities as are reasonably possible be obtained to scour out the accumulated deposits.

The average number of days per year when the Ohio River has been at or above any given elevation indicates that there have been on an average 122 days per year when the flow in the Mill Creek intercepter would be checked, and 53 days per year when it would be almost entirely suppressed in the lower section, these periods corresponding to the 20- and 30-ft. stages of the river, respectively.

The Mill Creek intercepter is 4 ft. in diameter in its smallest section. For this section the slope is 0.0015, and this slope continues until a size of 5 ft. 9 ins. is reached, where it changes to 0.0010. At the 7 ft. 3 in. section the slope again changes to 0.0006 and continues at that rate to the outlet where the size of the section is 8 ft.

The Duck Creek intercepter is below the bed of the creek throughout its course and is therefore low enough to receive the tributary trunk sewers without difficulty. The outlet is well above the level of extreme high water in the river and consequently the intercepter will not be

affected by fluctuations of river stage. This sewer ranges in diameter from 2 to 4 ft. and in slope from 0.0052 to 0.0012.

When built, the Ohio River intercepter will be substantially parallel to the Ohio River to intercept the present and future trunk sewers which would otherwise discharge directly into the river. No direct comparison of the several projects for the Ohio River intercepter is possible, since none of the projects is complete without the inclusion of the corresponding scheme for sewage treatment and a definite plan for sewage treatment will not be adopted for several years to come.

Unit Prices.—In all estimates of cost, except those made in connection with the studies of sewage treatment plants, the following unit prices have been used:

Excavation (including refill, sheeting, pumping) for trench with bottom width of 8 ft. and less, per cu. yd.	$ 1.25
Excavation (including refill, sheeting, pumping) for trench with bottom width more than 8 ft., per cu. yd.	1.00
Plain concrete masonry, per cu. yd.	10.00
Reinforced concrete masonry in sections from 5 ft. 3 ins. to 8 ft. 3 ins. diameter, inclusive, per cu. yd.	15.00
Reinforced concrete masonry in sections greater than 8 ft. 3 ins. diameter, per cu. yd.	14.00
Duck Creek outfall sewer, 45-in. section in tunnel, complete, per lin. ft.	27.00
Mill Creek outfall sewer, 8-ft. section in tunnel, complete, per lin. ft.	55.00
Manholes, per lin. ft.	6.00

ASPHALT PRODUCTION IN TRINIDAD.

The production of asphalt in Trinidad constitutes the chief source of mineral wealth of the colony. At Brighton the company which has the exclusive right to dig for asphalt on Government lands has built a jetty capable of accommodating ocean steamships. It also has extensive works for handling the crude asphalt and refining it. This company has also acquired large petroleum concessions in the neighborhood of the "Pitch Lake" and is now exploiting them on an extensive scale. The quantities of asphalt exported from 1910 to 1912 are given in the Chamber of Commerce Journal as follows:—

	1910. Tons.	1911. Tons.	1912. Tons.
Crude	143,249	149,844	155,908
Pure	15,734	19,283	20,169

The United States was the largest purchaser of Trinidad asphalt in 1912, receiving about 55 per cent. of the total amount exported; whereas the United Kingdom imported only 16 per cent., Germany 13 per cent., and Holland 8 per cent., the remainder going to different countries in small quantities. Mining for manjak was continued in two districts of the colony during the year and 1,530 tons of that mineral valued at £3,060 were exported to the United States and the United Kingdom.

A Boston publication reported recently that the British Columbia Copper Company has but one furnace in blast, indicating operations of no better than 33 per cent. of capacity. It is understood the management will consider closing down the entire plant. In May, there were produced 528,458 pounds of copper, 2,114 ounces of gold and 9,337 ounces of silver.

UNITED STATES' OPPORTUNITY AS BANKER.

CANADIAN municipalities are looking to the United States for funds. With the prevailing conditions in Europe, it is impossible to raise loans in Great Britain. The last municipal flotation overseas was that of South Vancouver early in July. The amount was £223,287 5 per cent. consolidated stock, at 91. In June, the city of Moose Jaw made a private sale in London of $465,000 5 per cent. debentures. This week a bond house of Montreal has offered to market a loan of $7,300,000 for that city in New York. The price is 96.

Despite the attitude of the United States government respecting loans to European governments engaged in warfare, it seems improbable that Washington will frown upon the bankers who undertake to help to finance Canada's peaceful enterprises. In the early part of last century the United States depended on Europe, and especially on Great Britain, for most of the new capital needed for its development. To-day the accumulations of the United States people are greater than those of any other nation. It is true that additional amounts of foreign capital are still invested in the United States, but the amount is insignificant in comparison with the country's own savings. The wealth of the United States is growing, according to Sir George Paish, at the rate of about $7,000,000,000 per annum, whereas the investments of Europe in the country rarely exceed $300,000,000 in a single year.

The annual growth of banking deposits in the United States in normal years is about $1,000,000,000; the issues of new capital by subscription, so far as the amounts are ascertainable, are about $3,000,000,000; and the sums spent on buildings in the leading cities of the country alone reach $1,000,000,000. Allowing for a certain amount of duplication in these totals on the one hand and on the other for the large sums spent in buildings in all the small cities and villages, upon farm improvements, new factories, mines, lumber propositions, additional stock and machinery, etc., the rapidity with which the wealth of the United States is growing will be evident. There is an excellent opportunity for the United States to strengthen financial relations with the Dominion. Canadian banks and bond houses will continue to do their share of the business as in the past, but obviously the temporary loss of Great Britain as a buyer of Canadian securities should benefit the United States.

REINFORCED CONCRETE PONTOON.

A reinforced concrete pontoon has been constructed to the order of the Sydney Harbor Trust by Stone and Siddeley, of Sydney, Melbourne, and Geelong. The pontoon is to be placed in position at the eastern end of Circular Quay for the use of the Lavender bay and Parramatta river ferry services.

The dimensions of the pontoon are: 100 feet in length, 53 feet 3 inches wide at one end, and 67 feet 7 inches at the other; depth, 7 feet 9 inches, with a 32-inch freeboard. The bottom is flat and the sides and ends are sloped to an angle of 70°. Special attention has been given to the design of the steel work with a view to enable the construction to withstand the excessive strains likely to occur should vessels be berthing at each side of the pontoon at the same moment. In the construction of the top and bottom of the pontoon allowance has been made for a live load of 150 tons, which will be distributed between the posts.—Commonwealth Engineer.

Editorial

ENGINEERING ADMINISTRATION.

It is the purpose of a new course to be started this fall at the Massachusetts Institute of Technology to take the middle way and afford to the students practical proportions both of engineering and of administration. The man who graduates from this new course will set out into practical life equipped with the essential things in the training of an engineer and a man of business. His later success will depend, as in all other cases, on his innate capacity and his power of profiting by the experiences of life.

The new course is, apparently, not designed to make bookkeepers, auditors or accountants in any professional sense, but to furnish the fundamentals in these practices to business men holding administrative positions involving financial responsibility. The student will be instructed in the terminology of the accountant, will learn the places of assets, liabilities, good-will, franchises and the balance sheet; the meaning of profit and loss account, the theory and analysis of accounts in general and of depreciation. Cost accounting will be set forth in principle, with standard methods of determining costs not only of material but of processes, labor and machines. Distribution of indirect costs and overhead expenses will be shown, and the value of cost data toward economy together with various of the inventories and wage payment methods. There will be information given the student on the relative value of investments, of different kinds of securities, government, railroad, industrial, public utility, etc., and of different kinds of bonds.

In matters of transportation, it is proposed to introduce studies in handling freight, terminal facilities and warehousing, the making of railway rates and the classification of freight. Export business will naturally bring with it some study of the nature of this business, ocean rates, customs regulations, tonnage duties and port regulations. Port and inland differentials will be discussed, and private car lines and special transit privileges.

In matters of industrial organization, the new course will enter into the study of the kinds of such organization from the individual to the trust or holding company, the differences in corporation laws and the influences determining the choice of state in which to secure the charter. There will be lectures on the internal organization of the corporation, the directors, their duties and liabilities, the rights and responsibilities of the different factors to the corporation and the principles governing elections and meetings. Financing of corporations, dissolution, reorganization, state supervision and taxation will be other items in the study of corporations.

The courses that consider business management will take cognizance of the organization of the establishment. There will then be the management of labor, selection and placing of employees, bonuses, efficiency methods, welfare inducements, and the training of the men.

This is an important step towards preparation for that new kind of engineering, the problems of which are those of organization, administration and finance. There is a world-wide demand for men who are not only capable constructive engineers but men who can co-ordinate and organize the resources of a community or of a nation for the accomplishment of a mighty purpose. It is in this relation that Col. Goethals has been spoken of as the greatest engineer in the world to-day. He is a prototype of the engineer of a few years hence.

PROGRESS IN THE IRON INDUSTRY.

There are two usual routes open to the man who wishes to reach the head of a great industrial corporation; one is, as the shop phrase expresses it, "through the boiler room," and the other through the office. The one who begins at the bottom of the mechanical plant gets of necessity a thorough knowledge of the technical end of the work. He must acquire what is nearly as essential to him, the business knowledge, as best he can and usually in irregular fashion and from persons not experts in teaching. The man who enters the office must, to an extent, work down and will be obliged to learn as best he can something of engineering.

However interesting and picturesque the work of the iron master may be, from the taking of the crude material from its bed in the earth to the turning out of the finished iron and steel, the industry, like the great majority of others, is constantly undergoing great changes. They are not only in the interests of a more uniform and a purer product, but for greater safety of life and a smaller amount of labor. A few details showing the rapidity and cheapness with which some of the work is carried on may interest our readers.

In the Messabe range in the Lake Superior district, the iron ore is loaded by steam shovels carrying from four to six tons each. A twenty-ton car is loaded in five minutes or less. These cars are hauled in trains to the ore docks, from which the steamers, carrying from ten to twelve thousand tons each, are loaded in from two to four hours.

Forty to fifty million tons of ore were brought down from Lake Superior last year and unloaded at the various lake ports by machines, which take from five to seventeen tons per shovelful. The largest machine is able to load a fifty to seventy-ton car in less than five minutes. This ore is carried to blast furnaces in trains, often numbering 100 cars; and some trains carrying over 7,000 tons of ore.

The blast furnaces are of enormous size and production. Most of them exceed 500 tons of pig iron per day. Many of them turn out over 200,000 tons per year.

The steel works are on an enormous scale, twenty-ton Bessemer converters being not uncommon, while open-hearth furnaces, making 100 tons per heat, are quite numerous. No one thinks in these days of building smaller than fifty-ton open-hearth furnaces, except for steel castings. The first open-hearth furnace built in this country, forty-three years ago, had a maximum capacity of five tons. Four to six open-hearth furnaces are charged by one open-hearth charging machine, which is controlled by one man. To do this work in the old-fashioned way, by hand labor, would take from thirty to forty men.

The rolling of the steel shows the same progress in labor saving. The great rail mill at Gary, Ind., if kept supplied with ingots, can easily produce 5,000 tons of finished rails in twenty-four hours. This is more than one month's production of many mills in Europe.

These figures show what has already been done and the magnitude of the business. It has gone far beyond what the most optimistic a few years ago thought possible.

INDUSTRIAL SITUATION IN GERMANY.

MILITARY and naval Germany in its insane war lust is paralyzing industrial Germany. At the conclusion of hostilities, the nation's industry and commerce will have suffered a blow, from which it will take at least a quarter, perhaps a half century, maybe more, to recover. Modern Germany presents two outstanding facts, the great increase of the population since 1871 and the growing dependence of the population upon industrial and mercantile pursuits. Industry and trade in Germany maintain directly a population of about 34¾ millions, or more than half the entire population of the German Empire.

Chief among the causes which have helped to place Germany into the front rank of industrial nations is its possession of valuable mineral wealth and of capital to develop them. It has the largest known reserves of coal of all European countries. Upon that foundation, its iron and steel industries have been built rapidly and efficiently. It has copper, lead, zinc and other minerals in fair quantity and great wealth in its salt mines. It has practically a monopoly of potash, and supplies the world with that product.

The industrial hub of the country is the district which stretches from Dusseldorf on the Rhine land to Hamm in Westphalia, and covers a large part of those provinces. Speaking of that district, the Cologne Gazette prophesied some time ago that before long the district between Duisburg and Hamm would form "one enormous settlement, a single expanse of houses from 45 to 50 miles long and from 15 to 20 miles broad."

While Germany is still lagging behind in shipbuilding—the Clyde yards alone turning out a larger tonnage than all the German yards together—good progress is being made nevertheless. That is in some measure due to the naval policy of Emperor William, which would have been well if confined to peaceful work, but directed partly to the building of a gigantic navy, it likely will prove disastrous in the comparatively near future.

Year by year, Germany has become more independent of other countries in industrial products. Comparing the statistics of 1897 with those of 1911, the value of Germany's imports increased in that period by 49 per cent. and that of the exports by 129 per cent., while the increase of population was 23 per cent. Although the country is still largely agricultural, it is no longer able to feed its population. About one-half of the agricultural land is divided into relatively small holdings, while one-quarter is held by large proprietors.

The railways have been State-owned for a generation. Four years ago the country had about 18 miles of railway to every hundred square miles of surface, a ratio exceeded in Europe only by Belgium, Holland, the United Kingdom and Switzerland, in the order named. In his striking picture of the growth of industrial Germany, Mr. W. H. Dawson, in a notable volume on the subject, states that the railway system of that country and the development of its natural and artificial waterways have helped to build up industry and commerce and economic efficiency each to an equal degree.

Another powerful factor in the industrial life of Germany has been the concentration of capital. For instance, ten industrial concerns and nine financial institutions have aggregate capital of $638,750,000, an average of over $33,000,000. Nearly all these large undertakings, including the Krupp gun and shipbuilding firm, with capital of $45,000,000, and the Deutsche and Dresdner Banks, each with $50,000,000 capital, have grown to their present size as a rule by amalgamation with rival enterprises. The firm of Krupp, in which Emperor William has a substantial financial interest, employs 70,000 persons. Now industrial Germany and its 35,000,000 workers, with the other half of that Empire's population, is thrown into war by Germany's military madmen.

ONTARIO STEEL PRODUCTS' REPORT.

The profit and loss account of the Ontario Steel Products Company, Limited, shows net profits for the year ended June 30th, of $106,437. This amount is after providing for depreciation of properties, reduced market value of securities and the entire cost of organization. Deducting bond interest of $36,000 and preferred dividends of $52,500 there remained a sum of $17,937. The company's fixed assets including real estate plant, power rights and goodwill total $1,785,451. The current assets, amounting to $2,259,689 are divided as follows:—Cash, $3,351.94; bills and accounts receivable, $96,459.33; inventories, $346,107.45; securities (at market price), $26,144; deferred charges to operations, $2,175.

On the other hand the company has current liabilities of $118,913, made up as follows:—Bank overdraft, $14,881.27; bills and accounts payable, $72,907.14; bond interest due July 2nd, 1914, $18,000; preferred dividend payable August 15th, 1914, $13,125. The reserve for depreciation, etc., is $22,838.94.

In discussing the company's report, Mr. W. Wallace Jones, the president, states:—"The company shared in the generally unfavorable conditions which existed during the past 12 months, and consequently all the plants were not run to their full capacity. Furthermore, a disastrous fire at the Gananoque Spring and Axle plant seriously interfered with operations, at a most inconvenient time; and while the direct loss was fully covered by insurance, the disorganized conditions that obtained during rebuilding operations seriously affected profits from these works. This fire, which completely gutted the spring works and damaged the axle works at Gananoque, occurred on October 1st, 1913. Rebuilding operations were commenced on October 15th, the building being completed on December 20th, and manufacturing operations resumed on January 2nd. The new building, which is larger than the one destroyed, is strictly fireproof construction, and the insurance rate has been substantially reduced in consequence.

"During the year large extensions and improvements at the shovel plant have been satisfactorily completed, but owing to trade conditions are not being operated at the present time. In view of the development in the auto spring business, the directors recently purchased the property of the Canadian Malleable Range Company, at Chatham. This property is very conveniently situated, and the price paid was reasonable. The directors also have purchased from the Thousand Islands Railway Company a piece of land which later on will be used for an extension to the shovel plant. The McNee property, adjoining the spring and axle warehouse at Gananoque, has also been purchased at a reasonable price, and will give additional and badly-needed storage capacity for springs and axles. The directors have not deemed it prudent to proceed with the suggested factory at Windsor at the present time.

"During the year the plants have all been put in a state of high efficiency, and several new lines of goods have been put on the market. Contrary to the usual custom, the company has written off all organization expenses this, the first year; and have also set up a substantial reserve for future bad debts."

The company has first mortgage 6 per cent. bonds of $600,000. These are due on July 2nd, 1933. It has authorized capital stock of $1,500,000 of which $750,000 are 7 per cent. cumulative preferred shares and $750,000 ordinary shares. All this is paid up.

On August 15, the Panama canal will be opened to commerce for ships not needing more than 30 feet of water. At present war department officials at Washington are perfecting plans for this opening, though the official opening and ceremony will not take place until March, 1915, when a much greater depth will be available.

ENGINEERS' LIBRARY

Any book reviewed in these columns may be obtained through the Book Department of The Canadian Engineer.

CONTENTS.

BOOK REVIEWS.

Business Administration, Its Models in War, Stagecraft and Science.—By Professor Edw. D. Jones; published by the Engineering Magazine, Co., New York. 275 pp.; size 5½ in. x 7½ in.; cloth. Price, $2.00

The subject of this book is treated in three directions: the administrator as general, the administrator as scientist, and the administrator as diplomat. Professor Jones is not an apostle of any special doctrine or practice of management. He looks at the subject in a prospective state by familiarity with the world's greatest thought and action, and he seeks to find in the life and achievements of great generals, statesmen and scientists fundamental principles applicable to the more limited work of modern industrial leaders. He looks upon administration as a process dealing chiefly with the human factor and the operation of universal laws. He conceives of the administrator as a leader of men, even more than a trustee of properties. He realizes that there has been a deplorable diversion between modern industrial and business conduct and modern ethical and moral ideals, and he seeks to show that by a change of viewpoint they may be brought into reconcilement and harmony. He conceives indeed that the recent and rising activity of interest in industrial management is a symptom of the effort at this reconcilement—a movement like the rise of chivalry which tempted the rugged virtues of the warrior with the gentler characteristics of religion, loyalty and courtesy.

Apart from the book itself a seeker of foremost literature upon the subject at hand might well define from the following brief outline of the author's career his ability and comprehensive grasp of the essentials underlying business administration. Professor Jones was educated at Ohio University and the University of Wisconsin. Later at the universities of Halle and Berlin he enlarged upon the subject of economics. Since 1895 he has been in the University of Michigan, first as instructor in statistics and economics, later as assistant professor in economics and commercial geography, and since 1902 as professor of commerce and industry. In the United States Commission to the Paris Exposition he was an expert in social economy. At the St. Louis Exposition he was a member of the International Congress of Arts and Science. As author of "Economic Crises" and of various monographies on the resources and industries of the United States Professor Jones has become recognized as an authority, and the book now under consideration as the latest publication of the Works Management Library of the Engineering Magazine Company will be received with interest and satisfaction.

It is not a book for those who are seeking a ready-made system, but it is a book which will be unusually interesting and profitable to those who are seeking stimulus and direction for their ideas.

American Machinists' Handbook.—By Fred. H. Colvin, A.S.M.E., and Frank A. Stanley, A.S.M.E.; published by McGraw-Hill Book Company, New York; 673 pp.; fully illustrated; size 4 in. x 6½ in.; bound in leather; price, $3.00 net.

This is the second edition of a very useful reference book of machine shop and drawing room data, methods and definitions. The writers had in mind, in the compilation of the work, the fact that every man engaged in mechanical work of any kind, regardless of his position in the shop or drawing-room, frequently requires information that is seldom remembered and is not usually available when wanted. By their endeavor to supply this information in the most convenient form the authors have rendered a great service to young mechanics as well as to practical men in all branches of machine work. The co-operation which manufacturers and individuals tendered them in its construction is an evidence of the general need which has been recognized for a long time in the mechanical arts.

The second edition is larger than the first edition by 160 pp. It has been very carefully revised and each section has been brought up-to-date to correspond with the changing conditions of shop and drawing-room work. Many of the changes therein are due to the suggestions made by the users of the handbook.

In a review it is somewhat difficult to give a clear idea of the scope of a work of this kind. The following section headings, however, each of them divided into various subsections, which will not be numerated, will be found of value:

Screw Threads; Pipes and Pipe Threads; Twist Drills and Taps; Files; Work Benches; Soldering; Gearing; Milling and Milling Cutters; Turning and Boring; Grinding and Lapping; Screw Machine Tools; Speeds and Feeds; Hunch Press Tools; Broaches and Broaching; Bolts, Nuts and Screws; Calipering and Fittting; Tapers and Dovetails; Shop and Drawing Room Standards; Wire Gauges and Stock Weights; Horsepower Belting and Shafting; Steel and other Metals; Steam Hammers and Drop Forging; Knots, Eye-Bolts, Ropes and Chains.

In addition, there are many general reference and miscellaneous tables and a general outline of shop trigonometry.

The dictionary of shop terms is well illustrated and comprises almost 100 pp. It is one of the most useful, not merely owing to its comprehensiveness but to its connection with, and incorporation in, the handbook itself. The index re-

lates to nearly 2,000 items receiving consideration in the work. It has been very carefully worked out and is a valuable asset to speedy reference, so important in a work of this kind.

Asphalts, Their Sources and Utilizations, 1914 Edition.—By T. Hugh Boorman, C.E.; published by the Wm. T. Comstock Co., New York; 192 pp.; 55 plates; size 7 in. x 10 in.; cloth; price, $2.00.

This new edition contains much additional information, practically all of which deals with the developments in road building during the last five years. Five chapters have been added treating respectively of rock asphalt, maintenance, asphalt macadam roads, coal-laid asphalt roads, bituminous road surfaces, and asphalt blocks for roads. The new edition contains eight new plates, including a series of standard tests for asphalt cements for pavements and roads. The book will be found useful by commissioners of highways and municipal engineers because of its authoritative information and the completeness with which the subject is covered.

An addendum has been published in connection with it and is being sold at 25 cents. The pamphlet has been provided so that those having copies of the former edition may be able to obtain the additional matter without having to purchase a new complete volume.

Practical Calculations for Engineers.—By C. E. Larard and H. A. Golding; published by Chas. Griffin & Co., Limited, Strand, London; 387 pp.; 175 illustrations; 31 tables; size 5½ in. x 7½ in.; cloth. Price, $1.00.

This is the third and considerably revised edition of the authors' work, written primarily for engineering students, apprentices, mechanics, foremen, draughtsmen, and others practically engaged in engineering work. The first edition was published in 1907, and none of the information and calculations is old or out of use.

The general principles which the authors have kept steadily in view in the preparation of this work include modern methods of making rapid calculations by the use of the slide rule; some of the more important engineering problems with which every young engineer should be familiar; graphical methods (illustrated by engineering problems) for the ready interpretation of the results of experiment and other work; and, the importance of making a study of the business side of the profession. The first few chapters are confined to elementary calculations, approvals, approximations, technical and mensuration, and calculation of weights. The work goes on to discuss calculations by common logarithms, mechanical calculating devices and the use and value of squared paper. Section 2, comprising 7 chapters, is devoted entirely to mechanics taking up the principles of work, power and energy, acceleration, momentum and centrifugal force, etc., applying them to practical examples in each case. Section 3 is devoted to steam engineering and its various calculations, while the concluding chapter takes up comparative costs of power production for steam, gas, and oil engines.

For the non-technical mechanical engineer engaged in power production the book will be found of considerable assistance. It is not recommended for those who have had extensive technical training in this work, as there is little new information contained therein that would be of further assistance to them, but the work will be found especially suited to satisfy a long-felt want for a book that goes into the subject of steam engineering in such a way that the man who has little more than an average grounding in the principles of arithmetic can very well understand.

Flight Without Formulae.—By Commandant Duchene of the French Genie, translated into English by John H. Ledeboer, B.A.; published by Longmans, Green & Co., London and New York; 211 pages; 84 illustrations; size 6 in. x 9 in.; cloth. Price, $2.25.

The translator in his preface states: "Formulae and equations are necessary evils; they represent, as it were, the shorthand of the mathematician and the engineer, forming as they do the simplest and most convenient method of impressing certain relations between facts and phenomena which appear complicated when depressed in everyday garb. Nevertheless, it is to be feared that their very appearance is forbidding and strikes terror into the hearts of many readers not possessed of a mathematical turn of mind." The writer goes on to state that it is this prejudice that has deterred many from the study of the principles of the aeroplane, and the book under discussion forms an attempt to cater to this class of reader. When it is stated that there is not a single formulae in the whole extent of the work, those who have refrained from studying the literature of aeronautics owing to the many mathematical computations which almost invariably appear in the books devoted to the work, will be relieved to know that there is now on the market a volume which treats of every one of the principles of flight and of the problems involved in the mechanics of the aeroplane without demanding from the reader the most elementary knowledge of arithmetic.

The book is divided into 10 chapters, the first 5 being on flight in still air, taking up the subjects of speed, power and the power plant. The next 4 chapters discuss stability in still air; viz., longitudinal, lateral and directional stability and turning. Chap. 10 takes up the effect of wind on aeroplanes.

Taken altogether, the book consists of simple discussions on the mechanics of the aeroplane that have been so masterfully handled by the writer as to absorb the attention and interest of the non-mathematical mind.

Metal Statistics, 1914.—By B. E. V. Luty and C. S. J. Trench; published by the American Metal Market Co., New York; 287 pp.; size 3½ in. x 6 in.

This is the 7th annual edition of this work on Metal Statistics, and a great deal of useful information is to be found therein for buyers and sellers, as well as for plant managers and engineers, as the data is remarkably comprehensive in the ferrous and non-ferrous metal fields. The latest edition is considerably larger than previous publications. The editors make acknowledgment to the United States Geological Survey, the New York Metal Exchange, and other authorities whose statistics have been used with respect to metal production, etc., in the United States and other countries.

High Power Gas Engines.—By H. Dubbel, translated from the German and edited and expanded, so as to include British engines and British practice, by F. Weinreb; published by Constable and Co., London; 197 pp.; 423 illustrations and 13 folding plates; size 7¼ in. x 10½ in.; cloth. Price, $4.50 net.

When one encounters a text book with this size of page one is generally inclined to petition for some standardization, long talked-of in the matter of size of text books. In this particular instance, however, the grievance is counteracted by the clearness characteristic of the many illustrations which the book contains. The half-tones are exceptionally clear,

whereas the sectional drawings and diagrams in most cases are, if anything, on the large scale—which reflects again upon the question of size. With this off his mind the reviewer, in turning to the subject-matter of the work finds it a treatment of the theory, principles of operation and the most important constructional features of large 4-cycle and 2-cycle gas engines. As a guide for the student or designing engineer it will be found to contain the same essential and technical details as have been typical of similar works on steam engines in years past. Further, its value to engineers who have not specialized upon large gas engine work is to be emphasized.

The book, or rather the theoretical part of it, deals with the question of efficiency, also compression and mixture ratios, the latter being dealt with under assumption of both constant and variable specific heats. More special attention has been given, however, to the constructional features and conditions governing the design of various engine parts which makes the book, with its clear and carefully drawn illustrations, one of great assistance in design.

Other points that have received attention are the question of cooling and the consideration of large forces acting upon the piston, these points being so important as to have influenced the design of large gas engine parts in a very distinct manner.

In translating the work Mr. Weinreb calls attention to the German text dealing only with large size double-acting gas engines, whereas the growing tendency in Great Britain is the use of the multi-cylinder single-acting type up to, for example, 1,500 b.h.p. For this reason he has included this type in the translation, observing that the troubles formerly experienced with large cylinders seem to have led to the development of the more moderate sizes. The chapter headings throughout the work are as follows: The Cycle of the Gas Engine; Output and Cylinder Dimensions; the Governing of the Four-Cycle Engine; Valve Gear of Four-Cycle Engines; the Two-Cycle Engine; Valve Gears; Ignition; the Cylinders; Valves and their Cooling; Pistons and their Cooling; Piston Rod Couplings; Stuffing Boxes; General Design of Principal Parts; Calculation of the Flywheel Weight; Starting; Piping.

Technical Mechanics, Statics and Dynamics.—By Edw. R. Maurer, Professor of Mechanics in the University of Wisconsin; published by John Wiley & Sons, New York; Canadian selling agents, the Renouf Publishing Co., Montreal; 356 pp.; 529 illustrations; size 6 in. x 9 in.; cloth. Price, $2.50 net.

The first edition of this work was published 10 years ago and it will be remembered that it was received with considerable satisfaction by students of engineering. As stated in the preface of the book, "Although the title might suggest such, it is not comparable to books commonly called 'Theoretical Mechanics,' generally intended for students of mathematics or physics nor to books on applied mechanics, generally including a treatment of strength of materials, hydraulics, etc." In 'Technical Mechanics,' the subjects discussed from the theoretical side have each a direct bearing on engineering problems and the applications illustrate principles of mechanics with a view to training students in the use of such principles rather than in the furnishing of direct information.

The present edition is a practically rewritten book and contains considerably more material than the previous work, including a new collection of problems. The chapter on attraction and stress which appeared in previous editions has been removed so that the new arrangement is as follows: Chap. 1, Composition and Resolution of Forces; Chap. 2, Forces and Equilibrium; Chap. 3, Simple Constructions; Chap. 4, Friction; Chap. 5, Center of Gravity; Chap. 6, Suspended Cables, Wires, Chains, etc.; Chap. 7, Rectilinear Motion; Chap. 8, Curvilinear Motions; Chap. 9, Translation and Rotation; Chap. 10, Work, Energy and Power; Chap. 11, Momentum and Impulse; Chap. 12, Two-dimensional (plane) Motion; Chap. 13, Three-dimensional (solid) Motion. The book contains two appendices, the first of which entitled "Theory and Dimensions of Units" is substantially the same as Appendix "A" of the first and second editions of the work. Appendix "B" devoted to moment of inertia and radius of gyration of plane areas, has been added, as writers on strength of materials usually refer to works on mechanics for a discussion of this subject. The volume concludes with 193 problems illustrated and arranged to follow consecutively the general method of analysis adopted throughout the book. With each problem has been given a number, in parenthesis, which refers to the article pertaining to that problem. The work as a whole is a technical discussion written specially for engineering students, the author himself a professor of mechanics in a well-recognized university has made evident throughout the work his authoritative conception of the academic requirements necessary for the modern method of training in an engineering school. It will be found to reiterate the satisfaction with which the previous editions have been accepted and its thorough revision will make it of extreme value as an authority on the subject.

Mechanical Movements, Devices and Appliances.—By Gardner H. Hiscox, M.E.; published by the Norman W. Henley Publishing Co., New York City; 409 pp.; fully illustrated; size 6 in. x 9 in.; cloth. Price, $2.50.

This book is the 14th edition, considerably enlarged over previous editions, of a work describing mechanical movements and devices used in constructive and operative machinery and in the mechanical arts. Practically speaking, it is a sort of mechanical dictionary, illustrated by over 1,800 engravings, and commencing with a rudimentary description of the early non-mechanical powers and detailing the various motions, appliances and inventions used in the mechanical arts up to the present time. The latest edition contains about 160 new and added mechanical movements and devices and includes a chapter on straight line movements, which makes the work a useful book of reference for those engaged in mechanical studies and pursuits, particularly for those who have to do with inventions and machine design.

The section headings are as follows: Mechanical Powers; Transmission of Power; Measurement of Power; Steam Power; Steam Appliances; Motive Power; Hydraulic Power Devices; Air Power Appliances; Electric Power and Construction; Navigation and Roads; Gearing; Motion and Devices Controlling Motion; Horological Mining; Mill and Factory Appliances; Construction and Devices; Drafting Devices and Miscellaneous Devices.

Scales for Ascertaining the Dimensions of Pipes, Drains and Sewers.—By C. E. Housden, Sanitary Engineer to the Government of Burma, Eastern Bengal and Assam. Published by Longmans, Green and Co., London, England; 16 pp.; 5 plates; size 5 in x 7 in.; price, 40 cents.

This small book contains a number of scales for ascertaining the dimensions to the nearest inch of pipes or half-pipes and of any design of drain or sewer in which a semicircle or circle can be inscribed, adopting at will any discharge

co-efficient. The scales are taken from the author's book entitled "Water Supply and Drainage, Systematized and Simplified," in which work their construction has been fully explained. The book contains two very useful tables, Table 1, giving the value of the water area in square feet, the wetted perimeter, the hydraulic mean depth, and the discharge reduction co-efficient for different slopes of masonry drains and for drains in earth. Table 2 is similarly a useful table to be used in connection with the plates or diagrams for ascertaining pipe dimensions. Doubtless these scales will be found of considerable assistance to engineers of sewerage works.

PUBLICATIONS RECEIVED.

Coal Mine Fatalities in the United States, June, 1914.—The monthly statement of the Bureau of Mines, Department of the Interior, Washington, giving the statistics for coal mine fatalities in June, and also revised figures for preceding months. Compiled by Albert H. Fay.

Pollution of Boundary Waters—A 4-page leaflet, being a resume of testimony of consulting sanitary engineers in the matter of the pollution of boundary waters between the United States and Canada. Issued by the International Joint Commission, and published by the Government Printing Office, Washington.

Report of the City Waste Commission of the City of Chicago.—A 69-page report of the Commission created by the order of the Chicago City Council to make a comprehensive study of the subject of the collection, delivery, and disposal of garbage and waste. T. McLean, Jasper, M.Sc., Assistant Secretary, Engineer of the Commission, publishes the report.

Waste of Oil and Gas in the Mid-Continent Fields, United States.—A 57-page report, compiled by Raymond S. Blatchley, and issued by the Bureau of Mines, Department of the Interior, Washington, showing the past and existing waste of gas and oil in states including Kansas, Oklahoma and Northern Texas, and attempting to show the importance of conserving these natural resources.

Forest Insect Condition in British Columbia.—Bulletin No. 17 of the Second Series. An illustrated 41-page booklet, giving the result of a preliminary survey made by J. M Swain, Assistant Entomologist for forest insects, the object being to further the effort of conserving the timber resources of British Columbia. Issued by the Division of Entomology, Department of Agriculture, Ottawa.

Report of the Sewage Disposal Commission, 1913, Fitchburg, Mass.—Being the seventh semi-annual report which has been published since the establishment of the Sewage Disposal Commission at Fitchburg in 1910, and presenting an account of the doings, receipts, and expenditures of that body on the improved sewer system of the municipality for the six months ending December 31, 1913. The report contains illustrations and maps, and consists of 48 pp.

Report of Mining Operations in the Province of Quebec, 1913.—Issued under the authority of the Mines Branch, Department of Colonization, Mines and Fisheries, Province of Quebec; and submitted by Theo. C. Denis, Superintendent of Mines, as the annual report of the Mines Branch on the mining operations, mineral production, and geological field work of the Province of Quebec during the calendar year 1913. This report supersedes a preliminary statement which was published on February 23, 1914, was mainly statistical, and was submitted subject to revision. This report is 163 pp. in length, including a few illustrations.

Annual Report of the Topographical Surveys Branch, 1912-13, Department of the Interior, Ottawa.—This report consists of 226 pp., and, as a preliminary, gives the report of the Surveyor-General of Dominion Lands. The bulk of the work consists of 52 appendices, 10 of which are devoted to schedules and statements compiled by the Topographical Surveys Branch, the remaining 42 being reports and abstracts of reports from various surveyors. The book includes also 17 maps and profiles, and a fair amount of illustrations. The surveys made in Northern Manitoba and the Peace River district may be considered most interesting; since these were made on a larger scale than previously. Progress, however, is shown in all provinces of the Dominion.

Second Report of the Quebec Streams Commission.—Vol. 1, a 121-page booklet which has been translated from the French and contains a statement of the studies of a general nature which were carried on by the Quebec Streams Commission, Montreal, during the course of the year 1913, exclusive of the work accomplished during that period in connection with the proposed St. Maurice River water storage; Vol. 2, of 100 pages, being a supplement to the year's report, or the work done under the direction of the Commission in connection with the project for regulating the flow of the St. Maurice River, together with the plans and specifications of the works to be erected; and an appendix, under separate cover, containing maps made by the Commission.

Annual Report of the Minister of Mines, 1913.—459 pp., 7½ in. x 10½ in., containing illustrations and maps, and being an account of mining operations for gold, coal, etc., in the Province of British Columbia, and printed by authority of the Provincial Legislative Assembly. The work is compiled by William Fleet Robertson, Provincial Mineralogist, and gives the total mineral output of the province up to the year ending December 31st, 1913, showing in considerable detail the actual mineral production of the last year as based on smelter or mill returns, and making a summary of the production of each of the last four years. It thus illustrates by comparison the progress made in productive mining during this period.

Wood-Using Industries of the Maritime Provinces, Bulletin No. 44.—An illustrated 100-page bulletin compiled from reports received from over six hundred manufacturers in the Maritime Provinces using wood as a raw material. It reports on the quantity, value, and source of supply of the different kinds of wood used by the industries of the provinces; includes detailed descriptions of the different classes of industries and of the properties of the woods; takes up the ten kinds of wood used in greatest quantity and shows the extent to which the industries respectively use these; and appends a classified directory of the manufacturers who supplied the data used in the compilation. The report is the work of R. G. Lewis, B.Sc.F., assisted by W. Guy H. Royce, and is published under the Forestry Branch, Department of the Interior, Canada.

Evidence Given Before the Select Standing Committee on Agriculture and Colonization, Third Session, Twelfth Parliament, 1914.—This is the first of a series of four reports presented by the committee, and is compiled of the evidence of Mr. Wilson, M.P. for Wentworth, and Messrs. F. F. Espenchied and J. W. Purcell, of the Ontario Hydro-Electric Power Commission, taken by the Committee during the current session of parliament, and dealing with hydro-electric power as applicable to the farm; the evidence of Mr. John Bright, Live Stock Commissioner of the Department of Agriculture, on the production and marketing of live stock; the evidence of Mr. J. B. Spencer, of the Distributions Branch of the Department of Agriculture, on the methods of distribution in vogue

in that Branch; and the evidence of Miss Wileman on the establishment of a free labor bureau system in Canada. The book includes maps and a fine list of illustrations.

Report of the Building and Ornamental Stones of Canada, Vol. II.—This report, which is published by Wm. A. Parks, B.A., Ph.D., under the Mines Branch, Department of Mines, Ottawa, forms the third part of the Monograph on the Building and Ornamental Stones of Canada, of which Part I. constitutes a general introduction and Part II. deals with the stones of the Province of Ontario. The work consists of 264 pages, 6½ x 9½ inches, including appendices and illustrations. The field work upon which the report is based was done during the summer of 1911, when, within a period of two and a half months, sixty quarries were visited, as well as a considerable number of abandoned quarries and prospects. But, though this report is by no means confined to quarries in actual operation, it does not pretend to include every opening that has been made for the production of building stone. The object was to represent by a typical example every important district and to give due consideration to every stone commercially available at the present time. The sketch maps accompanying the report were prepared by Mr. R. R. Rose, and are designed to show the general geology of the region, and more particularly to point out the location of the important quarries; only a few quarries not in actual operation being indicated, and no attempt being made to show the numerous small pits that have been opened for the obtaining of limestone for flux or for lime-burning.

CATALOGUES RECEIVED.

Gurley Automatic Water Stage Registers.—A 31-pp. pamphlet showing and illustrating the use of water stage registers manufactured by W. & L. E. Gurley, Troy, N.Y.

Railway Motor Gears and Pinions, Bulletin "A" 4199.—A small booklet showing the various grades of gears and pinions handled by the Canadian General Electric Co., Limited, Toronto.

Evidence of Toncan Metal.—A small booklet of illustrations issued with a view to giving visual evidence of Toncan Metal in actual use. Published by the Stark Rolling Mill Co., Canton, Ohio.

Clyde Land-Clearing Machinery.—An attractive 16-page catalogue, finely illustrated to show the logging, hoisting, excavating, stump-pulling, and land-clearing machinery manufactured by the Clyde Iron Works, Duluth, Minn.

Industrial Buildings, Limited, designing and supervising engineers and contractors of building construction and equipment, Toronto, has issued a small booklet showing the company's method of construction in modern industrial buildings.

The Cement-Gun, the Apparatus, Process and Product.—A well illustrated 106-pp. booklet, being a compilation of the record of the development of the cement-gun since its inception as a commercial enterprise three years ago. Edited by Arthur E. Lee, and published by the Cement-Gun Co., Inc., New York, N.Y.

The "Badger" Catalog, No. 13.—A 32-page booklet issued by the Canadian Allis-Chalmers, Limited, and descriptive of badger engines for gas, gasoline, or kerosene, built by the Christensen Engineering Co., Milwaukee, Wis., and dealing with those which are specially adapted for the operation of grain elevators and grist mills.

Drinking Water Systems.—A 45-pp. booklet, illustrated, to show the value of Nonpareil Cork Covering for drinking water systems in mills, factories, hotels, office buildings, hospitals, public buildings, etc. Issued by the Armstrong Cork and Insulation Co., Pittsburgh, Pa., for which firm the Kent Co., Limited, 705 Lumsden Bldg., Toronto, are the Canadian distributers.

Ice-Handling Equipment.—A 64-page booklet, fully illustrated, and containing general information for purchasers of ice elevators, conveyors, lowering machines, ice tools, and icing station equipment, manufactured by the Gifford-Wood Co., with New England headquarters at Nos. 51-52 North Market St., Boston, Mass., and western headquarters at No. 103 North Jefferson St., Chicago, Ill.

Power, Its Economical Distribution.—A well finished and well illustrated booklet issued by the British Aluminium Co., Limited, 109 Queen Victoria St., E.C., London, England, being No. 108 publication on aluminium insulated cables. The object is to show the economy of the product, the easy solution of working and jointing problems in the use of the metal, and the low scrap value of these cables.

General Catalogue of the Dominion Equipment & Supply Co., Limited, Winnipeg.—A 414-page book, illustrated and indexed, describing in a brief and comprehensive manner the various lines of machinery, equipment, and general supplies manufactured and handled for the use of steam and electric railroad contractors, general contractors, bridge builders and structural steel erectors, coal mines, stone quarries, blacksmiths, factories, mills, municipalities, electric light plants, waterworks plants, etc., etc. The descriptions are carefully prepared and cover the essential points in representing the goods clearly and concisely. The lists and tables are the latest up to the time of going to press. The catalogue is issued for the year 1914.

BREAKING UP PAVEMENT BETWEEN CAR TRACKS.

An unusual and efficient method of breaking up old block pavement between the rails of a street railway track in preparation for replacing the track has been devised and is being used in Cleveland. To a car with a heavy steel framework and wooden sides about 2 feet high is attached a plow consisting of a heavy steel casting of suitable shape for lifting the paving blocks, and at the same time cutting the tie rods which hold the two rails of the track together. A counterweight is placed in the car to hold the plow in the desired position when the car is pulled along. The plow car with its counterweight weighs about 11 tons.

The plow is pulled by a service motor car equipped with four Westinghouse motors. This car is of steel, of the hopper type, behind the motorman's cab and the motor mechanism, and is loaded with blocks, then weighing about 50 tons. Three men and the crew of the motor car are all that are necessary to operate the plow.

With this apparatus it has been found that 1,300 square feet of pavement can be removed in one minute. On one occasion the pavement in a stretch of track 2,600 feet long was removed in 35 minutes. The only difficulties experienced have been breakages of the cable, which have not occurred often. The plow is used only one or twice a week, since an hour's work with it gives enough track to work on for about ten days. The plow has been in use for several months. It is described in a recent number of the Electric Railway Journal by its designer, Charles H. Clark, engineer of maintenance of way for the Cleveland electric railways.

On August 16 the Canal zone celebrated the opening of the Panama Canal. The official celebration of international significance has been set for next spring. The steamship Ancon, owned by the United States War Department, and leased to the Panama Railroad for service in the New York-Colon trade, was chosen as the first big boat to be put through, signalizing the opening of the canal to all ships up to 10,000 tons register.

Coast to Coast

Toronto, Ont. A passenger train service was opened by the C.N.R. between Toronto and Ottawa on August 18.

Montreal, Que.—The repairs to the water supply conduit were completed last week, and the city is being served again with its regular water supply.

Grand Falls, N.B.—On August 13th, the new bridge which has been constructed just below the Grand Falls and has just been completed, was formally opened for traffic.

Moose Jaw, Sask.—The new armory which has been erected at Moose Jaw at a cost of $110,000 has been formally taken over by the department of militia of the Dominion Government.

Ottawa, Ont.—A recent communication from Ottawa says that in that city there will be constructed this year about $600,000 worth of pavements, which is twice the amount that was undertaken last year.

Toronto, Ont.—It is anticipated that a definite compromise will be reached very shortly between the civic and provincial hydro-electric commissions relative to the much discussed question of hydro-electric power rates.

Sarnia, Ont.—Under the supervision of Town Engineer McLean, of Sarnia, a new concrete bridge for foot passengers has been completed across the canal in Bayview Park. The structure is of a very permanent as well as artistic design.

Montreal, Que.—The question of proceeding with public works being undertaken by the federal and provincial governments and by the municipal administration of Montreal, is being studied very carefully by the various labor organizations and associations of the city.

Winnipeg, Man.—The city council of Winnipeg has passed a report and supplementary report of the board of control containing accounts to the number of 455, totalling $158,007.98. Also accounts of the hydro-electric department were passed, numbering 59 and totalling $24,971.91.

Hamilton, Ont.—Steel contracts have been awarded and satisfactory bulk tenders have been secured for the erection of the Royal Connaught hotel in the city of Hamilton. The cost is now placed at about $1,000,000, or about $100,000 more than the early estimates. The commencement of the erection of the building will soon be in progress.

Brantford, Ont.—The raising of Lorne Bridge at Brantford by Mr. Reuben Rogers, contractor of Guelph, is proceeding at the rate of two feet per day; and the work is expected to be finished within the next 10 days. The new White Bridge, which has been constructed on the Hamilton road in the township, has been completed and publicly opened for traffic.

Valcartier, Que.—Mr. William Perry, hydraulic engineer of Montreal, is engaged upon the installation of the pumping plant for supplying the military camp at Valcartier, consisting of duplicate electric-driven pumps, having a capacity of 80,000 gallons per hour under a pressure of 80 pounds per square inch. Pipes are being laid over the ground for a general water supply.

Trenton, N.S.—A water system is in process of construction at Trenton, N.S., at a total cost of about $20,000. A reservoir has been almost completed about 250 feet above the business part of the town; and at present, a deep well Deane pump with 20 h.p. motor is being installed beside the reservoir by the Messrs. Doane Engineering Co., of Halifax. This same firm has just secured the contract for extensions to water pipe in the town.

Victoria, B.C.—Mr. J. F. Whitson, Commissioner of Roads for Northern Ontario, has finished his program of work for this year, which has entailed an expenditure of $850,000 out of the $5,000,000 appropriation voted two sessions ago by the provincial government. The remainder of the $1,000,000 which was to be expended this season is still proceeding under contract and is chiefly clearing.

Edmonton, Alta.—Representatives of the Edmonton Industrial Association have waited on the city commissioners regarding the contract between the city and the association relative to the gas well at Viking. The association is advocating that the city take over the drilling operations, pay the amount called for under the contract between the association and the drilling company and reimburse the citizens who have been financing the scheme.

Victoria, B.C.—Difficulty in establishing a satisfactory foundation for the Hudson's Bay Company's new block at Victoria is being experienced. The architects have insisted that, before the superstructure is started, a footing must be made entirely on solid rock. Up to date, bed-rock on the north-east corner of the site had not been obtained; though, in one case, excavation had been carried to a depth of 60 feet, and nothing beyond blue clay reached. The work is in the hands of the B.C. Construction and Engineering Company, general contractors for the building.

Point St. Charles, Que.—Work has been progressing very rapidly at Point St. Charles upon the excavation of a cave-in which occurred recently to the sewer in Mill Street. Four emergency pumps, each with a capacity of 2,000 gallons per minute, had to be erected to remove the stagnant sewage from the streets affected by the damaged sewer; and a steam shovel was also employed to hasten the repair work necessary. The result of the break has been to draw attention to the necessity for widening the Wellington Street subway, which was made entirely impassable by the overflowing sewage.

Victoria, B.C.—The province of British Columbia is to benefit by the construction of a fair share of public buildings, should the Dominion Public Works Department proceed with the awarding of contracts for those for which tenders have already been called and received. The projects in view comprise post offices for Merritt, Courtenay, Ashcroft, and Prince Rupert; a detention house and examination warehouse at Union Bay; and a third-class immigration shed at Prince Rupert. In the event of there being no alteration in the original programme, it is expected that this work will be inaugurated without loss of time.

Quebec, Que.—From across the ocean, built by Cammell and Laird at their Birkenhead works, has come the "Leonard," a costly car ferry and ice-breaker for the N.T.R. Company. It is to be used to connect the Quebec and Levis ends of the line until the Quebec bridge is completed. The naval architecture of the ferry is interesting. Her tidal and promenade decks are built a considerable distance above her main deck. Her speed is about 15 knots an hour, and she has four funnels. Her tidal deck has three lines of tracks, each 270 feet in length. She is propelled by two sets of triple expansion engines, and she has a length of 326 feet, a beam of 65 feet and a draft of about 15 feet.

Winnipeg, Man.—The board of Greater Winnipeg Water District passed recently estimates amounting to $190,815. Included in these were $61,000 to the Algoma Steel Corporation for steel rails; $45,000 to the Northern Construction Co., and $48,000 for ties to O'Brien and McDougall. The board also received reports on constructive work and supplies, showing as the most important progress which has been made: the completion of clearing the right-of-way, involving 2,583 acres; the completion of more than one-third of the work in connec-

tion with the Falcon River diversion dyke; and the completion of boring operations for water at Deacon, which has resulted in the obtaining of a supply of 40,000 gallons per day.

Wallaceburg, Ont.—A progress report on the work being done by the Thrasher Company of Toledo states that all the work at the pumping station for the new waterworks system has been completed, and the construction of the station has been commenced. While dredging for the pipe line to be laid across South Wallaceburg, about 25 spiles and many old trees had to be dug out of the sewer bank, and divers had to be employed frequently. The work in the town is somewhat behind due to trouble being experienced by the contractors on account of sand cave-ins. On Wellington Street, where the pipe has to be laid at a depth of 20 feet to pass under the river, the entire sewer is being planked to the full depth. The lack of pipe also is delaying outside construction.

PERSONAL.

CHAS. J. GIBSON, formerly of Haileybury, has been appointed by the town council of Bowmanville to the office of Town Engineer.

H. C. COX, president of the Canada Life Assurance Company, has been elected a director of the Canadian General Electric Company in succession to his brother, E. W. Cox, recently deceased.

R. W. McCONNELL, a member of the staff of the Geological Survey, Dominion Government, Ottawa, has been appointed Acting Deputy Minister of Mines, following the resignation of R. W. Brock, as Deputy Minister of Mines.

DR. C. W. DRYSDALE, of the Geological Survey ot Canada, who has engaged at the government's camp at Rossland, B.C., has completed his work there and is now at Ymir, in Nelson mining division of West Kootenay, B.C., making a study of the ore deposits at that camp.

ROBERT ROSE, of 295 Jarvis Street, Toronto, and also of Victoria, B.C., an engineer who has gained much knowledge of the Orient and its languages, as well as much experience among British and Canadian manufacturers of power machinery, is perfecting arrangements with several large engineering firms in Eastern Canada to represent them in Shanghai, China. It is understood that in that country there is an ever-increasing demand for transport and power machinery, and Mr. Rose, with his qualifications, will doubtless be successful in the undertaking of opening this new export business.

JOS. BILLINGHAM has been appointed to the position of Superintendent of Motive Power for the Grand Trunk Pacific Railway Company, and succeeds G. W. Robb, who resigned recently from the office. Mr. Billingham is a native of England, and his first position of importance was with the London and Northwestern Railway. Subsequent to his connection with this railway company, he has been master mechanic for the Burlington and Ohio Railroad, European manager for the Galena Signal Oil Company, and, directly previous to his new office, superintendent of works for the American Locomotive Company at Schenectady, N.Y. Mr. Billingham's new headquarters will be at Transcona, Man.

JOHN S. BATES has been appointed to succeed A. G. McINTYRE, resigned, as superintendent of the Dominion Forest Products Laboratories in connection with the McGill University. Mr. McIntyre is now in charge of a new paper mill at Bathurst, N.B. Mr. Bates was born at Woodstock, Ont., and is a graduate of Acadia University in arts and science. After leaving Acadia, he went to Columbia University, New York, and graduated in chemical engineering, specializing in pulp and paper. He made a study of the utilization of Southern pine waste while at Columbia, and since the conclusion of a brilliant course there has had practical experience with the Union Bag and Paper Co., of New York, and Arthur D. L. Little, Inc., chemists, of Boston. Mr. Bates has already entered upon his new duties.

THOMAS TURNBULL has received the appointment of assistant chief engineer for the Canadian Northern Railway Company, with offices at Winnipeg, Man. Mr. Turnbull began his engineering experience in 1881 as transitman on location for the Canadian Pacific Railway, and later became resident engineer on construction on that road. In 1889-91 he was employed by the Newfoundland government as engineer in charge of a location party and construction work on the Halls Bay Railway. From 1891 to 1897 he was assistant engineer of maintenance and construction on the Western Division of the Canadian Pacific. For three years following he was chief engineer of the Canadian Northern Railway lines west of Winnipeg. In 1900 he was engaged in contract bridge work on the Canadian Pacific, and during the following year on reconnaissance work for the Dominion Government. From 1902 to 1904 Mr. Turnbull was again in the employ of the Dominion Government as inspector of surveys. From 1904 to 1910 he occupied the position which he now holds, that of assistant chief engineer for the Canadian Northern Railway. In 1910 he went to the Hudson Bay Railway as assistant chief engineer, and remained in that position until 1912, since when he has been chief engineer of the Edmonton-Dunvegan Railway.

REGINALD W. BROCK has resigned the office of Director of the Geological Survey and Deputy Minister of Mines, and has accepted an appointment as head of the Applied Science Department of the new University of British Columbia. Mr. Brock was a student of the University of Toronto from 1891-92. During the summers of these years, Mr. Brock acted as field assistant to the Geological Survey. On the organization of the School of Mining in Kingston, he enrolled as a student in Queen's University, graduating in 1895. The summer of 1895 was spent at the University of Heidelberg; and the subsequent autumn, Mr. Brock was given temporary charge of the Department of Mineralogy at Queen's University, from which he resigned to become a permanent member of the staff of the Geological Survey of Canada, chiefly in British Columbia. After five years in the office of this department, another year was devoted to study again at the University of Heidelberg; following which, Mr. Brock became Professor of Geology in the School of Mining at Queen's University. Since that time, also, he has maintained his connection with the Geological Survey branch, spending the field seasons in British Columbia, where his most recent work has been the detailed examination of the Rossland mineral area, and his valuable report on several mines of that district made about three years ago at the requests of the different companies.

OBITUARY.

The death occurred recently of William R. Sinclair, railroad and general contractor, at his home, 1412 Portage Avenue, Winnipeg. The deceased was 67 years of age, was a native of Scotland, and has been a resident in Manitoba for 50 years. Mr. Sinclair was one of the promoters of the South Eastern, now a part of the Canadian Northern Railway, being one of the first contractors engaged on that work.

BERTRAND G. DYE met death by drowning on August 23rd at Balmy Beach, Toronto. Mr. Dye was an engineer, occupying the office of superintendent with the firm of Tate Electrics, Limited, and previously was connected with the work upon the Toronto filtration plant. The deceased was a native of South Norwood, Surrey, Eng., and a graduate of King's College, London.

SECOND INTERNATIONAL WATER-POWER CONGRESS.

The second International Water-Power Congress will be held during September 7 to 10 at Lyons, France, under the auspices of the Ministers of Public Roads and Agriculture. After the convention trips will be conducted to important hydro-electric developments in the Alps. There will be three sections, one on legislation, another on finance and a third on technical questions. The first section has seven questions to deal with—(1) summary of water power legislation in Austria, Canada, England, Germany, Italy, Norway, Russia, Spain, Sweden, Switzerland and the United States, (2) water rights on unnavigable streams where no logging is prevailing, (3) laws for water-power plants using water on public domain, (4) laws for water-power plants using water in unnavigable streams, (5) international rules for the utilization of rivers belonging to two countries, (6) export and import of electrical energy, and (7) laws for regulation of rivers and utilization of water powers in government forest districts. The second section will discuss the following topics: (1) Economical results connected with the management of the River Rhone, (2) reservoirs for river regulation, (3) levees and their influence on industries using the energy of water, (4) the influence of the government on the economical development of water power, (5) capitalization of water powers developed by private interests and those developed by governments or municipalities, (6) local profits due to utilization of power, (7) undertakings for regulating river discharges, (8) water power and the metallurgical industries, (9) water power and the electrification of railroads, and (10) water power and agriculture. The section for technical questions will deal with—(1) hydro-electric plants bypassing rivers, their dams and other structures, (2) protection of rivers, (3) measurement of discharges, (4) surge tanks, (5) hydro-electric laboratories, (6) metal pressure conduits, (7) pressure conduits of reinforced concrete, (8) turbines, (9) backwater from dams, and (10) transmission of energy.

AMERICAN HIGHWAY ASSOCIATION CONGRESS.

Governor Slaton, of Georgia, has requested the Governors of all the other states to act favorably upon the invitation of Austin B. Fletcher, president of the Fourth American Road Congress, to name official delegates to the Congress, to be held at Atlanta, Ga., November 9 to 13, 1914. Already forty-seven organizations have signed the official call. The parent organizations are the American Highway Association and the American Automobile Association. Co-operating prominently through the holding of special sessions, the American Bar Association, the American Bankers' Association, and the National Civil Service Reform League will cast the weight of their prestige in behalf of the Congress. Hundreds of county boards will be represented by their chairmen or county engineers to profit by the discussions of the most eminent road builders of America; to study the eminently instructive government exhibit, which includes designs of every known type of road; and to compare critically the machinery, materials and engineering instrument exhibits from hundreds of manufacturers. So closely are city, street and county road problems now related that an exceptionally large number of cities will this year delegate their street superintendents and city engineers, or their mayors, to the Congress.

Logan Waller Page, Director of the United States Office of Public Roads, will preside at one or more sessions of the Congress. Austin B. Fletcher, State Highway Engineer, of California, will open the sessions as President, and will be assisted by the Vice-Presidents, E. M. Bigelow, State Highway Commissioner of Pennsylvania; A. N. Johnson, formerly State Engineer of Illinois; W. E. Atkinson, State Highway Engineer of Louisiana; and Charles A. Magrath, Chairman, Ontario, Canada Highway Commission.

An elaborate series of social entertainments has been planned by Atlanta, which will include receptions, banquets, and excursions. At least six thousand delegates are expected, or two thousand more than attended the 1913 meeting in Detroit. And co-operation of a most thorough character is assumed by the railroads, as they have already granted a round trip lower than has been granted for years to national meetings.

SIXTEENTH ONTARIO MUNICIPAL ASSOCIATION MEETING.

On September 2nd and 3rd will be held in the City Hall, Toronto, meetings of the Ontario Municipal Association, at which will be discussed the following questions, introduced by the following officials of various municipalities: "A Government Minister and Department of Municipal Affairs," Mr. S. H. Kent, City Clerk, Hamilton; "Municipal Accounts and Audits," Mr. A. K. Bunnell, City Treasurer, Brantford; "Settlement of Administration of Justice Accounts," Mr. N Vermilyea, Reeve of Thurlow; "The Relation of a University Education to the Performance of Municipal Duties," Prof. James Mavor, Toronto University; "The Cost of Roads," Mr. W. A. McLean, Chief Engineer, Government Highways Department; "County Municipal Associations," Mr. K. W. McKay, County Clerk, Elgin; "Purification and Protection of Water Supplies," Dr. J. W. McCullough, Secretary of Provincial Board of Health; "Railway Taxation for Municipal Purposes," Mr. W. Johnson, City Solicitor, Toronto.

An address of welcome will be delivered by Mayor H. C. Hocken, of Toronto; and an address upon the present position of municipal affairs will be delivered by the President, Mr. J. G. Richter, of London.

Copies of the programme of this, the sixteenth annual meeting of the association may be had from F. S. Spence, City Hall, Toronto.

COMING MEETINGS.

NATIONAL PAVING BRICK MANUFACTURERS' ASSOCIATION.—Secretary, Will P. Blair, 832 B. of L.E. Building, Cleveland, Ohio. Eleventh annual convention and paving conference, Buffalo, N.Y., September 9th, 10th, 11th, 1914.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown. Indianapolis, Ind., Secretary.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—11th Annual Convention; 5th American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau St., New York, N.Y.

A weekly paper for engineers and engineering-contractors

NEW GOVERNMENT DRY DOCK AT LAUZON, QUE.

DETAILS OF DESIGN, INCLUDING CAISSON STOPS, APPROACH, AND PUMPING EQUIPMENT, NOW UNDER CONSTRUCTION FOR THE DEPARTMENT OF PUBLIC WORKS.

THE new dry dock which the Department of Public Works of the Dominion Government has under construction at the village of Lauzon, two miles east of Levis, on the St. Lawrence River, opposite Quebec, will possess many features that will place it among the foremost of such structures. The proposed dry dock is to supplant one already in service at this point. The relative locations of the old and contemplated structures may be noted in Fig. 1, which shows also the general layout of the later development, including the approach slip to be built in conjunction with it.

The work has been under way since last season. The contract for the construction of the dock was let in July, 1913, to the firm of Messrs. M. P. and J. T. Davis, the contract price being $2,721,116. On October 24, 1913, Premier Borden dedicated the work. Since that time the contractors have been pursuing the excavation work for the dry dock proper. This excavation, as will be noted from Fig. 2, is almost entirely in rock. Very little earth removal is required and this applies also to the amount of dredging necessary.

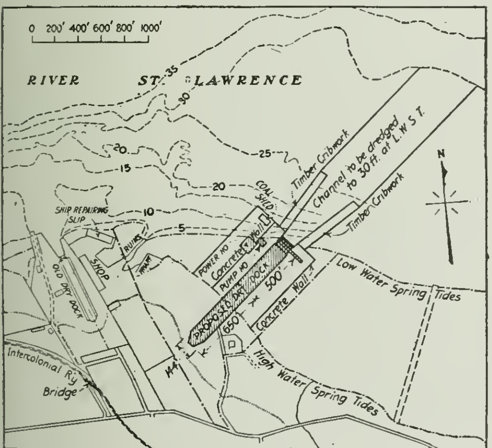

Fig. 1.—Location of the New and Old Government Dry Docks at Lauzon, Quebec.

The dock will be 1,150 ft. in length from headwall to caisson stop. The width of the entrance is to be 120 ft., while the depth on the sill at ordinary high-water spring tide will be 40 ft. The dock will be divided into two parts, as shown in Fig. 3, general plan, the object of which is to be able to use the mid-caisson stop for smaller vessels. A steel rolling caisson, details of which are shown in Fig. 5, will be used to close the outer entrance, while a steel floating caisson, plan and sections of which are shown in Fig. 6, will be used to close the inner entrance, or, in cases of emergency, the outer entrance also.

Fig. 1 also shows the approach channel which is to be dredged to a depth of 30 ft. and to be guarded at the entrance to the dock by concrete walls supported by timber cribs. Between these guide piers and the rolling caisson a sill for the floating caisson is provided. It will be located 20 ft. from the face of the former and will enable it to be unwatered when repairs are necessary.

As shown in Fig. 3, the dry dock will be 144 ft. wide at the top of the coping and 120 ft. in width at the caisson seats. The width will be 120 ft. at the bottom. The depth is approximately 40 ft. below high-water at ordinary spring tide, the fluctuation being 18 ft. between tide levels. The cross-section shows the two solid concrete

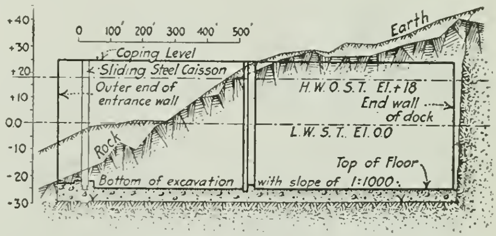

Fig. 2.—Profile Showing Excavation Necessary.

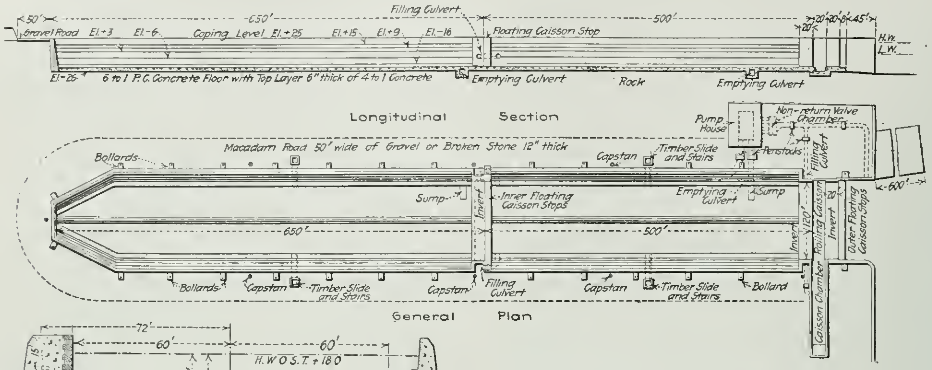
side walls integrally connected to the floor, which is also of concrete. The footings are on solid rock.

The excavation is being carried to a depth of 28½ ft. below the level of low-water spring tide, which is used as the datum line. This is the depth required at the inner end of the dock, the depth of rock varying, as shown in Fig. 1. The bottom of the excavation will have a slope of 1:1,000. It will be 122 ft. in width, sloping up to ground level on a 1:2½ batter. The slope of 1:1,000 mentioned above brings the forward end of the cutting approximately 29½ ft. below datum.

The solid concrete side walls of the dry dock are to be of gravity type in places where they have to support earth fill, such as at the entrance, where the rock bottom recedes considerably, otherwise, the concrete walls will line the rock face of the excavation, retaining on their inner face the same profile as the gravity walls. Where stepped, they will have an average wall thickness of about

5 ft. of concrete. Whenever the gravity walls are built higher than the natural surface of rock they will have a 6-foot thickness of backfill of puddled clay, behind which ordinary earth filling will be used. The coping at the top of the wall and on the altar levels will be of cut granite, toward the outer entrance of the dock being 1 ft. in 1,000. The sides will be drained by two 6x12-in. gutters. Underdrains, beneath the floor and behind the side walls will remove any seepage water. The floor will be built of plain concrete in sections similar to the walls, the in-



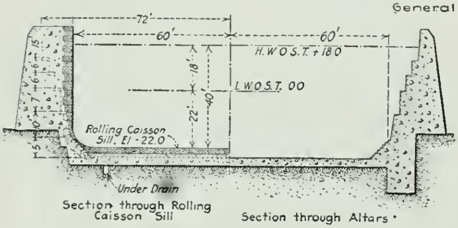


Fig. 3.—General Plan, Longitudinal and Horizontal Sections of Dry Dock.

terstices to be grouted on completion. One feature of the floor formation that deserves special mention is that it will be provided with three rows of granite blocks 18 ins. in thickness, down the centre. The middle row will be 4 ft. in width and will be level on the top, while the row on either side will be 3 ft. wide and will conform to the slope of the floor.

As noted in Fig. 3, the head of the dry dock tapers to a point, in plan. The elevation shows that the altars are not continued but end in a plain sloping gravity head-wall.

On each side of the dock and at each end of the main sections stairs will be moulded into the concrete side walls. Timber slides will also be set centrally in each wall of both sections and at right angles to the dock walls. They will be 8x12 ft. in size and will slope backward from the bottom of the dock to ground level, as shown in Fig. 4. These are shown in Fig. 3, being placed on either side and near the centre of each section. The slides will be faced with granite 18 ins. thick, each block not less than $3\frac{1}{2}$ x 4 ft. in top surface.

in blocks 12 ins. thick and 3 ft. in width in the latter instance and in the form of granite slabs in the former.

The side walls are to be built in 30-ft. sections separated by a ¼-in. expansion joint. Each section will

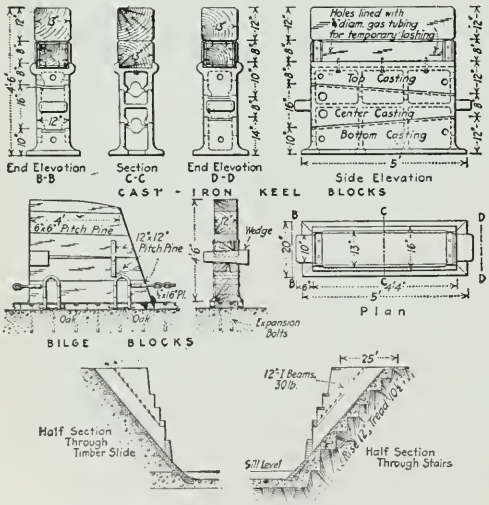

Fig. 4.—Details of Blocks and Block Slides, Also of Timber Slides.

be finished with a V-joint 1 in. in depth. The flooring of the dock will be 5 ft. in thickness, the elevation at the centre being 6 ins. higher than at the sides and the slope

Pumping Equipment.—The following is extracted from the specifications governing the pumps and power units:

The contractor shall furnish and set in place on suitable foundations and at the required elevation, six wrought-steel water-tube boilers each of sufficient capacity to furnish 500 h.p. and two boilers of 300 h.p. each, working under steam pressure of 200 lb., set in batteries of two boilers each. Each boiler may be built with two or more drums not exceeding 48 in.

The boiler should show an efficiency of 75% when fired with good coal containing 12,500 B.t.u. or over per pound.

There shall be three direct-current generators, 550 volts, one of 1,500 kw., one of 750 kw. and one of 300 kw., each driven by steam turbines of the Westinghouse-Parsons type, or by triple-expansion reciprocating vertical engines capable of developing 25% overload. These generators shall be built so as to allow the connections in multiple when required. A lighting direct-current gen-

erator shall also be installed of 100 kw. 220 volts to be driven by a vertical direct-connected compound engine mounted on same bed plate.

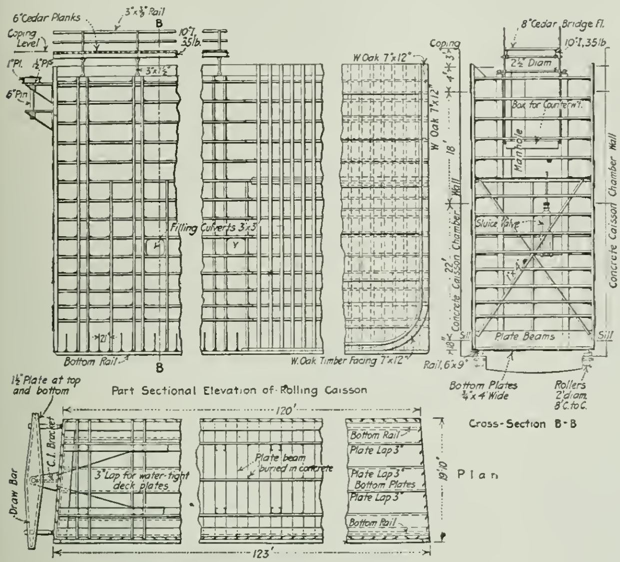

Fig. 5.—Elevation and Sections of Rolling Caisson.

The contractor shall furnish and install the following direct-current motors: three motors of 1,000 h.p. each for the main pumps, 550 volts of suitable speed for pumps; two motors of 125 h.p., 550 volts for the auxiliary drain pumps and of suitable speed; one motor of 125 h.p., 550 volts geared to worm operating the rolling caisson, speed, about 300 r.p.m. and reversible; one motor on rolling caisson, 15 h.p., 550 volts, with shaft extending on both sides and each end carrying three pinions and bevelled gear to operate the six caisson valves; four motors of 15 h.p. each 500 volts, provided with pinions and bevelled gear to operate the main culvert valves; two motors of 100 h.p. each on the floating caisson to operate the pump thereon; one motor of 10 h.p. with pinions and bevelled gear, fitted as specified for the motor on the rolling caisson to operate the sluice valves in the floating caisson. If required so to do, the contractor shall also install motors to operate any of the capstans to be placed on each side of the dock, in which case the motors shall be so installed as to be protected from dampness and rain and made detachable from their foundation.

The contractor shall furnish and install the undermentioned centrifugal pumps for the dock equipment, three main pumps of the vertical type to be placed in the pump house, each having a capacity of 60,000 Imp. gal. per minute, with suction and discharge pipe 58 in. diameter; the suction pipe to be provided with a bell-shaped extension; it shall be supported by angle irons riveted on the outside and fitted in the concrete floor of the pump house, the discharge pipe being solidly fitted in the wall of the non-return valve chamber.

These pumps to have cast-iron impellers, bronze shaft and cast-iron casing with two suitable bearings provided with forced oiling device and the shaft connected to the motors with flanges, all of which to be provided by the contractor and installed in perfect working order. These pumps shall show an efficiency of 72% when working against a head of 25 ft.

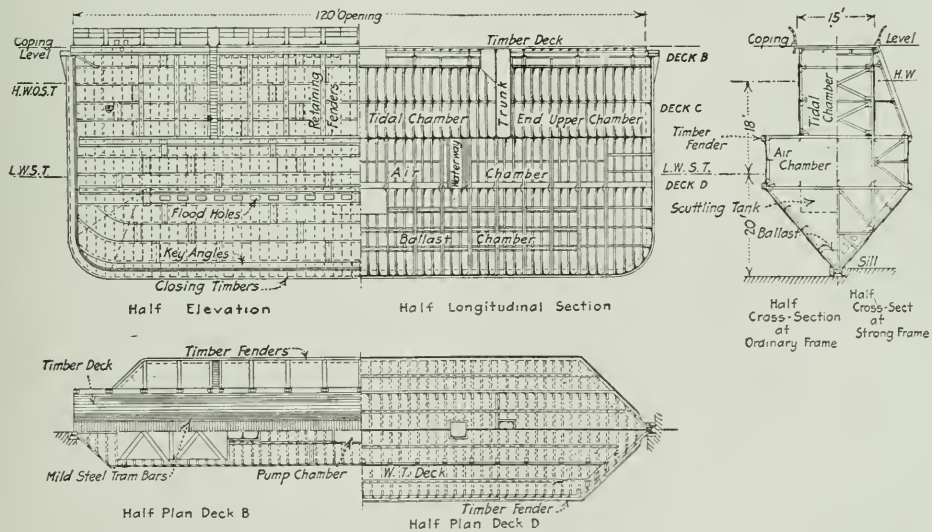

Fig. 6.—Elevation, Plan and Sections of Floating Caisson.

The contractor shall furnish and place in the pump house two drain centrifugal pumps of the vertical type with 18-in. suction and discharge pipes. The suction

shall be provided with a bell-shape extension and foot valve; proper means shall also be provided to charge the pumps. These shall have cast-iron impellers fitted on bronze shafts which shall be flange connected to the motor shaft. The discharge pipes shall be supported on bracket fastened to the walls of the pump house and carried to the main emptying culvert of the dock. A sluice valve shall be provided in the discharge pipe for closing same.

These pumps are intended to work against a head of approximately 40 ft. and shall show an efficiency of 70% when working against that head.

Caisson Gates and Entrance Walls.—The entrance walls mentioned above, and shown in Fig. 7, consist of timber cribs supporting on the top a mass concrete gravity wall 18 ft. in height. They will be 600 ft. in length and funnel-shaped in plan, giving an outer entrance width of 300 ft. The walls are to be each 75 ft. in width. The type of construction consists of a stone foundation to be laid on the earth bottom for a depth of 4 ft., this to be covered by smaller stones to a depth of 1 ft. On top of this the timber is to be laid to an elevation of 6 ft. above low-water. The timber formation is to be filled with stone and to be floored at the top to carry the concrete structure. The space between the concrete walls is to receive earth filling.

The entrance walls approach each other until at the outer entrance of the lock the width conforms approximately to the width of the dry dock. The steel rolling caisson, shown in plan and sectional elevation in Fig. 5, will vary in length from 120 ft. on one side to 123 ft. on the other. It will be 19 ft. 10 ins. in width and is to take the form of a hollow steel frame box properly ballasted to adjust itself in a floating position when in the water. A concrete chamber, shown in Fig. 3, is provided for housing the caisson when not in use. The caisson will be provided with a steel water-tight deck 22 ft. in height. On this the rising tide will be allowed to enter through openings permitting flooding at the rate of 4 ft. in height per hour. This will prevent the caisson from floating in times of flood tide. The caisson will be provided with filling and emptying culverts, as shown in Fig. 2. There will be six of them, each approximately 10 ft. square and constructed of steel and water-tight. When the caisson is to be pulled out of its chamber and across the dock to form the closure its weight will be transferred on rollers by rails shown in the cross-section of Fig. 5. These rails are to be 6 x 9 ins. in section and to be of medium hard steel. The large sectional area is to prevent deflection at times when the caisson is undergoing repairs and there is no hydrostatic pressure underneath. The rollers are to be 2 ft. in diameter and placed 8 ft. centre to centre. The caisson chamber is to be covered with white pine 4 ins. thick resting on steel I-beams placed 30-ins. centre to centre, set in the concrete wall.

Fig. 6 gives details of the floating caisson which is to be used to close the inner entrance under ordinary conditions or the whole dock in cases of emergency. It will be constructed of mild steel and will have water-tight ballast, air and tide chambers, etc., such as are common to floating gates to provide for easy handling when afloat. It will also have 6 filling culverts similar to those already described. It will be equipped with two centrifugal pumps, having a total capacity of 10,000 gal. per minute against a head of 40 ft. These are to be used to remove water ballast when necessary. The caisson is to be provided with timber sills and sides, designed to butt against the sills and vertical walls built into the concrete side walls at the junction of the two main sections of the dock. When the full length of the dock is to be used this floating caisson is to be towed outside of the dock altogether.

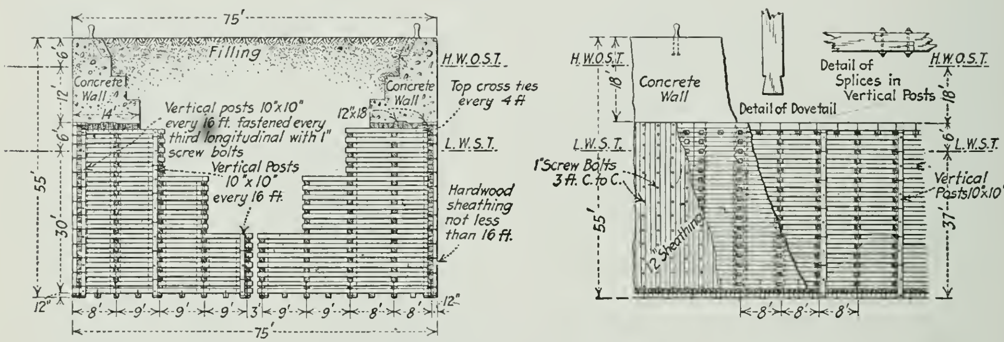

Fig. 7.—Details of Entrance Cribs.

The method of filling and emptying the dry dock is as follows: The culverts are arranged so that each part of the dry dock may be filled or emptied independently. Water is admitted through the filling culverts, shown in Fig. 2, and led into the front part of the chamber around the rolling caisson. The rear chamber is filled through a culvert curving around the floating caisson, as shown by the dotted line. When it is stated that one chamber may be filled or emptied independently of the other it is to be noted that the rear chamber cannot be filled unless the front chamber is full of water. In emptying, the water is conveyed through the sumps beneath the side walls, as shown in the illustration.

When the dock is in use the vessel will be supported by blocks, shown in Fig. 4. The cast-iron keel blocks are to be in three pieces, as shown. Altogether they attain a normal height of 4½ ft. They will be capped with timbers 13 ins. square. The bilge blocks will be of pitch pine provided with sliding irons and oak slide blocks. The bilge block slides will be of white oak and will be situated along the entire length of the dock at 16 ft. centre to centre.

The contract, as stated, was awarded to Messrs. M. P. and J. T. Davis, of Quebec, who are at present engaged upon the work. We are indebted to "Engineering News" for the drawings illustrating this article.

PETROGRAPHIC RANGE OF ROAD-BUILDING MATERIALS.

IT frequently falls to the lot of a petrographer to classify stone which it is proposed to furnish for a special piece of work, and to give an opinion as to its fitness or its likelihood of meeting the requirements of specifications. In most cases these requirements are very far from being specific, in a petrographic sense, i.e., precise rock names are rarely used, whereas some general term or some phrase descriptive of the quality is common. The commonest term of all is "trap."

A few quotations copied from standard specifications covering regular contracts under various state and municipal departments, and bureaus of highways, are given as representative of this usage by Mr. Chas. P. Berkey, in the School of Mines Quarterly of Columbia University:

(*a*) "Only broken stone . . . of a hard and compact texture and of uniform grain will be allowed . . . . Disintegrated and rotten stone . . . will not be accepted."

(*b*) "The trap rock shall be of satisfactory quality equal to that used in . . . for macadam roads."

(*c*) "The mineral aggregate used shall consist of trap rock, newly broken, of uniform quality throughout, free from slaty and flat pieces, soft or disintegrated stone, dirt and other objectionable material."

(*d*) "The stone . . . must be trap or approved native rock. It must show a fresh, crystalline surface."

(*e*) "All stone must be . . . the same kind and quality, equally good in every particular as that shown in the Engineer's office."

(*f*) "Only good, solid stone shall be used. . . . Bidders will name the kind of stone they propose using in said work, also its location."

(*g*) " . . . shall consist of first quality trap rock . . . Mineral aggregate shall be clean, crushed trap rock of approved quality."

(*h*) "Crushed stone shall have a coefficient of wear, according to the Duval test, of not less than 8, and a cementation value of not less than 50."

(*i*) "The first course shall consist of sound rock . . . Unless otherwise specified, the stone of the second course shall be trap rock. . . . For the third course other material than trap rock screenings may be used if approved by the Engineer."

(*j*) "Stone for macadam shall consist of approved local stone, trap rock, or a combination of local stone and trap rock . . ."

(*k*) "The crushed stone shall be trap or other suitable rock, satisfactory to the office in charge."

(*l*) "The macadam shall be of limestone of approved quality. . . . The stone must be of good and uniform texture."

(*m*) "All stone for concrete shall be hard limestone, sandstone, trap, furnace slag, quartzite, or granite, acceptable to the Chief Engineer. Broken stone must be quarried from massive ledge, and any stone which shows a tendency to break into flat, thin pieces will be rejected."

(*n*) "The broken stone shall be trap, granite, or limestone, or such other stone taken from the line of work as shall be satisfactory in the judgment of the Engineer."

Such a summary is probably fairly typical. From it two or three generalizations may be made. For example: (1) The standard, so far as there is a standard, with which all rocks are compared in highway work, is "trap." (2) Trap is usually specified by name wherever there is any reasonable hope of furnishing it for the contract. (3) Wherever substitutes are encouraged they are either indicated by name, or are described in efficiency terms, or the responsibility is placed directly on the engineer in charge.

It is the general opinion, based on experience, that the "traps" are pre-eminently satisfactory for highway uses. But trap is not a very definite petrographic term. In a very broad way this means that the basic igneous rocks of massive structure, and having a tendency to diabasic or closely interlocked habit of the mineral constituents, are the best road material. The acid igneous rocks are not so successful, especially when there is heavy traffic sufficient to test the toughness of the rock. The metamorphic rocks, as a class, are not regarded with much favor. The clastic or fragmental rocks, as a rule, are not recommended, but limestones are very serviceable where hardness is not a prime essential. In every large class of rocks there are special types which prove to be of acceptable grade, but no large class compares with the basic igneous rocks for general efficiency under the most exacting conditions.

In spite of this apparent reduction to such simple terms in the matter of range of rock types regarded as acceptable, as a matter of fact, a great variety of rocks are actually used and are quite worthy of serious consideration. Many factors enter into the question of choice; it is not always a simple problem. There is little excuse for a community to demand trap in any except the most critical cases, unless there are trap ledges in the vicinity or somewhere near its borders. It may well happen, in many cases, that the increased efficiency is more than counterbalanced by the extra cost over local stone. In the average case, local stones everywhere merit serious consideration, and a little judicious discrimination will usually discover an acceptable one.

It is in this connection that critical knowledge of rock variation will be found useful. Names of rocks alone are not so useful as might at first appear, because all types vary greatly in minor points of texture, structure, chemical and dynamic modification, and consequent efficiency. No amount of mere classification can take the place of careful discrimination of structural variety within the principal types themselves.

It may be useful, however, to consider briefly the range of types coming within observation for such uses, and to indicate their petrographic grouping. Probably no publication on rock for highway uses has given a fuller list of varieties than Bulletin 44 of the Office of Public Roads, United States Department of Agriculture, Washington.

The following list has been compiled from this and other sources, and the terms are classified under the commonly used headings familiar to all students of natural rock materials. In it there is no attempt to indicate relative value for actual use. For reasons suggested in an earlier paragraph it is certain that particular varieties of a type which is usually considered of poor quality may very well prove to be much superior to the more faulty varieties of rock types that are generally regarded as high-grade. The descriptive terms following some of the rock names indicate the varieties that have been used; the terms are inserted just as they occur in the literature, without any attempt to reduce them to uniformity::—

I. Igneous Rocks:

(*a*) Volcanic fragmental materials:

1. Volcanic ash.
2. Volcanic breccias.
3. Rhyolite tuff.
4. Andesite tuff.
5. Basalt tuff.

(*b*) Surface flows (crystalline lavas, felsitic, and slightly porphyritic in texture and showing flowage structure):
6. Rhyolite and rhyolite breccia.
7. Felsite and brecciated felsite.
8. Trachyte.
9. Andesites: Augite; Hornblende; Andesite breccia.
10. Basalt: Vitreous; Olivine; Chloritized.

(*c*) Intrusive masses (dikes, sills, etc.; strongly porphyritic or intimately interlocked in texture):
11. Granite porphry.
12. Syenite porphry.
13. Camptonite.
14. Diabase ("trap" of highest grade): Hypersthene; Uralitic; Olivine; Augite; Gabbro; Meta-diabase.
15. Diabase porphry.
16. Peridotite.
17. Pegmatite.

(*d*) Plutonic masses (deep-seated in origin; granitoid in texture and massive structure):
18. Granite: Hornblende; Porphyritic; Muscovite; Micro-granite; Gneissoid.
19. Syenite: Augite; Quartz.
20. Granodiorite.
21. Diorite: Quartz; Augite; Basic; Porphyritic.
22. Gabbro: Hornblende; Hypersthene; Uralitic.

In the above grouping, the field relations are indicated in the sub-headings, and under each the rock types of which the names have been found mentioned in road tests, or rock lists for such purpose, have been arranged approximately in order from the more acid to the more basic in composition.

II. Sedimentary (clastic) rocks and associated organic accumulations and aqueous precipitates, together with special modifications:

(*e*) Simple sediments (arranged from fine to coarse grain):
23. Shale: Clay; Ferruginous; Carbonaceous; Calcareous.
24. Sandstone: Argillaceous; Calcareous; Ferruginous; Chloritic; Feldspathic; Arkose; Kaolinized; Biotite; Indurated; Metamorphosed; Conglomeritic.
25. Conglomerate.

(*f*) Organic in origin, with or without sedimentary intermixture, and usually with some modification:
26. Limestone: Shell; Fossiliferous; Clay; Argillaceous; Bituminous; Siliceous; Nodular; Oolitic; Cherty; Dolomitic.
27. Dolomite: Argillaceous; Arenaceous; Siliceous.

(*g*) Precipitates:
28. Travertine (tufaceous limestone).
29. Gypsum.

(*h*) Special segregations, etc.:
30. Quartz.
31. Chert: Calcareous; Oolomitic.
32. Flint.
33. Nematite.
34. Phosphate rock.

III. Dynamic fragmental materials:

(*i*) 35. Breccia: Quartz; Quartzite; Brecciated felsite.

IV. Metamorphic rocks (that have been recrystallized and have lost most of their original structural habit and in part their mineralogic habit. As a rule they have a foliate structure and break much more readily in one direction than in others):

(*j*) Fine-grained types (with good rock cleavage):
36. Slate or argillite: Clay; Siliceous; Calcareous; Indurated slate.

(*k*) Medium grained (rather massive and comparatively little foliate habit):
37. Quartzite: Calcareous; Sericitic; Feldspathic; Chloritic; Pyroxene; Epidote; Hornblende; Micaceous.
38. Graywacke.

(*l*) Strongly foliated and usually of medium grain (commonly of abnormal composition; i.e., some mineral other than feldspar in excess):
39. Schist: Quartzite; Mica; Biotite; Quartz-mica; Hornblende; Mica-hornblende; Hornblende - mica; Chlorite; Hornblende - chlorite; Garnet - hornblende; Quartz - hornblende; Tremolite; Talc schist (soapstone).

(*m*) Foliated structure, medium to coarse grain, sometimes banded and of normal composition (i.e., the usual feldspathic mineral makeup):
40. Gneiss of unstated relations: Quartz; Sericite; Hornblende; Arkose; Chlorite; Muscovite; Biotite; Pyroxene.
41. Granite gneiss.
42. Syenite gneiss.
43. Diorite gneiss.
44. Gabbro gneiss.

(*n*) Massive types:
45. Marble: Dolomite marble.
46. Serpentine: Hornblende serpentine.
47. Amphibolite.
48. Eclogite: Mica eclogite.
49. Epidosite.

This list represents in reality a very wide range. It is certain that many of them are of very low efficiency, but in spite of that they have been found worthy of consideration and test. Nos. 10, 13, 14, 15 and 21 are the prominent "trap" representatives. Diabase, No. 14, is the type usually meant when the term is used in specifications. But it is not a closely defined petrographic term and is often more loosely used.

The fact that these rock names appear as having been considered worthy of attention for road-building purposes does not necessarily indicate special fitness of all these types. Many of them are doubtless very poor grade compared with trap, but they may in spite of that be superior to the only other materials warranting practical comparison in a given case. Furthermore, the fact that any one of these has been used successfully cannot be taken as evidence that every occurrence of the rock of the same petrographic classification would be acceptable, since so much depends on the physical condition, freedom from decay, texture and special structural factors of each occurrence—to say nothing of other factors of control lying outside of the present line of discussion—such as availability of other competing materials, transportation difficulties, allowable cost, uses to which the road is to be put, etc.

No doubt it would be a great convenience for highway engineers if a special classification, in which the pro-

minent efficiency factors were given chief place, could be devised. The chief difficulties with such a scheme are:

(1) That it is an attempt to simplify data that are essentially not simple.

(2) That its basis could not coincide at all with that of any other rock classification; and, therefore,

(3) That the terms used in classification could not agree closely with those in common use.

The result would be, it seems to me, that we should have another classification to become familiar with instead of accomplishing a simplification. On the whole, there is as yet no better suggestion than that the commonly used terms for description and naming should be thoroughly mastered, and that the nature of the structural and textural basis of difference in quality should be fully understood, and that the geological and petrographic principles underlying the history of rocks should be a part of ones professional equipment.

ELECTRO-THERMIC MANUFACTURE OF STEEL.

This is a comparatively new industry, dating from about the year 1900. The advantages of heat produced electrically, for the manufacture of steel, over that produced by chemical reaction through the combustion of fuels are four in number. It is obvious that almost any temperature within reason can be obtained, and consequently slags rich in lime, and with a strong affinity for sulphur and phosphorus, can be smelted whose melting point is too high for the ordinary methods employed. It is also possible to deal with the titaniferous ores, which make the furnace charge too infusible for coke smelting. Alloys can likewise be produced which are too infusible to be formed in fuel-heated furnaces, such as ferro-titanium, ferro-tungsten, ferro-chrome, or ferro-silicon, which are richer than usual in the alloying element.

A second advantage is that an exactness and nicety in the control of temperature can be obtained, giving increased facility to the control of chemical reactions within the furnace, so that certain combinations of elements in the iron are made possible and the temperature at which the steel is finished and cast may be more exactly regulated. The metal obtained is also free from contamination by impurities contained in the fuel; the chief of which is sulphur, which is always present in the coke. Another point which has to be taken into consideration is that electric power for smelting purposes can often be obtained from some watercourse adjacent to the ores and fluxes, in situations where gas, oil, coal, or coke could be procured with difficulty.

GAS PLANTS AND MACHINERY.

The president of the Institution of Gas Engineers in England was reported recently as stating that with the exception of the method of heat purification, there has not been any striking change in either plant or machinery in the gas industry for some time past. The problem of carbonization is receiving close attention, but it is to be regretted that the committee appointed by the institution has not yet been able to arrange for the comparative tests being awaited by the industry as a whole. Of late, increasing attention has been given to questions of scrubbing and condensation in order to remove deleterious substances from crude gas in such a way as not to impoverish the finished product, and in such a way as to ensure that nothing remains that will impose an unnecessary burden on the purifiers, or interfere, or tend to interfere, with the value of gas as an illuminant and a heating agent.

WATER AND SEWAGE INSTALLATION AT ASSINIBOIA, MAN.

The water and sewer systems around Deer Lodge, in Assiniboia, the western suburb of Winnipeg, were officially opened on August 12th. If the plans of the Assiniboia council are compassed, water and sewer main connection will be carried from the Winnipeg city limits to Sturgeon Creek. The plans have been made and are being carried out with the end in view that, when the time comes to connect up with the Greater Winnipeg Water District scheme, the connection will be ready and easily completed. The new system has, moreover, been constructed so as to afford a means of protection against fire.

Under supervision of G. W. Rogers, A.M.I.C.E., the municipal engineer, the new system has been installed with most creditable speed. Work was started last November, and since that time nearly 7 miles of sewers and water mains have been laid. The work, when complete, will cost approximately $200,000.

The water is obtained from an artesian well, 365 feet deep; and a small pumping station 52 x 30 feet in dimensions, has been erected.

The pumping plant is complete in every detail and has a capacity of 12,000 gallons an hour. It will supply a population of 2,000. All the machinery is in duplicate, so that in the event of a breakdown the water supply will not be shut off for a single instant. The electrical equipment consisting of two 25-h.p. units, together with the arrangement of switch board and all the electrical apparatus, was installed under the direction of R. Lynn, the municipal electrician. There is a 70-pound pressure at the head of the pumps. The building and solid concrete foundations upon which all the machinery and storage tanks rest were erected by the Progress Construction Co. The entire machinery plant was put in by the Refrigeration and General Engineering Co., of Winnipeg; which firm, in addition to installing the plant, put in a complete system of fire hydrants, which are distributed all over the district.

In the pumping station, probably the most important installation is that of 2 steel tanks, the combined capacity of which is 36,000 gallons. There will always be this amount of water in reserve in addition to that around the well. Outside the building there is a concrete tank, the top of which is flush with the ground. This tank is 13 feet deep, 12 feet in diameter, and has a capacity of 5,000 gallons.

The system employed at the new plant is to pump the water from the well to this outside tank with 2 air compressors. It is then pumped into the 2 steel tanks within, and from there into the mains under air pressure. In this manner the water is aerated to a certain extent. The plant is so arranged that water can be pumped directly into the mains in case of fire. The system of laying the water mains is such that in case of a leak it will only be necessary to shut off a small area until excavations are made and the repairs attended to. This sewage is discharged directly into the Assiniboine River by gravitation, the high water-mark being much lower than the residential district.

The figures contained in the report of the superintendent of Mines for the Province of Quebec show that in the course of the last fiscal year, the mines of Quebec yielded a production of 13,119,811, or nearly 2,000,000 more than in 1912. As usual, asbestos leads all mineral products, the quantities extracted reaching the value of $3,839,504. Quebec Province alone produces 80 per cent. of the world's consumption.

THE EVOLUTION OF RAILWAY MOTOR GEARING.*

By W. G. Carey.

THE design of the gear equipment of the first small electric railway motors was adapted from established practice in the construction of gear trains in stationary apparatus. Abundant space was available for adequate cast iron gears. With increase in size of motors it became convenient to substitute cast steel for cast iron in order to secure increased strength while conserving interchangeability on existing trucks; and thereafter for many years cast steel gears with machine steel pinions continued to be used in universal practice. The speed reductions from the armature shaft to the axle ranged from about 3 to 1 to 4.78 to 1, and pinions and gears wore out in about these ratios. The obvious advantage of increasing the life of the pinion to approximately that of the gear in order to improve average conditions of mesh and to reduce the cost of frequent renewal of pinions led to early experiments in case-hardening of pinions. In applying this process, practice satisfactory in other arts was followed and little attempt was made to modify, for the special conditions, the process as usually carried out. The first case-hardened pinions exhibited consequently a considerable measure of warping from the heat treatment, which fact involved high cost in rejections in manufacture. Also, this warping and other results of the treatment caused in many cases destructive wear of the companion gear, and the net results were such that no really great interest in any form of heat treatment of gear-

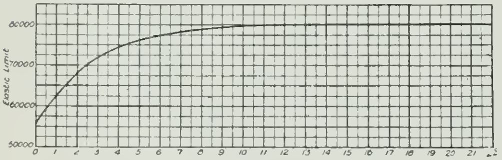

Fig. 1.

ing was felt until increased size of motors, for which aa active demand was arising, made imperative an increase in the strength of materials. The pitch of teeth and width of gear face had been increased to the limit allowed by available space on the trucks, and the strongest cast steel practicable for machine operations was found inadequate; therefore, to meet the severest conditions resort was had to alloy steels, with partial success in keeping equipments in service. Experiment to determine the alloy steels best suited for the purpose required, however, a long time and involved heavy expense, and heat-treated carbon steels tried out at the same time afforded excellent results. Painstaking study by manufacturers of railway apparatus, aided by the broadminded co-operation of operating engineers, soon resulted in the determination of suitable material and the development of methods in heat treatment adequate for the severest conditions in present normal practice.

Incidentally, the modification of the material and its heat treatment, together with increased strength, produced considerable increased hardness, and, at least for city service where the strength of untreated gears was still adequate, the old idea of a pinion harder than the gear, tending to equalize the life of the two, was in a measure realized, and within a very short time the untreated pinion was entirely discarded, even for service in which the strength of the heat-treated steels was entirely unnecessary.

Only experiment could determine certainly the effect of the hard pinion on the untreated cast gear, and some curious results developed in special cases. In one of the first installations on a considerable scale the hardened pinions wore out completely in about half the life of the old untreated machine steel pinions, and this proved to be due to the presence in the gear grease of considerable quantities of very hard sand prevalent in the neighborhood, which, getting into the gear case, became embedded in the surface of the soft gear teeth, forming a lap for the rapid destruction of the pinion teeth. On the whole, however, with good methods of lubrication and maintenance of equipment, heat-treated pinions having a hardness not exceeding approximately 300 in the Brinnell scale appear to afford greatly increased life without measureable reduction in the life of an untreated companion gear.

Continued experiment in case-hardening developed means of avoiding most, if not all, of the original trouble of warping in treatment, and the process was applied experimentally on a considerable scale to the cast gears as well as to pinions; and increased life, altogether out of proportion to the increased cost, was immediately obtained. Split gear castings, however, still gave some trouble from warping on account of their irregular sections. At that time split gears were in considerable demand, although the use of solid gears had already commended itself strongly for many reasons. Split gear bolts had always given trouble and it was easier to obtain sound castings in the more regular sections in the solid gear, and these considerations had begun to have a considerable influence in hastening the provision, in repair shops and inspection barns, of wheel presses and other facilities for handling solid gear equipments. In the present state of the art of case-hardening pieces of such size and shape as motor gears, this matter of warping is not so serious a matter, as its control has been greatly improved; but at that time a general readiness to substitute solid gears greatly facilitated the trial of case-hardened gearing on an extensive scale in service.

This material is essentially a low carbon steel with the surface impregnated with additional carbon and heat-treated. The usual practice is to shroud portions not required to be hardened so that only the tooth surfaces are exposed to the "cementing" process, as the incorporation of additional carbon is called. Therefore, only the carburized portion hardens in quenching. It is usual practice to carry the depth of impregnation of carbon in the tooth surface to about the limit of allowable wear, which, in three-pitch gearing, is approximately 1/10 in. This, however, is subject to very definite control and is varied within limits for various conditions.

The surface of case-hardened gear and pinion teeth shows hardness about 95 in the scale of the Shore schleroscope. It is not practicable to measure this material with the Brinnell instrument for the reason that the uncemented core will not stand up under the pressure necessary to effect an indentation, and such pressure also causes deformation of the pressure ball. The schleroscope is also to some extent misleading, as different conditions, such as size of parts tested or method of their support in test, give rise to considerable inaccuracies. In experienced hands the most reliable comparison of hardness of specimens of materials of this class is a file test, though this may be entirely misleading in comparison of different alloy

*From the General Electric Review.

steels. Modern case-hardened carbon steel which gives a schleroscope reading of 95 can just be scratched with a very fine Swiss file.

This class of gearing, because of the price at which it could be marketed, was manifestly a great improvement in economy of operation, wherever it might be found sufficiently strong to withstand the shocks of service. No test, other than that of service, has been devised for determining its resistance to service stresses, but that the limit of its strength is below the requirements of the heaviest modern service appeared probable and has since been demonstrated. In the first days of its use much virtue was attributed to the toughness of the low carbon core, but this toughness cannot manifest itself under stresses on the whole tooth, and a tooth strained beyond its strength breaks short. It is evident that substantially the entire tooth strength must be found in the hardened case, and the factor of safety, even with the enormous elastic limit of this high carbon case, promised to be too low for safety in the heaviest equipments throughout the very long period of its probable service. Although this gearing has been used very conservatively on motors of

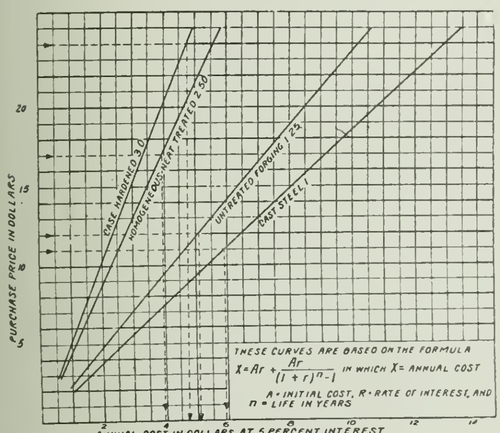

Fig. 2.

over 125 h.p., and then only in the light of careful study of operating conditions, the original estimates of strength have been closely borne out. Breakage has occurred in certain carefully watched test equipments after two years of service where wear had hardly begun. This has in some cases undoubtedly been due to fatigue of the case from repeated shocks closely approaching the elastic limit, and in other cases to subsidence of the soft tooth core resulting in cracking of the case.

It is therefore known to-day that, while with motors of less than about 100 h.p. this type of gearing is sufficiently strong to resist fatigue until worn out in service, its application with heavier equipments can only be advised in the light of a very definite understanding of the conditions of operation. With such heavier equipments, especially in high speed service with rapid acceleration and liability to abnormal shocks such as are produced by commutator flash-overs or line breaks at the collector, the case-hardened gearing appeared and has already been proved to have an inadequate factor of safety.

Attention was then turned to a modification of the homogeneous heat-treated gearing with a view to increasing its hardness to attain increased life and a greater elastic limit, which was essential in order to defer fatigue beyond the extended limit of wear. The physical characteristics of heat-treated steels depend upon a considerable number of variable factors in the constitution of the steel, the manner in which it is worked, and methods of treatment. The constitution of the material can only be definitely controlled within certain limits which are well recognized in steel manufacture, and variations in the constitution affect final physical characteristics, though the variations may be corrected in a measure by corresponding variations in treatment. Such methods, if carried to too great a refinement, are prohibitively expensive, and the development of the desired new type of gearing involved a method of analysis and an adjustment of treatment which would be commercially practicable.

The type of heat-treated gearing which had become recognized as a heavy service standard showed elastic limit varying in regular production from eighty to ninety thousand pounds per square inch, although occasionally specimens showed still higher values and certain other specimens with elastic limit varying down to 70,000 lb. per square inch were put into service in the earlier days of this development. Throughout several years a record was kept of mileage and physical characteristics of all specimens broken in a service of known character, and the curve in Fig. 1 shows relation between elastic limit of broken specimens and the time required for fatigue to the breaking point in normal service.

This shows that maximum stresses on the gear teeth, which could be determined in no other way, are equivalent to about 70,000 lb. per square inch in the teeth, since all specimens broken early in service show approximately this value. Higher values are shown to afford longer life, until the specimens broken toward the limit of wear invariably show an elastic limit of approximately 80,000 lb. per square inch, and in no cases have specimens showing higher values broken in service.

With a lower ductility, it was assumed—and it is in all probability true—that a larger factor of safety would be necessary to defer fatigue beyond the limit of wear, and a composition was selected and methods of working and treatment determined which would give an elastic limit of 140,000 to 150,000 lb. This steel shows a hardness approximately 500 in the Brinnell scale, and, while no very definite comparison with hardness of case-hardened gearing is possible, such rough comparison of the Brinnell and schleroscope scales as is possible and the file test indicate the hardness to be approximately 85 per cent. of that of case-hardened gearing.

Commercial application of this type of gearing has been made with the greatest care, and it has not yet been trusted in the heaviest service, although since its first commercial use two years ago about 7,000 equipments of this gearing have been installed with motors of all power up to 150 h.p. and there is no record of breakage of a single tooth within the limit of wear.

It has been pointed out that various factors had contributed to a marked tendency to substitute solid for split gears. This tendency was manifest in all classes of service, and its wide spread made possible the realization of an old idea of using forged blanks in place of castings for axle gears.

The manifest advantage of forgings in entirely eliminating shrink strains and other faults not altogether avoidable in castings was important, but not all of the desired end. It was practicable to machine steel of a higher carbon content, and the strength and toughness could be greatly enhanced by the operation of forging the

blank. The very great diversity of combinations of shape and dimension required involved an enormously expensive development cost and it is probable that this would have long deferred the general substitution of forged for cast solid gears, were it not for the fact that the development of the homogeneous heat-treated types absolutely required forgings, since the desired physical characteristics were unattainable in castings. The cost of manufacture is so far a little higher, but the difference would probably be justified by the certain and invariable integrity of the blank, even with the same life factor. In addition, however, the untreated forged gear shows approximately 20 per cent. higher elastic limit and nearly 25 per cent. greater hardness, and these characteristics afford an increased life approximately proportional.

There are then available in the art to-day three modern types of gearing, each of which may have its appropriate field, although there may be some difference of opinion as to where and to what extent these fields overlap. The first essential in the selection of a type is adequate strength for positive assurance against breakage within the limit of wear.

There are thousands of motors in operation which are destined to be superseded by more modern machines within the expected life of heat-treated gearing, and in such cases no advantage can be gained by the use, at higher cost, of a type which cannot be worn out within the life of the apparatus; and therefore the untreated forging is clearly the only type to be considered.

Also, many important systems have been completely equipped with case-hardened gearing, and the problem of changing over to another type, unless the two types can be successfully operated together, is a difficult one, and such a change must be effected gradually. Both of these considerations must be taken into account, although in the end practice will be standardized on the basis, first, of safety and then of annual cost of maintenance.

In the meantime, in substituting complete gear equipments of the modern heat-treated steels for untreated gears with heat-treated pinions having hardness of about 250 to 300 in the Brinnell scale, it is evident that some trouble will be involved in attempting to maintain the proper combinations, and the result of combining gears and pinions of widely differing hardness under all service conditions is very uncertain. While occasional instances of successful operation of even case-hardened pinions with untreated gears are reported, it is certain that such combinations will generally result in reduced life of the softer member, and in effecting changes in their practice most operators are taking the trouble to provide pinions of only moderate hardness for use with their untreated gears and meshing all new gears of more modern types with pinions of the same types.

For the purpose of estimate of maintenance cost, life factors of different types must be assumed and the following are based upon records of service under widely varying conditions.

Grade.	Life factor.
Untreated cast steel	1
Untreated forged steel	1.25
Homogeneous heat treated	2.25
Case-hardened	3

These estimated life factors, with cast steel taken as 1, are about proportional to the relative hardness of the respective types, which factor should, and apparently does, reflect fairly closely the average life in service. Based upon these factors and an assumption of 5 per cent. interest on investment, the curves in Fig. 3 show a comparison of the respective maintenance costs of the four types here considered, at the prevailing market prices of a representative gear for city service.

The market prices of this gear in the four different types are, respectively: cast steel, $11; untreated forging, $12; homogeneous heat-treated, $17; and case-hardened, $24. Following the dotted lines as indicated by arrows from these purchase prices in the ordinates, the respective annual costs will be found to be $5.90 for untreated casting; $5.10 for untreated forging; $3.95 for homogeneous heat-treated, and $4.75 for case-hardened gears.

It has been said that the heat-treated carbon steels now available have proved adequate for the severest conditions in present normal practice. It is known, however, that we are already near the limit of strength of this material, and the added demands of apparatus already projected, and of at least one existing application of somewhat special character, call for an additional factor of safety to maintain strength requisite for service to the limit of wear. Experiment on an extensive scale is being conducted with various alloy steels and various treatments, and encouraging results are promised, particularly with chrome-vanadium. Owing to its narrower base, the strength of the pinion tooth is measurably lower than that of the teeth of its companion gear, and there will undoubtedly be a wide range of applications in which alloy steel pinions may be used with carbon steel gears, and by virtue of an elastic limit of something like 170,000 lb. per square inch, which appears attainable, will equalize the difference and take us another long step in the development of this art in which we are so circumscribed by the fixed dimensions of the trucks.

MECHANICAL WATER FILTRATION.

The results obtained with mechanical filtration of water that is badly discolored and carries large quantities of suspended matter are highly satisfactory. Waterworks engineers may with advantage consider whether flood water which has been allowed to run to waste cannot be so treated as to become of value. Where gravitation works have been designed to take only a portion of flood water it is possible, according to Mr. T. Molyneaux, to extend greatly the resources of the watershed, and so postpone the consideration of some expensive scheme. Gravitation filters are composed of a layer of sand over layers of stones of varying thicknesses, and really are water strainers only. High-pressure filters are cylindrical vessels filled with sand through which water is forced at high pressure. One gallon in every 300 which passes is required for cleaning, which is done by reversing the filter and agitating the sand with radial arms provided in the casing for the purpose.

Before mechanical filtration is taken up on a large scale some amount of consideration must be given to the design of the plant. It has been pointed out that the unit commonly in use is 8 ft. in diameter, and capable of dealing with some 150,000 gallons of water daily; but there seems no reason why a larger plant should not be used. The obstacles in the way would appear to be only mechanical, and as such can be overcome without great difficulty. There is a plant in course of construction in which the units are of 9 ft. diameter, and it will shortly be seen how superior this is to the existing designs.

Mechanically-filtered water would be further improved if it were passed into a service reservoir before being sent into the mains, in order to allow a secondary deposition of matter in suspension, which no ordinary laboratory analysis shows, but which is undoubtedly present.

WARFARE AND THE ENGINEERING PRESS

VIEWS FROM ABROAD OF THE EFFECT OF THE EUROPEAN TROUBLE ON THE PROGRESS OF ENGINEERING.

THE effect of the outbreak and magnitude of European hostilities upon engineers and engineering has been reviewed with a general feeling of confidence by the engineering press. The first expressions of concern, while naturally reflecting retrenchment in constructional activities and readjustment of many factors influencing engineering, exhibit no trace of forebodings of a panicky nature. Even in England, where, according to the daily press, one might expect engineering and industrial work to cease, except that for the production of military supplies, the industries are active, the unemployed are comparatively few, and the British manufacturer has already set to work upon the task of preparing to secure as large a share as possible of the export trade which will be set a-begging when peace has again been secured.

The following editorial observations, which appeared in various engineering papers of England and the United States, should be read carefully by Canadian engineers. There is substantial argument to uphold the belief that the arrest by war of engineering work will not be long drawn out, and that it will be succeeded by greater activity than has been experienced of late:—

We can all perceive the ugly features of the war. Let us note a few of the consolations. Plant to the value of some hundreds of thousands of pounds must be reordered in this country. Against the factories which will run on reduced time must be set several others which have already started overtime. We heard yesterday of an electrical manufacturing firm who were compelled to work all through the last two week-ends. But we are not thinking so much of electrical works proper as of other industries which buy from us. For instance, the big armament firms are working day and night, the electrical equipment of ships has been accelerated, the Reading biscuit firms are on overtime, so are the army clothing establishments, the arsenals and certain dockyard departments.

So that, without wishing to argue that the war is, on balance, a benefit—it is obviously an immense evil altogether—there is not the least occasion for despondency. Our home trade is immensely greater than our foreign trade, and our trade with the affected countries was largely an importation of manufactured goods in exchange for our coal and semi-manufactured products The very considerable imports from Germany and Austria will not simply be dispensed with, to a large extent they must be replaced.

As the Government insure the safety of ocean traffic, America and the Colonies will not be deterred by war risks. Shipping will be continued, after some initial check, with Canada, United States, Africa, Australia, and the East. British manufacturers stand to replace German and Austrian competitors on a large scale, and for many years to come; now is their opportunity. They should supplant them, not only in our home market, but in such neutral ones as South America, an immense purchaser. These firms partly importing and partly manufacturing in this country will probably decide to increase their British works, though not immediately. What we cannot produce ourselves, or get from Europe, we can probably obtain from America or elsewhere. Even the greatest of calamities bring good to somebody or other; the present upheaval will probably divert our trade to different channels. But we sincerely hope and believe that our trade does not, like that of Germany, incur any risk of crushing, or even of arrest, taken as a whole. What, it may be asked, of our sales to Germany? Assuming their stoppage for a long period after the war, it must be remembered by way of consolation that Russia, one of Germany's very best customers, and afflicted with some sentiment in her temperament, will go elsewhere for her manufactured goods. England, France and America can no doubt oblige. Beyond hazarding these few guesses as to the probable tendency of events, it is early as yet to discuss the precise developments. The general summary is that things might have been very much worse. The public are accepting the calamity with unexpected calm, things wear their normal aspect, trams and trains run much as before, the shops are all doing good business, there are really few signs of the upheaval, apart from the placards and the scarcity of London general omnibuses.—*The Electrical Times*, London, August 6th, 1914.

* * * *

It is needless to take an alarmist view; on the other hand, it is wise to be fully prepared for the fortunes of war. The municipal engineer has at all times a great responsibility, but in time of war this responsibility is surely increased. To consider one of the many works for which he is responsible—the water supply. The greater the work, the greater is its vulnerability; one man with a spade could easily start a burst in an earthen dam, and one small cartridge might wreck the conduit which supplies a city. How soon might the most perfect pumping machinery be put out of gear or utterly ruined. Again, one may imagine how easily a great sewer might be blocked or even wrecked, and how seriously this might, under certain conditions, affect the district served. The same applies to power and electricity stations, to bridges and to docks. In the case of dock basins the malicious bursting of a wall might easily lead to the wrecking of a large number of vessels, while injury to dock-gates and caissons would be followed by the most serious consequences. It is idle to enumerate or to suggest the various ways in which harm might be done; every engineer knows only too well how easily the greatest works could be injured or wrecked, seeing that they have been designed and constructed for the purposes of peace, and not to withstand malicious attack.

Bearing these facts in mind it is clearly the duty of the municipal engineer at the present time to take every possible precaution against the possibilities mentioned. Reservoirs certainly ought to be watched and guarded where the supply of large communities is dependent upon them; similarly, long, exposed pipe lines ought to be watched. At present it would not be difficult for our country's enemies to damage aqueducts or reservoirs. It is a case in which the municipal engineer should carefully consider what works under his control are sufficiently important and vulnerable to require special

guarding, and next he would do well to see that they are efficiently watched. If his own staff of workmen are insufficient, as may well be the case, it is his duty to call attention to the fact, and the help of the police, military, and territorials may well be required. There will be a very large number of persons ready and willing to serve their country at the present time. These might be employed in guarding municipal works, but such service will be useless unless it is first directed by the municipal engineer. There are other dangers incident to a state of war. The bridges and highways may need special protection. Excessive loads may come upon them, and it is the duty of the municipal engineer to see that these are strong enough to sustain the loads, and where necessary to make provision for temporarily strengthening them. We do not wish to adopt any alarmist attitude; happily the risk of actual invasion is extremely remote. There are, nevertheless, other chances of trouble which should not be overlooked, and the proper guarding of municipal works at the present time is a duty which should be brought prominently forward, seeing how vitally the well-being of every citizen is affected.—*The Surveyor*, London, August 7th, 1914.

* * * *

The entire world must suffer on account of the terrible European situation, if not directly in loss of life and property, at least in temporary financial embarrassment. American financiers, however, and the Government are fully equal to the emergency as it affects this country. The closure of the stock and produce exchanges throughout the country, the preparation to issue emergency currency under the Aldrich-Vreeland act, the placing of clearing houses on a certificate basis and the enforcement in some States of the sixty-day-notice clause for withdrawals of savings deposits will all tend to prevent the panic which, with the absence of these measures, would undoubtedly ensue. A temporary curtailment of export trade, with its stimulating effect, must be expected; but even with Great Britain in the conflict naval strategists feel that the ocean lanes will be kept open, enabling us to dispose of our farm products, with which we are now unusually well supplied. There is every reason, therefore, for citizens of the United States to remain calm. No other country is so well prepared to meet the emergency. In a short time, probably, things will assume a settled condition and business will proceed almost as briskly as though there were no unusual disturbance abroad. There is ample cause for gratification, therefore, at the favorable situation of the Union in so terrible a season.—*The Engineering Record*, New York, August 8th, 1914.

* * * *

The calm and steady way in which London—speaking principally for the City and its financial organizations—has withstood the shock of the crisis is rational ground for assuming that no new alarm is likely further to unsettle it. The people who are laying in supplies of flour, of sugar, of condensed milk and so on, are in a large minority. Prices will rise, have already done so, in fact: but they are not likely to advance exorbitantly. Out of the evil, good will come. Canada and the United States, for example, may find their financial salvation by reason of the present grave condition of affairs. Afterwards there will arise such activity in trade, in metals, in stocks and shares as few can remember. These, however, are for the future. The immediate outlook is too serious to be illumined by more than hope, but that hope is fortified and cheered by the steadfast way in which the financial institutions of the City of London, and the people whom they affect, have met a situation that might have precipitated a panic which nobody could have called surprising.—*The Electrical Review*, London, August 7th, 1914.

* * * *

One of the most certain results of a great European war will be a world-wide scarcity of investment capital and a consequent rise in the ruling rate of interest. Indeed, such a rise has already taken place, partly as a result of the wars fought during the last dozen years and even more of the preparations for war on an enormous scale which the European nations have made. About the close of the 19th century, prior to the Boer War in South Africa and the Spanish-American war, the market value of investment funds in the highest-class securities was not far from 3 per cent. During the past year or more the average price has been probably 4 to 4½ per cent. Where the price of capital will go to in the event of a general European war, long continued, can only be conjectured. Such a war would destroy to a large extent the great reservoirs of investment capital in the principal European nations, to which all the rest of the world has resorted for the funds with which to carry on economic and industrial development. It may easily be that a year hence 5 per cent. or 6 per cent. or even 7 per cent. may be the ruling price for investment funds of the highest class. The rate on funds invested in ordinary enterprises, involving more or less risk, such as attaches to almost every private enterprise, must, of course, be correspondingly higher.

The far-reaching results of such a change in the value of capital it is impossible to foresee in full detail. It would have, of course, a vast effect upon the prices of commodities of every sort and of real estate. It will greatly limit the carrying out of works of permanent improvement, in which engineers are so largely concerned, since capital will be difficult to obtain and can only be secured at a high price. It will mean the cancellation of a great number of new enterprises because the reservoirs of capital that were to have sustained them will be dried up.

Of especial interest to many engineers is the question, What is to be done concerning the half-dozen great international engineering congresses which were scheduled for next year?

Besides the great international engineering congress to be held in San Francisco, together with numerous other international congresses relating to many branches of science and industry arranged for there, the International Railway Congress was to assemble next year at Berlin, the International Society for Testing Materials at St. Petersburg, the International Navigation Congress at Stockholm, and the Congress of Mining and Metallurgy at London. Doubtless all these congresses will have to be indefinitely postponed. It has been suggested that the American engineers might offer to welcome these various congresses in the United States. But even if it were attempted to hold the meetings here, the attempt could hardly result otherwise than in failure. With the great nations of the world at each other's throats, it is not to be expected that their representatives, many of them government officials, could be brought together in peaceful and friendly conference only a few months hence. Indeed, who is wise enough to foresee the profound changes in nations, in politics, in policies, in races, which may grow out of this terrific conflict? It sounds like a mockery, the circular before us regarding an international exhibition of art and civilization to be held at Dusseldorf next year. But that is only one of

several such international events, including our own great exposition at San Francisco, which must be either abandoned, or, if held, must do without exhibits from the chief industrial nations of Europe.

The best that may be hoped from the present terrible conflict is that when it is ended by peace, it may be a peace accompanied by universal disarmament, a peace that shall relieve the nations from those crushing burdens of preparation for war and leave them free to solve those problems of social readjustment which are the pressing problems of this century.—*The Engineering News*, New York, August 6th, 1914.

* * * *

Whilst the engineer gives place to none in the detestation of war and in efforts to avert it, to him it has an interest which it cannot have for the layman. The engineer was originally a soldier, the maker and destroyer of fortresses, the maker and user of cannons, and to him war has never meant merely the victory and defeat of opposing armies. With philosophic detachment he sees it as a scientific test of painfully wrought theories, of new materials and new offensive and defensive engines. Time has not lessened but greatly increased his influence on the art of war. Even in the short interval that has elapsed since the South African campaign he has given to the Army and Navy many new things, and if he could stand wholly apart from the horrors of the gigantic conflict with which he is now face to face he would look on the trials to which the material he has devised and made is to be put with an interest as lively and as dispassionate as that of the astronomer who seizes the rare eclipses of the sun to test his theories and new apparatus.

So far our great ships of war have had no chance of showing what value is to be placed on new designs, but now that war is declared we shall learn if the lessons of the proving ground and the theories of the study are well founded. We shall know at last if the gun is really better than the armor; we shall learn if the $13\frac{1}{2}$-in. gun is indeed superior to the 12-in.; we shall learn if the 4-in. quick-firer is efficient to ward off the attacks of destroyers. The problem of the submarine will be solved. Whether she is really as dangerous as the subtlety and secrecy of her attack have led us to suppose will be found out. We shall discover, too, if the torpedo itself is as formidable as it seems, and whether the immense improvements in it, which it owes to the engineer, have really made it the most fearful and deadly of naval arms. It is possible, too, that the greatest of all naval problems may be set at rest. Perchance some pre-Dreadnought ships may find themselves in conflict with the latest warships of the world, and we shall discover if the theory of the all-big-gun ship is well founded. Amongst other works of the engineer that will be put to the test of war between first-rate Powers the turbine must be mentioned. Whether it will endure the rough handling as well as the old reciprocating engines, whether it will be as faithful and dependable in its duty, is a question the answer to which all Admiralties and all engineers await with anxiety. Whilst the test of naval material of war is still in doubt, land material is already undergoing probation. Here the engineer has a host of new things to watch with interest. Our war in South Africa taught us many things about field artillery, and those lessons have been embodied in our 18-lb. field piece, which we believe is better than any in the world, though the new French field gun, a mysterious weapon about which little is known, may be superior to it. It is believed that the Germans, just as they have remained true to a smaller calibre naval gun, have also adhered to a smaller field gun; it is reported to throw a 15-lb. shell. Whether it makes up in muzzle velocity for what it lacks in weight remains to be seen. But it is not only in the guns themselves, but in their carriages, that much that is new has to run the gauntlet of war. The old form of carriage that recoiled with the gun is now a thing of the past. The modern field gun-carriage is an elaborate structure with recoil cylinders and running-out springs. The gun runs back with but little movement of the carriage and the rapidity of fire is greatly increased. No one yet knows what effect such a highly developed weapon may have upon the issue of a battle. Again, mechanical transport is almost a new thing which has hardly been tested on the actual theatre of a war on a large scale. Many excellences must be developed, many faults found. Those who are responsible for its design, no less than the engineers all over Europe, who have carried out the desiderata of their war offices, can hope for nothing better than that it should not be found wanting under the crucial test. Coming to still greater novelties, we have to learn how the aeroplane and seaplane comport themselves, whilst the value of the airship must be decided once and for all. With the purely military value of aeronautics the engineer is but little concerned. Whether the fact that the enemy can watch from the sky every step an army makes and report it by wireless telegraphy to headquarters, is to cause, as some aver, a great modification of tactics, is a matter of secondary importance to him from the professional standpoint. What he does want to know is that the machines he has developed with such infinite trouble and at the cost of many brave lives are capable of performing trustworthily the duties assigned to them. He has brought into war a new factor of enormous moment—a factor of which many in England think we have been too slow to take advantage of.

Besides the few obvious things we have mentioned, there are hundreds of others in which the engineer is directly interested. Every ship is full of small items which change with every new vessel as some new invention or development of an old one is brought forward. Take, for example, the range finder, of which the accuracy is now so great that it will tell the distance of an object correct within 25 yards in 10,000; the new uses to which electricity has been put; the development of wireless signalling; the new system of laying mines, and so on and so on. On every side the hand of the engineer is seen, and no one in Europe will watch the progress of arms in the greatest conflict the world has ever seen with more keenness than he.—*The Engineer*, London, August 6th, 1914.

* * * *

Municipal bonds have naturally felt the effect of the war in Europe, along with all other securities. During the first six days of this month ten or more cities received no bids for bonds offered and two thought it advisable to postpone advertised sales. But this is not to be wondered at nor should cities become alarmed thereby as to their future finances. During July the market for municipal bonds was better than ever, many selling on a basis of 3.71 per cent. to 4.40 per cent.; and the war situation can certainly have no effect on the stability of the finances of United States cities.

Railroad and industrial securities might be affected in their actual as well as their market value by the effect of the war upon commerce; but the only effect upon municipal bonds would seem to be the general withdrawal of money from investment, and this will be but temporary, in the judgment of financiers. When money

again seeks investments, in a few days or weeks, the municipals will, it would seem, be still more favorably considered than during the past few months.

We advise cities, therefore, not to rashly close down work or postpone projects indefinitely, thus throwing many citizens out of employment, but to act on the assumption that in a very few weeks they can raise money on terms at least as favorable as a year ago and possibly as those of this spring. On the other hand, however, every effort should be made to avoid selling at high rates of interest long-term bonds which will commit the city to the payment of such interest for many years to come. —*Municipal Journal*, New York, August 13th, 1914.

* * * *

The forces of war are powerful, with their perfection of death-dealing mechanisms and their high development of strategical plans for circumventing the enemy. But the present-day forces of peace—the forces of commerce, of education, of brotherhood, of mutual tolerance and good feeling—are still more powerful, and will, we are confident, prevail before too many lives have been lost or too much of the material prosperity of the belligerent peoples has been destroyed.

It has been one of the incongruities of the recent upheaval that some of the delegates to a peace conference in one of the European countries had to turn back home because of the beginnings of war. But this incident is worthy of more than a grim smile. The feelings which prompted the calling of the peace conference are still in the breasts of the people and will demand a cessation of hostilities.

While most of the nations of the world are, from a military standpoint, better prepared for war than they ever were before, these same war organizations are considered by the rank and file of citizens as relics of a former age. The organization of present-day governments is very little along the lines of offensive and defensive warfare, and very much along the lines of building up peaceful lines of industry for the welfare of their citizens. The nations of the world are on a far-reaching, interdependent commercial basis which will not long brook the interference of war.

The present has been accused of being a severely commercial age; but in a crisis of this kind it is this strong commercial tendency which will prove one of our bulwarks of safety and will insist on a speedy return to a peace basis.

From the standpoint of the contractors' interests, we are sufficiently optimistic to believe that the first scare is the worst, and that business can very rapidly get back on to a most satisfactory basis. It is true that some municipal bonds have not found ready buyers within the past few days; but capital will gradually come out from under cover as it sees business assuming its normal aspect, and will be ready to finance legitimate enterprises as usual. The dealer in machinery and equipment, too, will find that an even greater export market has been opened up to him.—*The Contractor*, Chicago, August 15th, 1914.

An increase of 125,732 tons in the unfilled orders on the books of the United States Steel Corporation was reported in the corporation's monthly statement issued at New York on August 10. This is the fourth month in which increases in the unfilled tonnage have been reported after the long period of almost uninterrupted decline in unfilled orders, which began in January, 1913. The orders now on the books of the Steel Corporation amount to 4,158,589 tons, compared with 3,998,160 at the end of May. A year ago at this time the Corporation's unfilled contracts amounted to 5,959,079 tons.

UNITED STATES COAL OUTPUT IN 1913.

According to a statement recently issued by the United States Geological Survey, based upon figures compiled by Dr. Edward W. Parker, the production of coal in the United States during 1913 was the highest on record, the total being 570,048,125 net tons (2,000 lbs.). This shows an increase of 35,581,545 net tons, or nearly 7 per cent., on the output of the previous year. It is considerably more than double the output of 1900, and more than eight times the production of 1880. The value of the coal mined in 1913 is stated at $760,488,785, as compared with $695,606,071 in 1912. The increased activity indicated by these figures was well distributed throughout the 29 coal-producing States, 23 of which showed increases and only 6 decreased production, the decrease in one of these, Colorado, being due solely to labor troubles. Twelve of the States showing increases made record yields.

Pennsylvania mined more coal in 1913, both anthracite and bituminous, than in any previous year in the history of the industry. The production reached the total of 265,306,139 net tons, valued at the mines at $388,220,933, and which is one-fifth of the world's output. Of this 91,524,927 tons were anthracite, valued at $195,181,127, and 173,781,217 tons were bituminous, valued at $193,039,806. The total tonnage broke the previous record for 1912 by 19,079,053 net tons, or nearly 8 per cent., the proportionate increase being about the same for both anthracite and bituminous. The gain in the value of anthracite, however, was $17,558,501, or about 10 per cent., over 1912, and in bituminous coal $23,669,309, or 14 per cent. The total gain over 1912 was $41,227,810, or nearly 12 per cent.

STEEL PLANT CLOSING.

Relative to the closing of the Dominion Steel plant at Sydney, N.S., an official of the company stated that the action was taken due to the stop to all industrial activity caused by the war. The Steel company has its yards full of wholly or partly manufactured material. It has 20,000 tons of rails which cannot be delivered. On the whole the company has well over two million dollars' worth of material unsold, or sold and not yet delivered. With regard to the order for 10,000 tons of rails recently received by the company, the specifications would involve starting up a blast furnace; and the order would only give work for a short time. It seemed better to hold this order as a nucleus until others can be added to it, so as to make work, when begun, fairly continuous. There is business in sight for bar steel to keep the mill running for some little time. The officials hope that it will not be many weeks before they will have enough business to justify recommencing in such a way as to keep running for a reasonable time.

The output of the Dominion Coal Company, Glace Bay, N.S., for June, 1914, amounted to 452,270 tons, which is to be compared with the largest previous output of 438,272 tons produced in October, 1913. It is stated, moreover, that the output for June would have been 50,000 tons greater, had it been possible to work the mines to full capacity. The production of the Dominion Coal Company for the first half of 1914 was 2,254,043 tons from the Glace Bay mines and 199,961 from the Springhill mines, comparing with 2,295,082 tons from Glace Bay and 193,797 from Springhill in the first half of 1913. There is, therefore, only a difference of 34,000 tons between the two half-years.

A High Surge-Tank.—A surge-tank on the differential principle has been constructed at the hydro-electric plant of the Salmon River Power Company, Altmar, N.Y. The structure is 180 feet high to the top edge of the tank, which has a height of 80 feet and a diameter of 50 feet, and stands on a base built up of ten lattice columns. The tank has to take care of surges from a column of water 9,625 feet long and 12 feet in diameter. A 12-foot riser connects the bowl-shaped bottom of the tank with the pipe-line. Inside the tank is a 10-foot vertical pipe tapered from 10 feet 8 inches diameter at the bottom end to 15 feet at the upper end. The annular space between the mouth of the 12-foot riser and that of the 10-foot 8-inch pipe allows part of the water to flow straight out into the tank, while the rest passes up the 10-foot pipe. The effect is to throttle the surges very considerably.

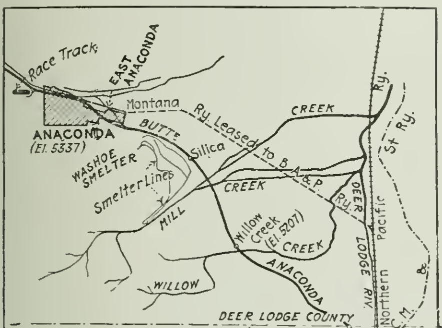
ELECTRIFICATION OF THE BUTTE, ANACONDA AND PACIFIC RAILWAY.

THE Butte, Anaconda and Pacific Railway has been entirely under electrical operation for the past six months. The installation is most interesting everywhere as it marks a new departure in electrification. Prior to it, railway electrification for the most part was influenced largely by the demand for rapid suburban and interurban service, by the frequency of that service and by other considerations, such as smoke abatement in cities. The above electrification is the first on record however, to have been made for the express purpose of securing greater economy. Further, as the first road to use 2,400-volt direct current, it is likewise worthy of note.

The first electric locomotives were put in service about June 1, 1913, and set to hauling ore. By January 1, 1914, according to information furnished by the General Electric Company, they had hauled nearly 2½ million tons of ore and had travelled approximately 201,000 miles. The change from steam to electric haulage was made without any change in the personnel of the train crews and without any delays or alterations in the schedule.

Prior to the installation, the Butte, Anaconda and Pacific Railway was a single track main line about 30 miles in length with about 85 miles of sidings, yards, etc. There is a maximum grade of 0.3% against loaded cars and of 1% against empties. The heaviest train has been 50 loaded ore cars, approximately 3,400 tons. The line extends from Butte, where connection is made with several trunk lines to Anaconda, and is the only rail outlet for the latter city. The ore traffic between the two cities is considerable, as is evidenced by the above figures of the first seven months of operation. The smelters are situated in Anaconda while the ore mines are in or near Butte. Fig. 1 illustrates the location of the electrified system and the relative situation of the two cities.

Energy for the operation of the system is obtained from Great Falls, Montana, which has for some time been supplying electrical power for the operation of the mines and smelting plants in the above cities. The power plant consists of six hydro-electric units with a nominal rated capacity of 21,000 kw. The current generated is of 66,000 volts, 60 cycles, 3-phase. It is transmitted at 102,000 volts over a distance of 130 miles by two parallel lines to the sub-station at Butte. Another transmission line carries power at 60,000 volts to the Anaconda sub-station, 26 miles distant. These two sub-stations are equipped with 2,400-volt motor-generators. Each set consists of a 3-phase, 60-cycle, 720 r.p.m. synchronous motor direct connected to two 500-kw., 1,200-volt direct connected generators arranged to operate in series for 2,400 volts.



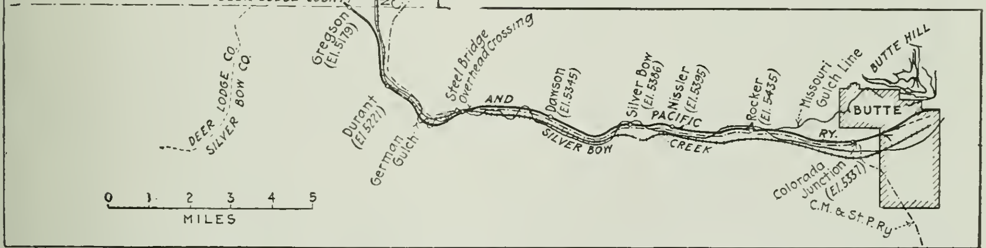


Fig. 1.—Route of the Butte, Anaconda and Pacific Railway.

Fig. 2.—One of the 2,400-volt Direct Current Freight Locomotives.

The overhead construction was especially designed to give the flexibility necessary for the satisfactory operation of the pantograph trolley used on the locomotives. The trolley used over all tracks is of copper and is supported by an 11-point catenary suspension from a stranded steel messenger cable. The trolley wire is reinforced between the sub-stations with two copper cables tapped to the trolley at intervals of 1,000 ft. The rails are connected by No. 0000 bonds at every joint.

The locomotive equipment consists of seventeen 80-ton units, two for passenger service and fifteen for freight. The ore trains are being hauled by two coupled units. The locomotives are of an articulated double-

truck type, with all the weight on the drivers. The double unit, 160-ton locomotives for freight purposes are capable

Fig. 3.—Ore Train, Hauled by One of the Two-Locomotive Units.

of giving a continuous sustained output of 2,100 h.p. and have a free-running speed of 35 miles per hour. They are geared for slow speed also. The passenger locomotives, on the other hand, are geared for a free-running speed of 55 miles per hour, or 45 miles per hour with three passenger cars. Curves as sharp as 20° occur on portions of the line, although the average curvature is from 6° to 10°. The locomotives are designed with sufficient flexibility to operate on a curve of 31° at slow speed.

The following information respecting the construction of the locomotives may be of interest:

Length inside of knuckles	37 ft. 4 in.
Length over cab	31 ft.
Height over cab	12 ft. 10 in.
Height with trolley down	15 ft. 6 in.
Width over all	10 ft.
Total wheel base	26 ft.
Rigid wheel base	8 ft. 8 in.
Track gauge	4 ft. 8½ in.
Total weight	160,000 lb.
Weight per axle	40,000 lb.
Wheels, steel tired	46 in.
Journals	6 x 13 in.
Gears, forged rims, freight locomotives	87 teeth
Gears, forged rims, passenger locomotives	80 teeth
Pinions, forged, freight locomotives	18 teeth
Pinions, forged, passenger locomotives	25 teeth
Tractive effort at 30% coefficient	48,000 lb.
Tractive effort, at one hour rating	30,000 lb.
Tractive effort at continuous rating	25,000 lb.

Fig. 4 shows the general design of a separate tractor truck recently added to the equipment and to be used in conjunction with the electric locomotives.

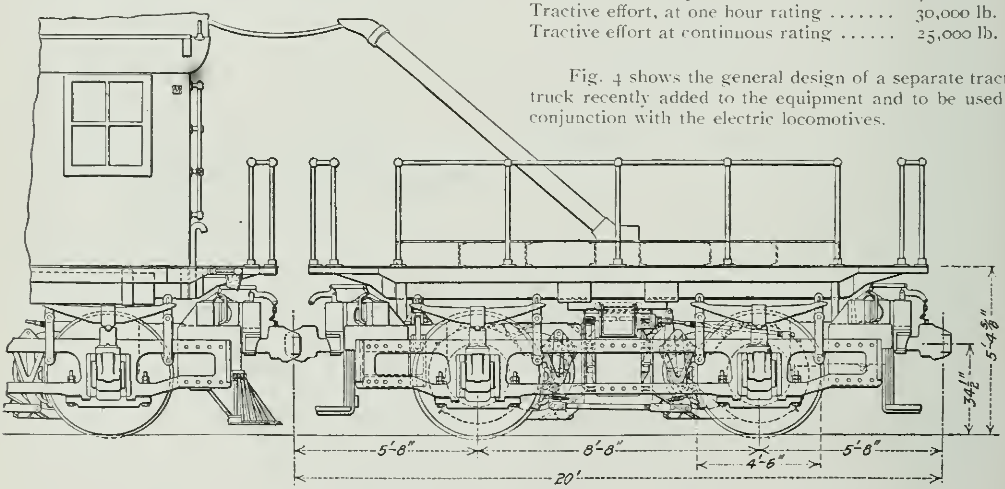

Fig. 4.—Separate Tractor Truck, for Use with Electric Locomotive.

RAILROAD SLEEPERS FOR SCOTLAND.

In view of the fact that an increased and more direct steamship service is anticipated between British Columbia and Glasgow, when the Panama canal is open, the Glasgow authorities have announced what specifications are required for railroad sleepers, or ties, in that market. At present the trade is for the most part with the Baltic for sleepers made from what is known as red wood.

The blocks from which the sleepers are to be cut should be of good sound timber, straight, free from shakes, large or loose knots, or other blemishes, and reasonably free from sapwood, water and dirt.

The sleepers should be cut from blocks not less than 8 feet 11 inches long, each block being sawn up the middle so as to form two sleepers. The blocks should be of such transverse dimensions that at least 90 per cent. of the sleepers shall be, after sawing, 10 inches broad and not less than 4⅞ inches thick, with a flat surface on the upper side not less than 7 inches in width throughout the entire length of the sleeper. The remainder, which must not exceed 10 per cent. of the total quantity, should be, after sawing, 10 inches broad, and not less than 4¾ inches thick, with a flat surface on the upper side not less than 6½ inches in width throughout the entire length of the sleeper.

The sleepers should be accurately gauged, and all those which do not comply with the requirements specified above should be rejected. Some buyers do the sawing of the blocks in Glasgow. Other details would be a matter of correspondence between buyer and seller.

SURGE TANK PROBLEMS III.

ANALYSIS AND GRAPHICAL REPRESENTATION OF PROBLEMS DUE TO CONDITIONS OF VARYING OUTFLOW TO PARTIAL OR COMPLETE SHUT-DOWN OR OPENING.

By PROF. FRANZ PRASIL.

Authorized Translation by E. R. Weinmann and D. R. Cooper, Hydraulic Engineers, New York City.

Case C.—Variable Outflow.

In the following, we consider first the influence of a gradual shut-down and opening of the penstock, and secondly the case when the outflow is variable with respect to time. The movement during the period of a gradual shut-down will be quite different from that after the shut-down. Therefore, we must consider both cases separately.

(1) Movement During the Shut-down.—We assume that the closing occurs so that the outflow decreases in direct proportion to the time which is expressed by the formula:

$$q = Q_1\left(1 - \frac{t}{\mathrm{T}}\right) \quad (56); \quad \mathrm{T} = \text{time for complete shut-down}$$

Therefore,

$$c = c_1\left(1 - \frac{t}{\mathrm{T}}\right) \qquad \frac{dc}{dt} = -\frac{c_1}{\mathrm{T}}$$

Similar to equation (23) we get the special principal equation (57) in the following form:

$$\frac{d^2z}{dt^2} + \frac{1}{T_0}\cdot\frac{dz}{dt} + \frac{z}{T^2} + \frac{c_1}{T_0}\left(1 - \frac{t}{\mathrm{T}}\right) - \frac{c_1}{\mathrm{T}} = 0 \quad (57)$$

The general integral of this equation may be obtained by means of the theory of linear differential equations of the second order.

The general member is $z_1 = R\,e^{-\frac{t}{2T_0}} \sin\left(\beta + \frac{t}{T_1}\right)$

The particular integral $z_2 = b_1 + b_2 . t$ when b_1 and b_2 may be determined by inserting the value of z_2, also $\frac{dz}{dt} = b_2$ and $\frac{d^2z}{dt^2} = 0$ in equation 57.

Therefore,

$$\frac{b_2}{T_0} + \frac{b_1}{T^2} + \frac{b_2 t}{T^2} + \frac{c_1}{T_0} - \frac{c_1 t}{T_0 \mathrm{T}} - \frac{c_1}{\mathrm{T}} = 0 \quad (58)$$

As the conditions of this equation must be fulfilled for all values of t the two equations follow:

$$\frac{b_2}{T_0} + \frac{b_1}{T^2} + \frac{c_1}{T_0} - \frac{c_1}{\mathrm{T}} = 0; \quad \frac{b_2}{T^2} - \frac{c_1}{T_0 \mathrm{T}} = 0 \quad (59)$$

$$\text{As } h_1 = \frac{c_1 T^2}{T_0} \qquad b_1 = h_1\left[\frac{T_0}{\mathrm{T}}\left(1 - \frac{T^2}{T_0^2}\right) - 1\right] \qquad b_2 = \frac{h_1}{\mathrm{T}}$$

The general integral is obtained by the form $z = z_1 + z_2$.

Therefore,

$$z = R.e^{-t/2T_0} \sin(\beta + t/T_1) + b_1 + b_2 t \quad (60)$$

And with differentiation with respect to t $\left(tg\,\gamma = \frac{2T_0}{T_1}\right)$

$$s = \frac{R}{T} e^{-t/2T_0} \sin(\gamma - \beta - t/T_1) + b_2 \quad (61)$$

In order to obtain the constant for the integration, consider that for $t = 0$, $z = z_0 = -h_1$, as in case (A), but that $s = s_0 = 0$, because the shut-down occurs gradually. Therefore:

$$R \sin\beta = -h_1 \frac{T_0}{\mathrm{T}}\left[1 - \frac{T^2}{T_0^2}\right]$$

$$R \cos\beta = -h_1 \frac{T_1}{2\mathrm{T}}\left[3 - \frac{T^2}{T_0^2}\right]$$

$$R = h_1 . \frac{T_0}{\mathrm{T}} . \frac{T_1}{T} \quad (62) \qquad tg\,\beta = 2\,\frac{1 - \frac{T^2}{T_0^2}}{3 - \frac{T^2}{T_0^2}} . \frac{T_0}{T_1} \quad (63)$$

For the graphical demonstration of these functions we may separate them into three equations. For instance, the z — function into

$$r = R\,e^{-t/2T_0\,\phi}; \quad z_1 = r \sin(\beta + \phi); \quad z_2 = b_1 + (b_2 T_1)\phi. \quad (64)$$

The value of r determines again a logarithmic spiral with the slope $tg\,\alpha = -\frac{T_1}{2T_0}$ with the initial vectors r_0 and β.

z_1 is obtained in the rectangular co-ordinate system by projection from the polar system as in the former cases. z_2 in the same rectangular co-ordinate system is a straight line which intersects the ordinate axis at the distance b_1 from the initial point and whose inclination to the axis of abscissæ is fixed by the direction constant $b_2 . T_1$. The algebraic sum of $z_1 + z_2$ gives z. (See Fig. 5.) But only that part of the curve which lies between the values of the abscissæ 0 and T is of practical importance because at the time T the complete shut-down has already occurred (as we assumed).

(2) Movement After Completed Shut-down.—After the shut-down has occurred, the movement of the water

surface continues as described in case (A). Therefore, from this moment the following equations are effective:

$$z = R_1 e^{-t/2T_0} \sin(\beta_1 + t/T_1) \qquad (65)$$

$$s = \frac{R_1}{T} e^{-t/2T_0} \sin(\gamma - \beta_1 - t/T_1) \qquad (66)$$ (see equations 32 and 35).

$$R_1 \sin \beta_1 = z_T$$

$$R_1 \cos \beta_1 = \left(s_T + \frac{z_T}{2\,T_0}\right)$$

where z_T and s_T are limiting values of the first period.

The demonstration of the movement may be developed according to the same method as in case (A). For the computation of the value of the most practical importance (the maximum elevation), we get

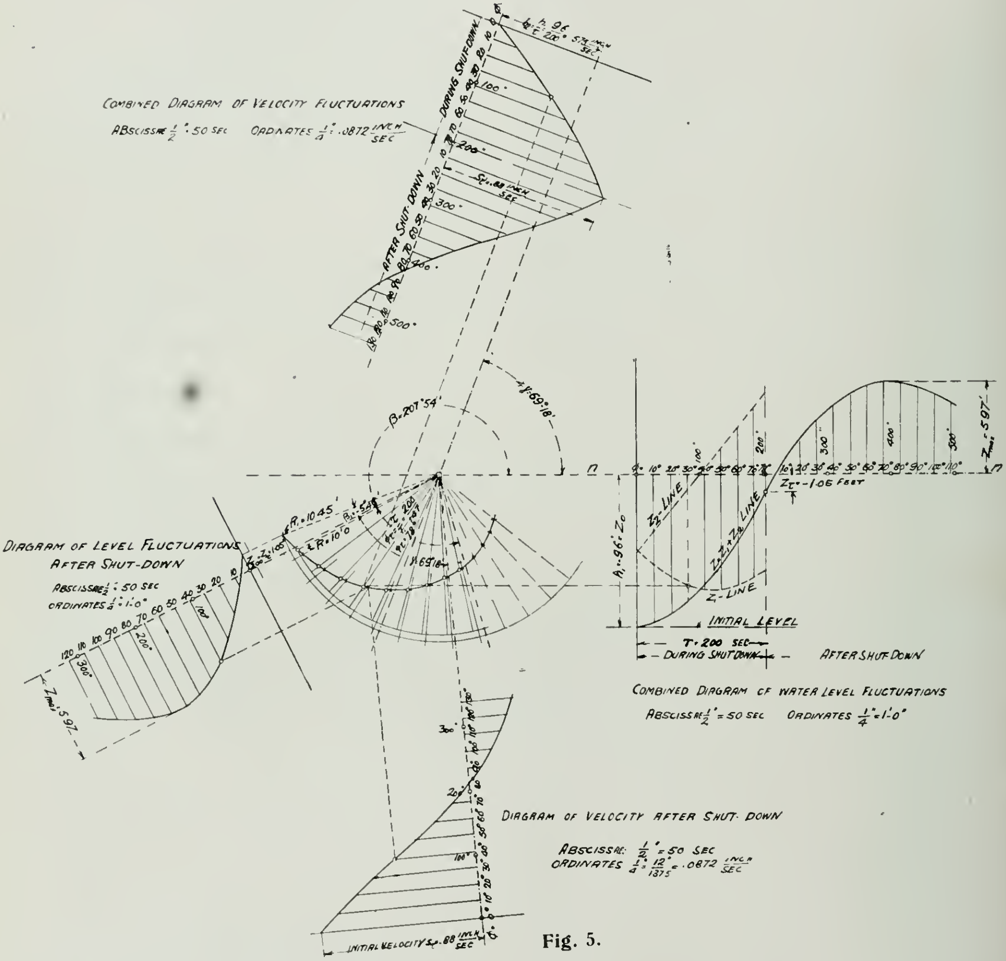

Fig. 5.

Where $tg\ \gamma = \dfrac{2\,T_0}{T_1}$

The constants R_1 and β_1 have to be determined from the value of z and s computed for $t = \text{T}$. In order to obtain an easier computation, we measure the time for the second period from the moment of the completed shutdown, so that the following equations for the determination of the constants R_1 and β_1 are in effect:

$$z \max = R_1 e^{-\frac{T_1}{2\,T_0}(\gamma - \beta_1)} \sin \gamma \qquad (67)$$

(3) Practical Example.—The computation in connection with the preceding example follows for a shutdown in 10, 100 and 200 seconds, with a discharge of 530 cubic feet per second.

With $T = 137.5$ seconds, $T_0 = 194.5$ seconds, $T_1 = 147$ seconds, $h_1 = 9.6$ feet, we get the following table:

for τ =	10 sec.	100 sec.	200 sec.
$b_1 = h_1 \left[\frac{T_0}{\tau}\left(1 - \frac{T^2}{T_0^2}\right) - 1\right] =$	+83.3 feet	—.264 feet	— 4.93 feet
$b_2 = \frac{h_1}{\tau} =$	.96 $\frac{\text{feet}}{\text{sec.}}$	.096 $\frac{\text{feet}}{\text{sec.}}$	.048 $\frac{\text{feet}}{\text{sec.}}$
$R = h_1 \cdot \frac{T_0}{\tau} \cdot \frac{T_1}{T} =$	200 feet	20 feet	10 feet
$tg\beta = \dfrac{2\left(1 - \frac{T^2}{T_0^2}\right) T_0}{\left(3 - \frac{T^2}{T_0^2}\right) T_1} =$	.530	.530	.530
	$\beta = 207° 54'$	arc $\beta = 3.628$	$\gamma = 69° 18'$; arc $\gamma = 1.210$
z_τ =	—9.10 feet	—4.85 feet	—1.05 feet
s_τ =	.097 $\frac{\text{feet}}{\text{sec.}}$	.091 $\frac{\text{feet}}{\text{sec.}}$	.0735 $\frac{\text{feet}}{\text{sec.}}$
$R_1 \sin \beta_1$ =	—9.10 feet	—4.85 feet	—1.05 feet
$R_1 \cos \beta_1$ =	+11.05 feet	+11.6 feet	+10.4 feet
R_1 =	14.30 feet	12.55 feet	10.45 feet
β_1 negative =	—39° 30′	—22° 44′	—5° 46′
arc β_1 =	—.6894	—.3968	—.1006
z max =	+6.53 feet	+6.40 feet	+5.97 feet

From the graphical demonstration (Fig. 4)* we see that the period of shut-down up to 100 seconds influences the maximum elevation a very small amount indeed. The explanation for this is that during this period the velocity of flow in the main conduit decreases very little. For the determination of the dimensions of the surge tank, we have, therefore, to consider the results of the limiting case, that is, the sudden shut-down. The computation for that condition is a much simpler one, (case *A*). For a gradual opening, the same relations exist. The lowering of the level $n - n$ occurs to the same extent and for the same duration as the rise above the initial level in the case already computed.

Of special interest is the case of an outflow, which is variable in the sense that the outflow increases considerably during a certain time and decreases afterwards to the same amount as before or to some other amount, (for instance, in a plant for railway operation).

1. Analytical Investigation.—We assume now, that under circumstances similar to those above mentioned, the following law of outflow is effective:

$$q = \epsilon . Q_1 (1 + f \sin t/\tau)$$

so that for the time

$$t = o; \quad t = \frac{\pi.\tau}{2}; \quad t = \pi\tau \quad q \text{ becomes resp.} = \epsilon Q_1;$$

$$\epsilon Q_1 (1 + f); \quad \epsilon Q_1 \qquad (68)$$

after the time $t = \pi.\tau$ the outflow may be constant again. ϵ and f are natural numbers. f is the proportion of the maximum increase of the outflow to the normal outflow. So that

$$c = \frac{q}{A} = \epsilon c_1 \left(1 + f \sin \frac{t}{\tau}\right) \qquad \frac{dc}{dt} = \epsilon . f . \frac{c_1}{\tau} \cos \frac{t}{\tau}$$

Equation 23 may then be written:

$$\frac{d^2z}{dt^2} + \frac{1}{T_0} \cdot \frac{dz}{dt} + \frac{z}{T^2} + \frac{\epsilon . c_1}{T_0} + \frac{\epsilon . f . c_1}{T_0} \sin \frac{t}{\tau} + \frac{\epsilon . f . c_1}{\tau} \cos \frac{t}{\tau} = o \quad (69)$$

If we introduce

$$z = y - \frac{\epsilon c_1 T^2}{T_0} = y - \epsilon h_1; \quad \frac{dz}{dt} = \frac{dy}{dt}; \quad \frac{d^2z}{dt^2} = \frac{d^2y}{dt^2} \quad (70)$$

and further,

$$\epsilon . f . c_1 \left[\frac{1}{T_0} \sin \frac{t}{\tau} + \frac{1}{\tau} \cos \frac{t}{\tau}\right] =$$

$$\epsilon . f . c_1 \sqrt{\frac{1}{T_0^2} + \frac{1}{\tau^2}} \sin \left(\phi + \frac{t}{\tau}\right) \quad (71)$$

with $tg\,\phi = \frac{T_0}{\tau}$ then the equation 69 transposes to

$$\frac{d^2y}{dt^2} + \frac{1}{T_0} \frac{dy}{dt} + \frac{y}{T^2} +$$

$$\epsilon . f . c_1 \sqrt{\frac{1}{T_0^2} + \frac{1}{\tau^2}} \sin \left(\phi + \frac{t}{\tau}\right) = o \quad (72)$$

*See *The Canadian Engineer* August 27th, Page 370.

and it then follows again from the theory of differential equations of the second order that $y = y_1 + y_2$, that is,

$$y_1 = R.e^{-\frac{t}{2T_0}} \sin(\beta + t/T_1) \quad \text{general integral} \quad (73)$$

$$y_2 = b \sin\left(\psi + \frac{t}{\mathrm{T}}\right) \quad \text{particular integral} \quad (73)$$

The latter may also be written

$$y_2 = b.\sin\psi\cos\frac{t}{\mathrm{T}} + b\cos\psi\sin\frac{t}{\mathrm{T}} \quad (74)$$

The integration constants R and β may be obtained from the initial phase and the constants b and ψ by forming the equations

$$\frac{dy_2}{dt} = \frac{b}{\mathrm{T}}\cos\left(\psi+\frac{t}{\mathrm{T}}\right) = \frac{b}{\mathrm{T}}\cos\psi\cos\frac{t}{\mathrm{T}} - \frac{b}{\mathrm{T}}\sin\psi\sin\frac{t}{\mathrm{T}}$$

$$\frac{d^2y_2}{dt^2} = -\frac{b}{\mathrm{T}^2}\sin\left(\psi+\frac{t}{\mathrm{T}}\right) = -\frac{b}{\mathrm{T}^2}\sin\psi\cos\frac{t}{\mathrm{T}} - \frac{b}{\mathrm{T}^2}\cos\psi\sin\frac{t}{\mathrm{T}}$$

We then introduce these values in the differential equation and combine the members containing cos t/T and sin t/T

$$\left[-\frac{b}{\mathrm{T}^2}\sin\psi + \frac{b}{\mathrm{T}T_0}\cos\psi + \frac{b}{T^2}\sin\psi + \epsilon.f.c_1\sqrt{\frac{1}{T_0^2}+\frac{1}{\mathrm{T}^2}}.\sin\phi\right]\cos\frac{t}{\mathrm{T}} +$$

$$\left[-\frac{b}{\mathrm{T}^2}\cos\psi - \frac{b}{\mathrm{T}T_0}\sin\psi + \frac{b}{T^2}\cos\psi + \epsilon.f.c_1\sqrt{\frac{1}{T_0^2}+\frac{1}{\mathrm{T}^2}}.\cos\phi\right]\sin\frac{t}{\mathrm{T}} = o$$

and as these equations hold good for all values of t, the terms in both parentheses must become o. One thus obtains two equations with the unknowns b and ψ and considering that $tg\,\phi = \frac{T_0}{\mathrm{T}}$ and $h_1 = \frac{c_1 T^2}{T_0}$, it follows

$$b = -\epsilon.f.h_1 \frac{\sqrt{1+\frac{T_0^2}{\mathrm{T}^2}\left[\frac{T^2}{\mathrm{T}^2}+\frac{T^2}{T_0^2}-1\right]^2}}{1+\frac{T^2}{\mathrm{T}^2}\left[\frac{T^2}{\mathrm{T}^2}+\frac{T^2}{T_0^2}-2\right]}$$

$$tg\,\psi = -\frac{T_0}{\mathrm{T}}.\left[\frac{T^2}{\mathrm{T}^2}+\frac{T^2}{T_0^2}-1\right] \quad (75)$$

For the determination of the integration constants R and β, it must be considered that for

$$t = o;\quad z = -\epsilon h_1;\quad y = o;\quad s = o.$$

We obtain for this case the equations

$$R.\sin\beta = -b.\sin\psi$$

$$R.\cos\beta = -b\left[\frac{T_1}{\mathrm{T}}\cos\psi + \frac{T_1}{2T_0}\sin\psi\right] \quad (76)$$

During the variation of the outflow the following equations are effective:

$$z = \epsilon.h_1 + Re^{-\frac{t}{2T_0}}\sin\left(\beta+\frac{t}{T_1}\right) + b\sin\left(\psi+\frac{t}{\mathrm{T}}\right)$$

$$s = \frac{R}{T}e^{-\frac{t}{2T_0}}\sin\left(\gamma-\beta-\frac{t}{T_1}\right) + \frac{b}{\mathrm{T}}\cos\left(\psi+\frac{t}{\mathrm{T}}\right)$$

with $tg\,\gamma = \frac{2T_0}{T_1}$

ψ amounts generally to about $\frac{3\pi}{2}$ which relation simplifies the computation of R and β.

The variation ceases (as we assumed) after the time $t = \pi.\mathrm{T}$. The values which correspond to the elevation of the water surface and velocity at that time are obtained by the formulæ:

$$z_{\mathrm{T}} = -\epsilon h_1 + Re^{-\frac{\mathrm{T}}{2T_0}}\sin\left(\beta+\pi\frac{\mathrm{T}}{T_1}\right) - b.\sin\psi$$

$$s_{\mathrm{T}} = \frac{R}{T}e^{-\frac{\mathrm{T}}{2T_0}}\sin\left(\gamma-\beta-\pi\frac{\mathrm{T}}{T_1}\right) - \frac{b}{\mathrm{T}}\cos\psi \quad (77)$$

For further investigation, the formulæ of case (A) may be applied. In order to simplify matters, in the determination of the further movement, we measure the time from the instant of the beginning of the constant outflow and logically we must use the limiting values of the preceding phase for the determination of the integration constants R_1 and β_1.

If we do not hinder the variation of the outflow but maintain the law $\epsilon Q_1\left(1+f\sin\frac{t}{\mathrm{T}}\right)$, we see that the movement of the water surface in the surge tank takes the form of a forced oscillation; where the influence of the first member decreases with the increase of t and this the quicker the larger the value of $\frac{T_1}{2T_0}$ becomes in the member

$$e^{-\frac{t}{2T_0}} = e^{-\frac{T_1}{2T_0}\cdot\frac{t}{T_1}}$$

The movement of the level of the water surface is merely that of a harmonic oscillation. In such cases it is well known that the phenomenon of resonance may occur, if the period of the actuating influence has the same duration as the swinging bodies' own period, that is to say, if, in the case mentioned $\mathrm{T} = T$. The value of the amplitude of the forced oscillation is then

$$b = -\epsilon fh_1\frac{\sqrt{1+\frac{T^2}{T_0^2}}}{T^2/T_0^2} = -\epsilon fh_1\sqrt{\frac{T^2}{\mathrm{T}^2}+1}\,.\,\frac{T_0}{\mathrm{T}} \quad (78)$$

We obtain the angle ψ from $tg\,\psi = -\dfrac{T}{T_0} = -\dfrac{1}{tg\,\varphi}$ (79)

because $\dfrac{T_0}{\tau} = tg\,\varphi$ and $\tau = T$.

According to the theory of the phenomena of resonance, the amplitude of the forced oscillation becomes of infinite value when the damping force is infinitely small. The latter would be the case, using our terms, when $T_0 =$ infinite with which value the amplitude of the above-mentioned equation also becomes infinite. The phase difference between force and movement has thereby to be equal to $\dfrac{\pi}{2}$, which also finds its expression in this equation (79).

2. Graphical Demonstration.—The graphical demonstration of the movement of the first phase is not difficult. The demonstration of the values

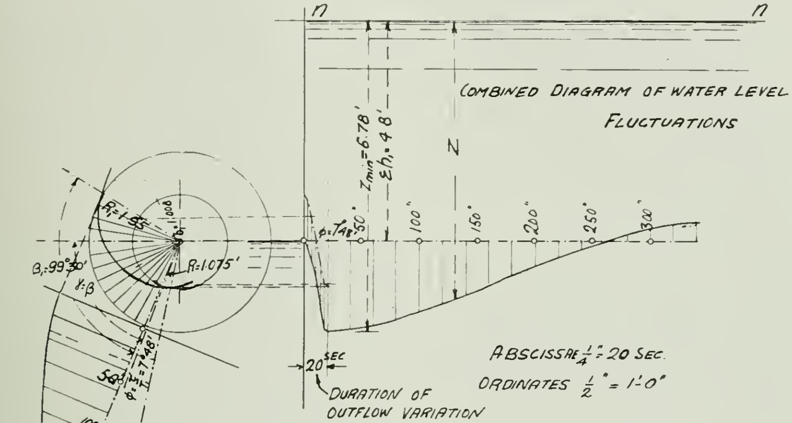
$$z_1 = R\,e^{-\frac{t}{2T_0}} \sin\left(\beta + \frac{t}{T_1}\right)$$

may be carried out in the same form as before by means of the projection of the logarithmic spiral. The demonstration of

$$z_2 = b.\sin\left(\psi + \frac{t}{\tau}\right) = b\sin\left(\psi + \frac{T_1}{\tau}\cdot\frac{t}{T_1}\right)$$

is obtained by projection of a circle, constructed with the radius b in the polar system, where the initial vector is inclined against the axis of abscissæ with an angle ψ.

In this case a rotation of the initial vector of z_1 by an amount of 2π corresponds to a rotation of the initial vector of z_2 by an amount equal to $\dfrac{T_1}{\tau}2\pi$. (See Fig. 6.)



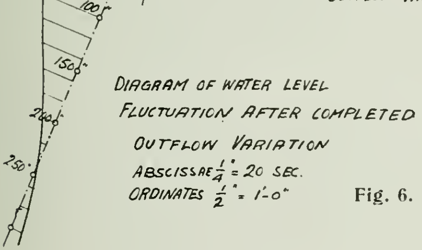


Fig. 6.

3. Analytical Example.—We use the same conduit and surge tank dimensions and assume the same friction conditions. As before, we take $\epsilon = 0.5$; with $f = 1$ and for $\tau = 20$ seconds we have an initial flow of 265 cubic feet per second which increases during the time $\dfrac{\pi}{2}.\tau = 31.4$ seconds to 530 cubic feet per second, and decreases after another period of 31.4 seconds (a total of 62.8 seconds) to 265 cubic feet per second. Therefore, with $T = 137.5$ sec. $T_0 = 194.5$ sec. $T_1 = 147$ sec. $h_1 = 9.6$ ft.

we get $\dfrac{T_0}{\tau} = 9.725$; $\dfrac{T}{\tau} = 6.875$; $\dfrac{T}{T_0} = .707$

$$b = -\epsilon f h_1 \frac{\sqrt{1 + \dfrac{T_0^2}{\tau^2}\left[\dfrac{T^2}{\tau^2} + \dfrac{T^2}{T_0^2} - 1\right]^2}}{1 + \dfrac{T^2}{\tau^2}\left[\dfrac{T^2}{\tau^2} + \dfrac{T^2}{T_0^2} - 2\right]} = -1.008 \text{ feet}$$

$$tg\,\psi = -\frac{T_0}{\tau}\left[\frac{T^2}{\tau^2} + \frac{T^2}{T_0^2} - 1\right] = -457.1$$

ψ lies in the fourth quadrant and is equal to 270° 7′ 50″, which is practically 270°. With the latter value $\sin\psi$ becomes -1 and $\cos\psi = 0$. We get

$$R\sin\beta = +b \qquad R\cos\beta = +\frac{T_1}{2T_0}$$

and therefore

$$tg\,\beta = \frac{2T_0}{T_1} = tg\,\gamma \qquad \beta = \gamma = 69° \; 18'$$

$$R = b\sqrt{1+\frac{T_1^2}{(2\,T_0)^2}} = b\,.\,T_1\sqrt{\frac{1}{T_1^2}+\frac{1}{(2\,T_0)^2}} =$$

$$b\,.\,\frac{T_1}{T} = -1.008\,.\,\frac{147}{137.5}$$

$R = -1.075$ feet, therefore

$$z = -4.8 - 1{,}075\,.\,e^{-\frac{t}{389}}\sin\left[69^\circ\ 18' + \frac{t}{147}\right] + 1.008\cos\frac{t}{20}$$

$$v = +\,.00782\,e^{-\frac{t}{389}}\sin\frac{t}{147} - .0503\sin\frac{t}{20}$$

If at the time $t = \pi.\tau$ the fluctuation of the outflow ceases it follows that

$$z_T = -4.8 - 1.075\,e^{-\frac{20}{389}\pi}\sin\left(69^\circ\ 18' + \frac{20}{147}\right) - 1.01 = 2.88\text{ ft.}$$

$$v_T = .00782\,e^{-\frac{20}{389}\pi}\sin\frac{20}{147} = .00275\text{ feet per second.}$$

For the movement that follows, we may use the equations (32) and (35)

$$z = -\epsilon h_1 + R_1\,e^{-\frac{t}{2\,T_0}}\sin\left(\beta_1 + \frac{t}{T_1}\right)$$

$$s = \frac{R_1}{T}\,e^{-\frac{t}{2\,T_0}}\sin\left(\gamma - \beta_1 - \frac{t}{T_1}\right) \quad \text{with } tg\,\gamma = \frac{2\,T_0}{T_1}$$

and R_1 and β_1 may be determined by the conditions $t = o$, $z = z_T$, $s = s_T$. We obtain

$R_1\,.\,\sin\beta_1 = -9.6 + 2.88 + 4.8 = -1.92$ feet

$R_1\,.\,\cos\beta_1 = .00275\,.\,147 - 1.92\,\frac{147}{389} = -.321$ feet

$R_1 = 1.95$ feet; β_1 lies in the third quadrant, i.e., negative.

$tg\,\beta_1 = 5.98975 \quad \beta_1 = -99^\circ\ 30' \quad \text{Arc}\,\beta_1 = -1.737$

$\gamma = 68^\circ\ 18' \quad \text{arc}\,\gamma = 1{,}210$

$$z = -4.8 + 1.95\,e^{-\frac{t}{389}}\,.\,\sin\left[-99^\circ\ 30' + \frac{t}{147}\right]$$

$$s = -.0142\,e^{-\frac{t}{389}}\,.\,\sin\left[11^\circ\ 12' + \frac{t}{147}\right]$$

Since at the time $t = o$ the velocity s is positive, a maximum first occurs. The time from the beginning of that maximum until the beginning of the second phase is $t_1 = 147\,(\gamma - \beta_1) = 433$ seconds.

$$z_1\text{ min} = -4.8 + 1.95\,e^{-\frac{433}{389}}\sin\gamma = -4.19\text{ feet}$$

The general course of the movement may be seen in Fig. 6.

In case of a continuous fluctuation of flow, expressed by the law $q = \epsilon Q_1\left(1 + f\sin\frac{t}{\tau}\right)$ with $\epsilon = .5$ and $f = 1$ the forced oscillation becomes nearly a constant harmonic oscillation of the amplitude one foot measured from $z = -4.8$ feet and for a duration of period of 137.6 seconds.

The case of resonance might occur if $\tau = T = 137.5$ seconds. This would be the case for an amplitude of the forced oscillation (measured from $z = -4.8$ feet) equal to

$$b = \pm\,\epsilon.f.h_1\sqrt{\frac{T_0^2}{\tau^2} + 1}\,.\,\frac{T_0}{T} = \pm\,11.7\text{ feet.}$$

Herein the duration of period would be $T\,.\,2\pi = 137.5\,.\,2\,.\,\pi$ sec $= 863$ sec $= 14'\ 23''$. It does not seem impossible for such periods to occur in regular operations as for railways, so that this investigation should be useful.

The preceding method, introducing a periodical function for the determination of a variable outflow in function of the time may be enlarged, introducing

$$q = \epsilon Q_1\left[f_0 + f_1\sin\left(\phi_1 + \frac{t}{\tau}\right) + f_2\sin\left(\phi_2 + 2\,\frac{t}{\tau}\right) + \ldots\right] \quad (80)$$

where we find the values for f and ϕ corresponding to a given variation of q by means of the Fourier series. The integration of the differential equation thus obtained involves no difficulty whatever. It is based upon the same method as that given in the last example. The values of z and s have the form

$$z = z_0 + R.e^{-\frac{t}{2\,T_0}}\sin\left(\beta + \frac{t}{T_1}\right) + \Sigma\,k_n\sin\left(\psi_n + n\frac{t}{\tau}\right)$$

$$(81)$$

$$s = s_0 + \frac{R}{T}\,e^{-\frac{t}{2\,T_0}}\sin\left(\gamma - \beta + \frac{t}{T_1}\right) + \Sigma\,\frac{n\,.\,s_n}{\tau}\cos\left(\psi_n + n\frac{t}{\tau}\right)$$

Naturally the computation requires great care. The graphical demonstration is obtained by superposition of the projections obtained from the polar system with the logarithmic spirals $r = R\,e^{-\frac{T_1}{2\,T_0}\cdot\frac{t}{T_1}}$ and the circles with the radii k.

(To be continued.)

Editorial

"Business as Usual"

ORDERS AND CONFIDENCE.

The opinion was expressed in these columns recently that the government authorities of Canada should do all in their power to continue public works in progress and to commence others. An announcement has come from Ottawa since then that the Dominion government will follow that policy. It is obviously sound economics. If the national machinery is stopped entirely—and the engineering profession is an important cog—only disaster can be brought upon the country. The advice given to Great Britain by a celebrated London authority is exceedingly applicable to the workers of the Dominion.

"Orders should be given," he says, "factories should be run, and everything should be arranged to maintain, as far as possible, the productive power and the income of the country.

"At such a time it is of the greatest importance that every one should endeavor to act as if great events were not impending. Were confidence seriously disturbed business would come practically to an end and our ability to face the difficulties that may be in front of us would be seriously impaired. Therefore, it is of vital importance that as far as possible, the events that are now taking place should not interfere with the daily life and the daily work of the nation.

"Every one, according to his ability, must endeavor to work hard in order that individual incomes and therefore the income of the whole nation, may be maintained at the highest possible level."

These are excellent sentiments and carried into practice will help considerably to overcome the adverse effects of war. Engineers, buyers and sellers of plant and machinery must give to the national situation at least their individual share of confidence and a share of business, even if it is somewhat reduced. To withdraw entirely both orders and confidence is inimical not only to their own interests but also to the general welfare of Canada.

THE COST OF NOISE.

Have the efficiency engineers about whose work we have heard much in recent years, given attention to the factor of noise in the engineering field and in machine plants generally? There is an enormous waste of labor and energy apparent in large works and in big factories, as a result of noise. To the engineer, it is as cumbersome in the final analysis, as so-called hustle is to the American business man. In a recent conversation reported in Metallurgical and Chemical Engineering the superintendent of a large stamp-mill made the observation that "noise costs money." The reporter goes on to say:

"We have been discussing the use of stamps as crushing machines and the comparative merits of various devices for crushing ore. One of the arguments advanced by this superintendent against the use of stamps was the tremendous and never-ending noise produced by the falling weights. In his opinion the din was responsible for many misunderstood directions and orders to employees, resulting in confusion, loss of time, and expensive mistakes. The point is readily perceived. The average mill employee is anxious to give the impression that he understands the boss's orders, and rather than ask a question for further information he will sometimes pretend to understand and then go and seek advice from a fellow workman. The order may be wrongly executed or not at all. The noise of the stamps contributes greatly to this condition, makes it difficult to give and receive orders, and undoubtedly causes many mistakes. The cost of noise may not be estimated exactly, but it is a real factor."

These are excellent contentions. It would be interesting to hear from the efficiency engineers operating in Canada, what they are doing in the course of their effective work, to reduce noise and consequently its heavy cost.

PANAMA CANAL OPENED.

The opening to traffic of the Panama Canal on August 15th was a great event in the commercial and engineering spheres. The construction of the Canal, various phases of which have been described from time to time in *The Canadian Engineer*, is considered, and justly, one of the greatest engineering events of modern days. There has been expended to date on the purchase and construction of the Panama Canal a sum of $360,173,375.33 These expenditures have been classified as follows to May 1, 1914:—

Administration	$ 7,004,684
Law	60,109
Sanitation	17,208,154
Construction	206,117,831
General items	90,167,566
Fortifications	6,200,505

For the benefit of commerce, it comes into being when shipping is disorganized by war. It follows the opening of the Kiel Canal, which was built largely for war purposes. A peaceful vessel, the Panama Railway steamer Ancon, was the first to pass through the famous Canal from the Atlantic to the Pacific. The battleships of belligerent nations may be among the earliest visitors to the great waterway. Their passage through the Canal is governed by regulations which were formulated in times of peace. They may not remain in the Canal for more than twenty-four hours, unless specially permitted. A war vessel of one nation must not follow the exit, from the Canal, of one of another nation, until after the expiration of twenty-four hours. The Canal has been opened at an inauspicious time. Rival battle-fleets are intent on serious gunnery. Commercial fleets are idle, lame or stealthy. But better times are in store. They may have come when President Wilson, in March, 1915, presides at the international celebration which will mark the official opening of the Canal.

A boat can make in eleven hours a trip through the Canal which otherwise would have taken thirty days. That is something the world's shipping will appreciate in due course. Europe is engaged at present in work of destruction. America, in the meantime, has completed one of the greatest engineering works of construction.

PERSONAL.

MESSRS. T. T. WILSON, J. B. PHILLIPS, W. YOUNGMAN, R. WHITSIDE, and F. MINNVILLE, are engineers recently appointed to positions on the staff of the Manitoba Highway Commission.

G. GORDON GALE, since 1907 connected as a superintendent with the Hull Electric Company, has recently been promoted to the general managership of the company. Mr. Gale graduated from McGill University; and, previous to his connection with the Hull Electric Company, he was assistant engineer of the electric plant of the Canadian Rubber Company. His positions as superintendent with the former company during the past seven years have been superintendent of power, acting superintendent, and for five years, general superintendent.

J. A. RUDDICK, chief engineer of the Dominion Coal Company, Sydney, N.S., has resigned his position to accept a similar one in Canada. While in charge of the construction department of the Dominion Coal Company during the past two years, Mr. Ruddick supervised the building of the new pier for the I.C.R., the coal-washer at Whitney pier—the only one of its type in Canada—as well as several large structures in connection with the company's different collieries. No details have been announced relative to Mr. Ruddick's new appointment.

M. A. LYONS, a graduate of 1910 from the Massachusetts Institute of Technology, has been appointed to the office of Chief Engineer to the Highway Commission of Manitoba. Mr. Lyons is to have general supervision of survey, design and construction of roads and bridges under the recent "Good Roads Act" in that province. His headquarters will be in the Parliament Building, Winnipeg. In 1911, Mr. Lyons became assistant engineer for the Canadian Pacific Railway in the irrigation department; in 1912, drainage district engineer for the Manitoba department of public works; and since 1913, bridge engineer for the latter department.

OBITUARY.

The death occurred on August 25th of Roderick J. MacDonald Parke, consulting electrical engineer, member of the Canadian Society of Civil Engineers as well as of the Canadian Society of Electrical Engineers, member of the Board of Trade, and at the time of his death managing director of the Automatic Electric Cook Co., Limited, Toronto. Mr. Parke is noted as the designer of the first long distance transmission plant in Canada, viz., from the Ragged Rapids, on the Severn River, to Orillia. He was chosen by Mr. Urquhart, former mayor of Toronto, to report upon the cost of distributing electricity throughout the city; and this report was used in part when the design now in operation was being prepared. He prepared plans for the Dominion Government and supervised the lighting construction of the old Welland Canal. He was formerly head of the firm of Parke & Leith, an agency for the British Aluminum Company, Limited; and, as a result of his labors in this industry, he founded the Canada Wire and Cable Company, Limited. The firm with which Mr. Parke was connected at the time of his death was promoted to exploit a patent invented by the deceased.

ADVANCE PROGRAM FOR NATIONAL PAVING BRICK MANUFACTURERS' ASSOCIATION.

Part of the program to be undertaken at the annual meeting at Buffalo, N.Y., September 9th, 10th and 11th, of the National Paving Brick Manufacturers' Association, has been given out by W. P. Blair, secretary of the association. Sept. 9th will be utilized by the members for their business meeting. A discussion with the brick committee of the American Society of Municipal Improvements over specification questions will be held on the evening of the 9th. The itinerary and program on the 10th will include a trip through the city and out into the country over the older as well as the newer highways, observing those under construction. On September 11th a trip will be taken over the Niagara Boulevard to Fort Niagara. Details may be obtained from W. P. Blair, secretary, Brotherhood of Locomotive Engineers Building, Cleveland, O.

FORT WILLIAM CONVENTIONS CANCELLED.

Notice has been received from Fort William, Ont., to the effect that, due to the unsettled conditions caused by the European war, it has been necessary to cancel the annual meeting of the Canadian Public Health Association, which was to have been held in that city during the month of September.

Due to the same cause, the 1914 convention of the Associated Boards of Trade of Western Canada, which was arranged to convene at Fort William on September 8th, 9th and 10th, has been postponed for an indefinite period.

CONVENTION POSTPONED.

The convention of the Union of New Brunswick Municipalities, to be held at St. John, N.B., has been postponed until November 17th and 18th.

COMING MEETINGS.

INTERNATIONAL WATER-POWER CONGRESS.—Under the auspices of the Ministers of Public Roads and Agriculture. Second international congress, Lyons, France. September 7th to 10th.

NATIONAL PAVING BRICK MANUFACTURERS' ASSOCIATION.—Secretary, Will P. Blair, 832 B. of L.E. Building, Cleveland, Ohio. Eleventh annual convention and paving conference, Buffalo, N.Y., September 9th, 10th, 11th, 1914.

NEW ENGLAND WATERWORKS ASSOCIATION.—Secretary, Willard Kent, Narragansett Pier, R.I. Annual convention to be held at Boston, Mass., September 15th to 18th.

ROYAL ARCHITECTURAL INSTITUTE OF CANADA.—Seventh Annual Meeting to be held at Quebec, September 21st and 22nd, 1914. Hon. Secretary, Alcide Chausse, 5 Beaver Hall Square, Montreal.

CONVENTION OF THE AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—To be held in Boston, Mass., on October 6th, 7th, 8th and 9th, 1914. C. C. Brown, Indianapolis, Ind., Secretary.

AMERICAN SOCIETY OF MUNICIPAL IMPROVEMENTS.—Charles Carroll Brown, Secretary, Indianapolis, Ind. Meets at Somerset Hotel, Boston, Mass., October 21st, 22nd and 23rd.

AMERICAN HIGHWAYS ASSOCIATION.—Fourth American Road Congress to be held in Atlanta, Ga., November 9th to 13th, 1914. I. S. Pennybacker, Executive Secretary, and Chas. P. Light, Business Manager, Colorado Building, Washington, D.C.

AMERICAN ROAD BUILDERS' ASSOCIATION.—11th Annual Convention; 5th American Good Roads Congress, and 6th Annual Exhibition of Machinery and Materials. International Amphitheatre, Chicago, Ill., December 14th to 18th, 1914. Secretary, E. L. Powers, 150 Nassau St., New York, N.Y.

A COMBINED GAS AND STEAM ENGINE UNIT

NOTABLE UNDERTAKING INVOLVING TWO 42 x 72 IN. GAS CYLINDERS, ONE 36 x 72 IN. H.P. AND ONE 68 x 72 IN. L.P. STEAM CYLINDER TO DRIVE A COMMON SHAFT.

By M. E. GRIFFIN, Mem. A.S.M.E.,

Mechanical Engineer, Franklin, Pa.

WHEN the additions to the power plant of the Ford Motor Company, of Detroit, are completed there will be housed in one engine-room gas and steam engines capable of developing over 30,000 h.p., and the complete installation will embody many novel and interesting features.

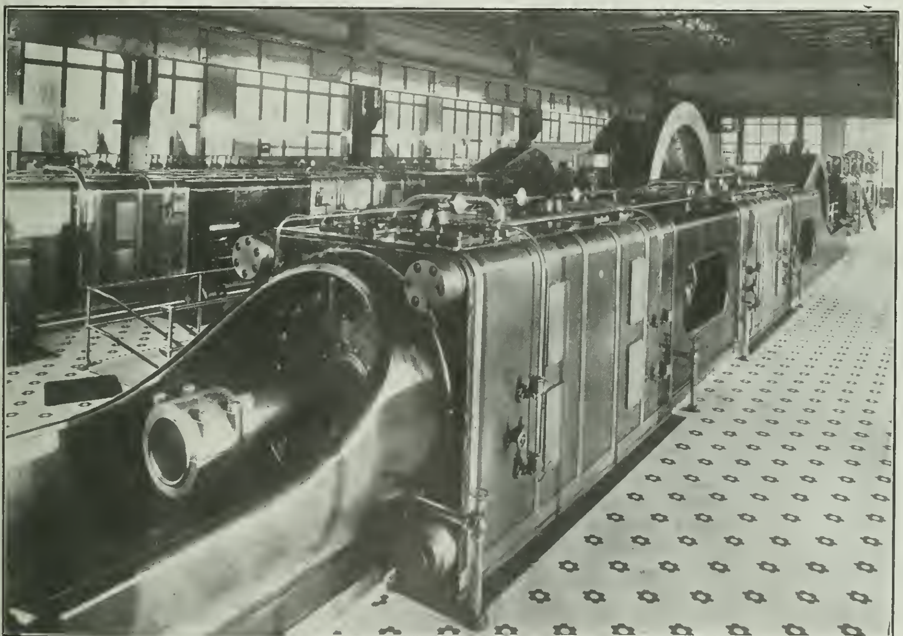

Fig. 1.—Side View, from Tail Rod End, of One of the Ford Motor Company's Engines.

When the plant was started the producer-gas engine was in great demand in the power field, and Henry Ford adopted this type of prime mover to operate his plant. His first gas engine was a 1,600 h.p., two-cylinder, double-acting tandem, having cylinders 35 in. diameter by 48 in. stroke, and operating at 100 r.p.m. This engine was direct-connected to an 850-Kw. Western Electric d.c. generator, and cross-connected to a 2,000-cu. ft. air-compressor of the central port hurricane valve design. The company from which this engine was purchased was unable to fulfil its contract and the purchasers completed its construction. This unit proved satisfactory, but the phenomenal increase in business soon necessitated additional power. Another producer-gas engine of greater capacity than any other internal combustion engine yet built in any country was decided upon. Edward Gray, the Ford mechanical engineer, designed this engine, embodying in it many special features which his many years' experience in gas engine design and operation suggested. It is what is called the one-story-and-basement type, with all the valve gear in the basement. There are 4 double-acting cylinders, 42 in. diam. by 72

in. stroke, arranged two in tandem upon each side. The engine is direct-connected to a 2,500-k.m. d.c. Crocker-Wheeler generator, and operates at 85 r.p.m., or a piston speed of 1,020 ft. per min. The generator is designed for 25% overload capacity, and the engine is rated at approximately 6,000 I.H.P.

The magnitude of this engine may be realized from the following data: The 20-ft. flywheel weighs eighty

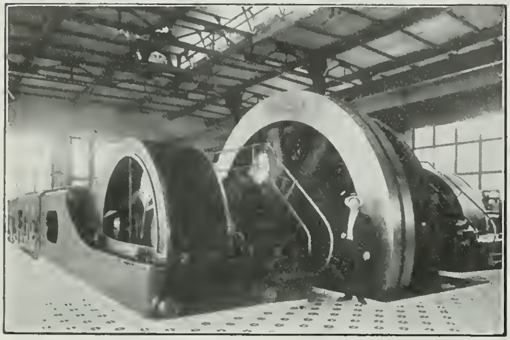

Fig. 2.—Front View of Engine in Fig. 1, Showing General Design and Massiveness.

tons, and the engine complete, without generator, weighs approximately 700 tons. The total length of the engine from rim of flywheel to the end of tail-rod guide measures 80 ft., and the overall width is 32 ft. The shaft in middle measures 32 in. in diam., and has an overall length of 26 ft., weighing, with crank discs, almost 100,000 lbs. Each complete connecting-rod weighs 10,300 lbs., and each bed or frame approximately 150,000 lbs.

Fig. 3.—Crank Shaft with Armature Rotor, Ready for Transportation.

The engine is designed symmetrically around the centre line, and the massive bed-plate, common to nearly all large gas engines, is omitted, the object being to make the engine self-contained and securely anchored on its foundation, allowing the cylinders perfect freedom to adjust themselves according to stress or temperature changes. The massive frames are reinforced longitudinally by 6-in. steel tie-rods, shrunk into place. The cylinders and distance-housings are secured to their respective beds by a continuation of 6-in. steel tie-rods and nuts.

The total weight of the pistons and rods is supported by the main, intermediate and tail-rod crossheads, all riding on bored guides. The main crosshead body is made in two parts and of annealed steel casting. The two halves or sides are held together by turned steel bolts in reamed holes, and the bolts at the throat are arranged to produce a clamping effect on the piston-rod, where it is screwed into the neck. The shoes are independent of, and secured to the crosshead by the trunnion method.

The main bearing is of massive and unusual construction, the caps being set into the housing in such a manner as to form a strut and tie, and are secured in place by 6-in. steel tie-rods placed longitudinally. The lower shells are water-cooled by means of brass coils, which were bedded in recesses in the cast-iron shell, and the babbitt metal, poured on top, encasing each, thus avoiding the possibility of trouble from waterjacket due to defective casting. The crank discs are of the counter-balanced type, made of annealed steel casting, and the crank pins are cast integral with the discs.

The lay shafts are located above the floor line, and are driven by semi-steel spiral gears from the main shaft (bronze gears were used at first, but found impracticable). These lay shafts are in sections, secured to each other by pin couplings, so that each section remains with its particular cylinder, and perfect alignment between crank and the walking-beam, which it drives, is preserved. On each lay shaft there is secured a crank for each end of the two cylinders in the set, and each crank operates both inlet and exhaust valves through the medium of the walking-beam at the end of its respective cylinder. The walking-beam and lay shaft carrier brackets are made double in order that the pins may have double support instead of being overhung. The design throughout eliminates overhung pins or bearings.

The inlet, or admission valve at each end of the cylinder, is actuated by a cam, the operating bell-crank lever of which is located between the sides of the walking-beam and pivoted at the centre. One end of the bell-crank actuates a hook, steel-faced, which engages with another hook-plate lever, fulcrumed in the projections on top sides of the walking-beam. An eccentric upon the governor shaft operates a cam, which trips the valve mechanism at any point of the stroke determined by the governor, similar to the cut-off arrangement of a Corliss steam-engine. The valve is closed by a spring, and cushioning is effected by an air dashpot. The admission is of the quantitative method, and the governor performs no other work than adjusting the position of the tripping cams.

The exhaust valve is operated by a cam, which receives its motion through a link secured to the extreme inner end of the walking-beam. The leverages of the cam are so proportioned that a very slight movement of the walking-beam produces a considerable movement of the working surface of the cam in sliding contact with the lower end of the exhaust valve projection. The arrangement is such that at a certain position the movement of the valve is rapid, but when the outer end of walking-beam is at its lower range of travel there is a pause in the exhaust valve mechanism. The pistons and rods are hollow and water-cooled. The water enters the rods at the intermediate crosshead by means of a telescopic oscillating arrangement, the outer end of which is pivoted below the engine. The piston-rod contains an inner tube for the inlet water to the pistons, and the

water outlet is around this tube, thus raising the temperature of the incoming water.

The engine just described has been in successful operation for about two years, and from the beginning of its operation the exhaust gases, instead of being wasted during the winter season, were utilized to heat water for the heating system of the immense plant. The idea of utilizing exhaust gases for this purpose is, perhaps, not a new one, but it gave rise here to an entirely original idea. When the unprecedented increase in Mr. Ford's business demanded more power he analyzed the economy question from all angles, finally deciding, if possible, to adhere to the internal combustion prime mover. From an efficiency standpoint he reasoned that he could not use nearly all the heat energy from the exhaust gases, as his system would not increase in the same ratio as the necessary power; therefore, if gas engines were to be installed, much waste heat would be the result. His final decision was for an increased installation, comprising steam and gas units, and it is without doubt one of the most daring engineering undertakings in the engine line thus far presented.

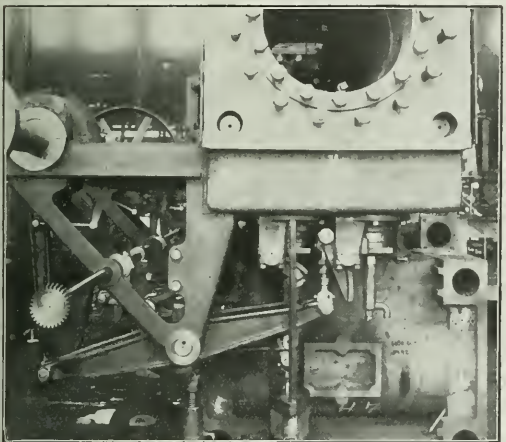

Fig. 4.—Valve Gear, with Exhaust Valve Cam in "Pause" Position.

During the past year he has placed orders for four 6,000 h.p. units, each direct-connected to a 2,250-k.w. d.c. Crocker-Wheeler generator. Each unit consists of a pair of 42 in. by 72 in. (stroke) gas cylinders, placed in tandem on one side, together with a 36-in. high-pressure and a 68-in. low-pressure by 72-in (stroke) tandem compound, condensing steam cylinder on the other side, the gas and steam engines driving a common crank shaft. The cooling water from the gas cylinders and pistons, which has its temperature raised usually to approximately 192° F., is to be used as feed water for the boilers, in which the steam will be raised to 150 pds. pressure, and, by means of a superheater employing exhaust gases, the steam will be superheated to a stage insuring its dryness. By using the available heat units thus, and operating the steam engines as condensing units, it is aimed to obtain the most economic, practical prime mover so far attempted. The intention is to use one condensing apparatus of sufficient capacity to accommodate the combined steam units, the piping and valves being arranged so as to cut one or more units in or out of commission as occasion demands.

The completion and actual operation of this new installation is awaited with keen interest by the engineering profession, because as a venture of such magnitude it possesses many intensely interesting and novel features hitherto undeveloped.

From a thermodynamic standpoint expert opinion differs, some admitting that it will be an economical success, while others argue that if the units were entirely of the internal combustion type, the total efficiency would be higher, on the supposition that the cost of coal necessary for the steam boilers, added to the initial cost of boilers, condenser, settings and auxiliaries will amount to much more than the expenditure necessary for producing gas.

Another feature causing much discussion is the question of regulation. While it is true that each new wheel will weigh 100 tons as against 80 tons in the case of the former wheel on the all-gas unit, it is also true that the impulses in the steam unit will not harmonize, so to speak, with those of the gas unit, and, therefore, the question of regulation arises, even with individual or combined governing mechanism.

The general design of the new units is similar to the former gas engine where conditions permit. The frames and all gas engine parts are duplicates of the gas engine heretofore described. The steam valve gear mechanism will be operated by lay shafts, and poppet valves are used where necessary in order to have the design of steam cylinders harmonize as nearly as possible with the gas engine cylinders. If perchance it is desired in the future to convert the units into all-gas units very little alteration will be necessary except exchanging the steam cylinders and their valve gear and piping.

UNITED STATES WATER-POWER BILL.

The water-power bill, relating to the construction of dams across navigable streams, and known as the Adamson bill, was passed by the House of Representatives of the United States on August 4. In accordance with its requirements, plans and specifications for such dams must be approved by the Secretary of War and the Chief of Engineers before work of construction is commenced. Approval may include the condition that water-power to operate locks, etc., be supplied without cost, or a reasonable annual charge may be made for the benefits that accrue to the grantee by the authority given under the act. The dam shall be located so as to be best adapted to a comprehensive plan for the improvement of the waterway for the use of navigation and for the full development of the water-power. The rights granted under the act extend over a period of 50 years beginning on the date of the original approval. Upon two years' notice prior to the expiration of the grant, the United States has the right to take over the property of the grantee necessary and useful for the generation, transmission and distribution of energy, the payment therefor being based on the actual cost of the lands purchased and used by the grantee and the fair value of the other properties taken over. Allowance will be made for deterioration but not for goodwill or profit in pending contracts. The Secretary of War is empowered to prescribe reasonable rates of charges for energy transmitted in "interstate or foreign commerce." When the energy is used within a state having adequate regulation for rates and service to the consumer the Secretary of War will not interfere with the established rules for rates and service.

The semi-annual report of the operation of towns and cities, included in the hydro-electric system, for the first six months of 1914 shows surpluses in every case. A number of reductions will result. The city of Galt, with an average monthly surplus of over $1,000, gets a 16 per cent. reduction which brings the domestic rate to about 2½ cents. Other towns are eager for reductions and it is expected a number will be granted. Toronto's rates have not yet been finally determined.

THE CORROSION OF IRON.

By F. N. Speller, B.A.Sc.,
Metallurgical Engineer, Pittsburgh, Pa.

In writing on the "Corrosion-Resisting Qualities of Modern Mild Steel vs. Old-Time Iron" in *The Canadian Engineer* of June 4th, 1914, Mr. A. T. Enlow draws attention to a few of the erroneous ideas which prevail on this subject which have been quite generally overlooked in recent discussions. Some of these points are of such practical importance that they will bear referring to again. He emphasizes the fact that chemical analyses showing the sulphur, phosphorus, silicon and manganese (and he might have added oxides and slag) may be very misleading as to the enduring qualities of the metal. He goes on to say: "The idea that the analysis tells the whole story has its origin in the statement, so often reiterated when the idea of a modern rust-resisting metal was first conceived several years ago, that 'the purer the material as regards the absence of foreign chemical elements, the better would it withstand corrosion.' At best this statement only conveys part of the truth."

Referring to the exceptional cases where old-time iron has withstood the ravages of time to such an extent as to be, in some cases, in a state of good preservation to-day, Mr. Enlow points out that this is no proof that the old-time irons were all of this character—quite the reverse is the case—for the few samples which can now be found are merely the survival of the fittest. In speculating as to the cause of the long life shown in these exceptional cases by old-time iron the author seems to reach the conclusions that this was due to the absence of manganese in this iron and the presence of something which, perhaps for lack of a more definite term, he calls "vitality." This, it is presumed, is lacking in iron which shows more rapid corrosion. There is no question but that modern iron and steel, no matter by what process it has been made, varies to some degree in quality according to how carefully the metal has been refined and worked. This was most probably true, if not to a greater extent, in regard to the old-time iron referred to.

Regarding the effect of manganese, I believe the author is inconsistent and reaches a conclusion which is not supported by evidence. It is well known that manganese alloys with iron more uniformly than any other element and shows very little tendency to segregate. Many comparisons have been made of low-carbon steel made in the open-hearth furnace without manganese and ordinary soft steel carrying .30 to .40 per cent. manganese. On the whole, these tests show no decided difference in corrosion. The writer has had an opportunity of studying the effect of hot aerated water in pipe lines made up of modern puddled iron and soft steel. Here the conditions as to uniformity were ideal. From over one hundred of such comparisons no difference in the extent or depth of the corrosion could be seen, although the wrought iron had a mere trace of manganese, and the soft steel carried over .30 per cent.; so that the manganese is no exception to the general conclusion which Mr. Enlow has drawn that "chemical analysis of the carbon, sulphur, phosphorus, silicon and manganese may mean much or little."

As to the absence or presence of "vitality," it is true that by aiming at exceptional purity and not using such additions as ferro-manganese, properly applied, the steel may be rendered very sensitive to subsequent heating, and, as a practical welder would say, "it is dry." The metal in this state may have a very high degree of purity as in the case of so-called "ingot iron," but probably due to this extreme purity it readily absorbs gases when heated, and when fabricated may be decidedly inferior to soft steel carefully made by standard practice and carrying sufficient manganese to protect the iron from oxidation.

While in the writer's opinion the various operations of refining and working the metal have a bearing on corrosion, there is another factor of far more importance which is too often overlooked. The writer had an opportunity a few years ago to study some old iron of French manufacture on the Panama Canal which had shown remarkable resistance to corrosion under adverse conditions. This material was found to be of a variable analysis, corresponding to modern soft steel in some cases and in others the metal was evidently made by the puddling process. A close examination showed that corrosion had not penetrated through the surface of the metal, which was protected by a film of tenacious scale. Upon removing this surface skin and exposing the clean metal under the same conditions it was found to corrode as rapidly as modern soft steel. This was tried out a number of times where other instances of more or less perfectly preserved old iron have come to light, and it invariably proved that on removing the protective skin from these metals corrosion proceeds quite rapidly, the metal being destroyed apparently as fast as in the case of unprotected steel of modern manufacture.

Considering the fact that the iron and steel made up to 30 or 40 years ago was slowly fabricated, so that, especially where hand-forged, the finish was not nearly so smooth as nowadays, it seems that the film of cinder which was left on the surface of the forged article adhered tenaciously, and in most cases was responsible for preserving the metal from corrosion. In some cases these cinders are in the nature of a thin enamel and are quite impervious to moisture.

From our experience I am quite in accord with the author's conclusion that "the physical qualities unquestionably have very much to do with this question . . .," but I am inclined to question the statement that as a rule old irons are more dense than modern mild steel. It is very important, in my opinion, that the metal be uniformly finished in the final stages of refining and afterwards carefully heated and given as much work as possible in the process of fabrication. It is of advantage to apply this work in more than one direction, as in forging operations, so as to get as uniform density as possible, and in working metal in this way as far as practicable all loose scale should be removed from the metal between passes so that the finished surface may be as uniform as possible. This is the ideal to which we have been working in the manufacture of soft steel to withstand corrosion. It is obviously impracticable to make the large tonnage which is produced nowadays by the old-time methods, even though it was proved that iron so made had superior durability. Modern requirements call for a smoother finish, and protection, where required, should be applied to the carefully-prepared surface after fabrication.

After all, it seems that durability in service is more often a question of protection of the surface of the metal from moisture, either accidental or by means of protective coatings, than by virtue of any inherent quality in the metal itself. Chemical composition, *per se*, so far as the common metalloids are concerned, seems to have less influence on the corrosion of iron than any other factor.

COST OF CANADIAN RAILWAY CONSTRUCTION

MOST RECENT COMPILATION OF FIGURES FROM CONSTRUCTION ACCOUNTS OF CANADIAN RAILWAYS, GIVING DETAILED AND ORIGINAL STATISTICS FOR THE YEARS 1906-1913.

By J. L. PAYNE,
Comptroller of Statistics, Department of Railways and Canals, Dominion Government, Ottawa.

THE construction account of Canadian railways during the past decade runs into amazing figures. I cannot, however, go into details for the years prior to 1907, in which year an entirely new system of statistics was made effective, and must, therefore, content myself in this relation to deal with the facts since 1906. For that seven-year period, from 1907 to 1913, inclusive, there was an addition to capitalization of $465,949,063, or an average of $66,564,152 per annum. Cash aid by the Dominion, the provinces and municipalities amounted to $49,171,811 during the same term, or at the rate of $7,024,544 per year. Joining these two items of capitalization and aid, we have a total for seven years of $515,120,874, which would be equal to an average of $73,588,695 per annum. It might fairly be assumed that this large total represented the outlay, dollar for dollar, on construction. The increased capitalization includes $193,000,000 of stocks, which ordinarily would yield little or nothing in cash; but, in this instance, all but $65,000,000 of the aggregate has been made up of Canadian Pacific issues, which were sold at a substantial premium. It might, therefore, be taken for granted that the actual expenditure did not fall far short of the liability.

On the assumption that construction cost is fairly represented in the growth of capital liability, plus cash aid, two or three interesting facts are disclosed by analysis. During the seven years immediately under review, 7,951 miles were added to operative mileage in the Dominion. Of course, all the capitalization in question did not produce railway mileage in actual operation in 1913. Liability must necessarily precede the handling of traffic. On the other hand, there was undoubtedly more than $100,000,000 worth of bonds outstanding which had not been brought into the account; so that operative mileage left out might be regarded as balancing liability omitted. On that basis of calculation, since 1906 capitalization equalled $58,410 per mile per annum, and cash aid $6,183 per mile per annum. Such averages clearly show that (1), on the whole, we have been building railways up to a good standard, and (2) that public aid has been extended in generous measure. It is not straining the truth to say that no other country has been making such great sacrifices to provide itself with transportation facilities.

The cash aid of something like $5 per family per annum during the past seven years is only part of the story. Within a little over ten years the Canadian people has made itself liable for principal and interest in connection with guarantees of bonds aggregating $320,000,000, including the liability of $45,000,000 on account of the Canadian Northern, voted by Parliament in May last. This would bring the total of aid in cash and guarantees up to not less than $25 per family per annum during the past decade. It may demonstrate a splendid faith, or, in another aspect, it may merely reflect a sense of urgent need. No matter in what light it may be regarded, the liability, direct and indirect, is a matter of serious importance. The Canadian Northern has received a large proportion of the aid, both in cash and guarantees; and that system will unavoidably have a considerable unproductive mileage for some years to come. That is to say, the construction work it has had under way, and is about to undertake, lies very largely in those portions of the north-west which have not hitherto been served by railways; and it is a railway axiom that pioneer mileage does well if it earns operating expenses for the first three years. Nevertheless, the rapid settlement of the western provinces may create traffic quite sufficient to provide for the large fixed charges of the Canadian Northern system when it has been completed and placed on an operating basis.

The construction of the Moncton-Winnipeg section of the Grand Trunk Pacific should also be taken into the account of public aid to railways. The expenditure by Government on this work has already reached $150,000,000, and the Minister of Finance has stated in Parliament that the final cost will be $235,000,000, including interest on capital outlay up to such time as the agreement with the company which is to take it over becomes effective. This would bring the public contribution up to a little over $34 per family per annum during the past ten years, with more to come. The cost of the Transcontinental has been placed at $100,000 per mile, and this fact should carry with it the assurance that Government has built 1,805 miles of line up to a standard not hitherto attempted in Canada. Whether or not Government was setting a pattern, it is obvious that the days of cheap and more or less makeshift railway construction have passed. A low-grade railway may have been defensible in earlier times. It was a case of that kind of construction or nothing. But in these days it is recognized as sheer waste to follow such methods. Experience has amply demonstrated that it is true economy to build on sound lines and with a view to future needs.

If, however, Canada has added on a large scale to her capital liability on railway account during the past seven years, it is clear that the next seven years, barring some extraordinary disturbance in the financial situation, will establish new records in both expenditure and additional mileage. This prediction is not based on mere optimism. It rests on facts. Just a year ago there were in the Dominion 18,648 miles of line in various stages of construction. That was more than the entire operative mileage of the country in 1901. Of these 18,648 miles reported as being "under construction," nearly 9,000 miles were actually under contract. About 3,500 miles were completed, and 6,560 miles had not passed the survey stage. These are big figures. While this vast work was scattered all the way between the two oceans, more than 70 per cent. of it was located west of Ontario. At this moment it cannot be said how many miles were moved into the operating column during the past year; but for every mile completed, it is probable the construc-

tion of another mile was begun. It will involve a very large expenditure to carry this mileage to a finish and to equip it for the movement of traffic. It will also mean the employment of an army of men not now identified with transportation.

The labor aspect of railway operations in Canada is not generally recognized. It may not be amiss, therefore, to present a few facts in that regard. In 1913 there were 609 employees per 100 miles of line, as compared with 551 in 1907. This magnitude will increase with the growth of traffic. The total number last year was 178,652; and that figure represents an average increase of nearly 10,000 per annum during the past six years. The wages bill in 1913 reached the large total of $115,749,825, and made up 63.59 per cent. of operating expenses. In fact, if the matter be carefully examined, it will be found that, directly and indirectly, transportation interests provide a living for about 20 per cent. of the entire population of the Dominion. On the other hand, the cost of transportation, viewed as a tax, rises above all other public imposts, both in magnitude and distribution. Speaking broadly, nobody can escape the levy for carriage, or its incidence; whereas customs, municipal and other forms of taxation may in large measure be avoided by a considerable number in every community.

The ancient controversy as to the priority of the hen or the egg has its counterpart in the question as to whether transportation facilities create trade or trade creates transportation facilities. Without expressing any opinion on the subject, I have long been watching the co-ordination of these forces; for they do co-ordinate. Traffic and trade must move together. They are dependent on each other. Trade cannot grow without marketing facilities; and, just as the ship preceded settlement, so the railway must provide the channel for a nation's commerce, otherwise, there will not be any considerable volume of commerce. Leaving the matter at that point, it will be helpful to see by ten-year periods how Canada's railway mileage has grown. Here are the facts:—

	Miles.		Miles.
1863	2,189	1893	15,005
1873	3,832	1903	18,988
1883	9,577	1913	29,304

Traffic has moved upward with available mileage. Could old and new mileage be separated, it would undoubtedly be found that the former carries the larger proportion of traffic. New mileage, as has been said, must to a large extent develop its business; and this is often a slow process. The following little table shows the total tonnage hauled and the volume per mile of line since 1883:—

	Tonnage.	Per mile of line.
1883	13,266,255	1,384
1893	22,003,599	1,466
1903	47,373,417	2,495
1913	106,992,710	3,651

It will be observed that the productivity of old mileage has more than offset the dilution brought about by new mileage; and the table as a whole may be taken as showing in a most striking way the expansion of the Dominion during the past thirty years. That expansion is exemplified in the fact that while there was the largest addition to mileage between 1903 and 1913 there occurred during that same decade the largest increase of freight traffic. Passenger business does not show the same ratio of development, as the following table makes plain:—

	Passengers.	Per mile of line.
1883	9,579,984	1,000
1893	13,618,027	907
1903	22,148,742	1,166
1913	46,230,765	1,577

There has been little change during recent years in the proportionate relationship of commodities to the total volume of traffic. For example, products of agriculture made up 16.85 per cent. in 1907, and stood at 16.31 per cent. in 1913. Products of mines and manufactures have shown the principal growth. The former grew from 18,460,172 tons in 1907 to 40,230,542 tons in 1913, while the latter expanded from 7,974,641 tons to 19,694,240 tons during the same period. Nevertheless, the percentage of each class to the whole was not materially altered, except in those two cases. This would seem to show that production has followed along constant lines, and that growth, as represented in traffic, has been fairly uniform among the seven classes.

In no other respect does the widening of Canadian railway interests show up so impressively as in earning power. Going no farther back than 1888, and giving the facts at five-year intervals, the following table tells a strong story:—

1888	$42,159,152	1903	$ 96,064,526
1893	52,042,396	1908	146,918,314
1898	59,715,105	1913	256,702,703

It will be seen that as between 1888 and 1898 there was an increase of 41.6 per cent., whereas between 1903 and 1913 the betterment amounted to 167.2. This highly satisfactory result was achieved without any increase whatever in ratio. Net earnings showed up equally well. As between gross receipts and operating expenses—the popular method of measuring net earnings, but not the sound way—there was an advance from $11,507,106 in 1888 to $74,691,013 in 1913. Thus, while gross earnings grew by 509 per cent. during the whole period of 25 years, net earnings grew by 548 per cent. During at least 18 years of that period, there was on one hand a slight reduction of freight rates; while on the other there was a steady and pronounced advance in operating cost as represented chiefly in wages, prices for materials, and so on. Our railways have, therefore, raised net earnings very largely by better methods of operation.

At this point it would seem to be opportune to pause and ask: What, probably, will be the effect of the war now under way on the railways of Canada? No one knows; no one can do more than conjecture. The situation is as novel as it is staggering. It is a distressing topic, since war in all its aspects means waste. War is destructive and not constructive. To just the extent that Canadian commerce is hindered and production restricted there will inevitably be a reduction in the volume of traffic. Traffic is the life blood of railways. As it declines earnings fall off, and as earnings fall off the railways must cut down operating cost. The immediate effect of such economies will be a diminution of the pay roll, and we have already seen that salaries and wages make up 60 per cent. of operating expenses. The injury does not, however, end there. For every five persons who obtain a livelihood directly from the operation of railways at least one other person is dependent on that source indirectly. It therefore calls for no particular prescience to foretell a hard and trying year before the railways of Canada and all associated interests.

How far will the war bring about an enforced halt in construction work? The importance and far-reaching

nature of such a question is obvious. Many thousands of miles of new line are in process of building, and other vast projects are assuming positive shape. The money markets of the world have been paralyzed, and money to the railway builder is what traffic is to the railroad operator. Therefore, we must look for some let-up in construction activity. It is inevitable. Let us hope it may be of short duration. When the war is over, we are likely to see a period of unparalleled expansion in Canada. We have the inchoate material for a development beyond our most sanguine dreams.

From the railway point of view, the recent troubled situation has been hurled upon us when we were proud of our progress and strong in our faith. Our railways had established a surprising record of growth, and great plans, expressive both of our transportation needs and our accumulating energy, were under way. In 1913 they had made an unprecedented addition to equipment, and were in a fine position to meet a swelling of traffic. Had all this happened as the result of mismanagement or miscalculation, from some cause suggesting internal weakness, the situation would be vastly different; but it came when our railway situation, viewed as a whole, was sturdy and sound. Therefore, while we may be embarrassed, we shall be able to take up again the immense work on this northern half of the American continent pretty much at the point where it suffered interruption.

NEW PLANT FOR TREATMENT OF WOODEN POLES.

The Lindsley Bros. Company are just installing at their pole yard in Nakusp, B.C., a plant for treating the butts of their British Columbia cedar poles. For the past two years this company has been operating a similar plant at Priest River, Idaho, and last year treated over 5,000 poles.

The treatment in this plant, as also in the Nakusp plant, just installed, consists in immersing the butts to a point 12 inches to 18 inches above the ground line in genuine avenerius carbolinium at approximately 200 deg. F. for a period varing from 10 to 20 minutes; the period of immersion varying with the condition of the poles and time of the year. It is found that this immersion is the most efficient and gives a penetration of the entire sapwood of the butt—the only place where decay is likely to affect the pole.

At the present time this company is treating some 7,000 poles for the Great Falls Power Company of Butte, Montana, which will be used in a 100,000-volt transmission line to be erected between Great Falls and Anaconda and designed to carry power for the electrification of the Chicago, Milwaukee and St. Paul Railway. About 4,000 of these poles, which are from 45 to 50 feet long, will be used for the main transmission line which will be of "A" frame construction with six unit, suspension type insulators. This will probably be the highest voltage transmitted anywhere in the world on wooden poles and is all the more significant as the Grand Falls Power Company have had considerable experience with steel towers. At the present time they have a 60,000-volt line and an 80,000-volt line carried on wooden poles.

This year the company have entered orders for over 12,000, their customers including some of the most prominent public service corporations in the United States and Canada, one of these being the municipal electric light plant of Ottawa, Ont.

SINKING A SEA-OUTLET.

In the treatment of sewage in seacoast towns, it has become the custom in almost all cases to use retaining tanks at a point close to the beach. The sewage is brought to this point and there passes through these tanks, giving a liquid effluent, and holding back the solid matter which is broken up, and the natural action of putrefaction takes place.

With the objection of having solid matter washed back on the beach, removed, it only remains necessary to place the liquid effluent at such a distance from the shore, and in a sufficient depth of water to insure a perfect dilution. Here the sewage effluent, being lighter, rises to the surface, mixes with the seawater, the dissolved oxygen of which completes the purification. This has been found very satisfactory in a depth of 20 feet or more of water, and at a distance of approximately 1,000 feet from shore.

So the problem arises to construct a sea-outlet which will withstand the heavy storms occurring along the coast during the winter months, for a sum of money within reach of the average seacoast town.

Fig. 1.—Twelve-Inch Pipe, 1,000 ft. Long, Being Submerged After Assembling on Shores.

An outfall was described by W. M. Aitchison, C.E., in a recent issue of "The Cornell Civil Engineer" that is worthy of note. It was installed April 22nd, 1913, to take care of the sewage of West Grove, New Jersey. After passing through the settling tanks in West Grove, the sewage flows through Ocean Grove to a manhole near the ocean from between the board-walk and the street, and from this manhole through the sea outlet into the ocean.

The outfall line was made up of 12-inch galvanized wrought iron pipe. The pipe came in lengths averaging 21 ft. and weighing approximately 48 lbs. per ft., with threaded joints fitting into recessed couplings.

While the material was being put on the ground a 3-drum hoisting engine was set up on the beach near the point where the pipe was to be installed. This being the anchorage of the whole operation, great care was used to have a substantial base. Eight-foot piles were driven in the sand, cross braced and capped, and the hoisting engine bolted to these caps.

For an off-shore anchorage five anchors were set at a place in a direct line with the proposed outfall, and at a distance of about 1,325 ft. from shore. The distance was determined with a light line drawn taut. The anchors were set in a line leading away from shore, the two nearest weighing 500 pounds and the remainder being somewhat lighter. These anchors were fastened together with a steel cable, and an 18-inch sheave attached to the nearest

anchor. Through this was run a ⅝-inch steel cable and both ends brought ashore.

The outlet end of this line was made up with a 45° L, looking upward, and a nipple leading into another 45° L reversed, allowing the open end when completed to be six feet from the bottom, thus being out of danger from filling with sand or becoming otherwise clogged.

A sea-anchor of the contractors' own design, and consisting of two castings and two clamps was fastened to the riser just described. One clamp was bolted over the nipple leading from the lower 45° L, and the other over the main pipe just in back of the same L, both clamps fitting close to the pipe. These were held by eight one-inch bolts. The sea-anchor weighed 2,200 lbs. in all, and was assembled on the beach just above high-water mark.

Starting at the lower L the pipes were joined together with the recessed couplings, the threads being painted with white lead to insure watertightness. Platforms were built at intervals of about 30 ft. from this point into the street. Rollers were set on these platforms at such elevations as would give an even fall from the street level and the pipe line was built up on these rollers.

Fig. 2.—View of Pipe After Being Hauled Overboard.

A street leading from the ocean at this point formed a very convenient means to continue the work on the pipe line. The pipes were assembled on this street and raised on small wooden trucks, the latter being fastened at intervals equivalent to a length and a half of pipe, until the entire length from the river was sufficient to place it 1,200 ft. from the inlet point and have the last pipe above high-water mark on the beach. This much completed, there was 1,000 ft. of pipe intact, starting at high-water mark and extending in shore, all resting on either trucks or rollers.

The sea-anchor was carried on a big truck with two wheels six feet in diameter, made of two thicknesses of 2-in. plank and each having a rim of 2-in. by 8-in. plank to afford surface bearing.

A hook on the rear of the axle fitted into an eye on the rear of the coupling, thus supporting the sea-anchor and riser, and holding the same free from the ground. Extending out from the axle was a long tongue, at the end of which was a clevice. One end of the steel cable already running through the 18-in. sheave off shore was passed through this clevice and fastened firmly to the sea-anchor, with the other end on a drum of the hoisting engine.

The open end of the riser was next stopped up by means of a wooden plug inserted with white lead. So, with the outer end watertight and raised on a truck the entire line is ready and in a movable position.

The hoisting engine was then used to haul the entire length to sea (Fig. 1), the weight of the sea-anchor keeping the truck and outer end of the bottom, and the air in the pipe causing the balance of line to be bouyed up. A 3-in. pipe line extending through the entire length of large pipe acted as ballast and held the line partly submerged. This condition removed all of the unnecessary friction, and left only the resistance of the large truck holding the sea-anchor and the small trucks and rollers supporting the pipe. This diminished as the pipe went farther to sea. The small trucks were removed as they came up to the platform supporting the rollers.

The object of the sea-anchor being suspended by this hook and eye method, it will be noted, is to form a convenient means of depositing the pipe in its place when so desired. When the cable line is slackened the weight of the sea-anchor pulls the rear of the axle down, and the tongue up, and at the same time the hook releases the eye, and the sea-anchor is dropped in its permanent place.

The hauling finished, the five anchors off shore were raised singly, starting with the most distant anchor and coming in. This slackened the cable and dropped the sea-anchor. The cable was then cut as close as possible to the arm-anchor, releasing the truck, and with this the off-shore work was completed. Fig. 2 shows the pipe after being hauled overboard.

The open end in shore, at a point just above high-water mark was reduced to a 2-in. bushing, and water was pumped through this into the large pipe until a pressure of about 40 pounds was reached, thereby blowing the wooden plug out of the riser and sinking the remainder of the pipe in its place.

A block and fall was used in shore to relieve the strain on the five off-shore anchors, one end fastened to the 12-in. pipe and the other to a second drum on the hoisting engine. It was estimated that a force of about ten tons was required to haul the pipe overboard, this diminishing as the work progressed.

Next the in-shore end was lowered to its proper depth and the line continued to the manhole.

One of the largest factors to be contended with is the shore current, tending to bend the pipe out of line before it is lowered to the bottom. This makes it imperative that the temporary anchors and the engine base be absolutely secure before the hauling is underway. Another difficulty is the necessity of awaiting the proper weather conditions. While it took but 2½ weeks to put everything in readiness it was a considerably longer time before a combined light westerly wind and low tide made possible its completion.

The total, actual pulling time required was 39½ minutes in the intervals of about 5 minutes each, with lapses between to make sure every part was in proper working order. The total time from start of haul to finish was 2 hours and 15 minutes. At the start of the haul the pipe moved at a rate of 20 ft. in one minute while approaching the end it had increased to 20 ft. in 13 seconds. The average working force was six men, with about six added on the day of the haul overboard.

NOTES ON THE DESIGN OF SEWERAGE REGULATORS AND STORM WATER OVERFLOWS.

In *The Canadian Engineer* for August 27th an article was published on the design of the new intercepting sewers for the City of Cincinnati and the investigative work leading up to their design. In connection with it there will have been noted that adequate provision was not made therein for the entire storm water run-off, and that the excess is to be taken care of by separate storm water overflows. This subject, together with that of sewage flow regulation, is also treated in the Cincinnati sewerage report, and from it the following is abstracted:—

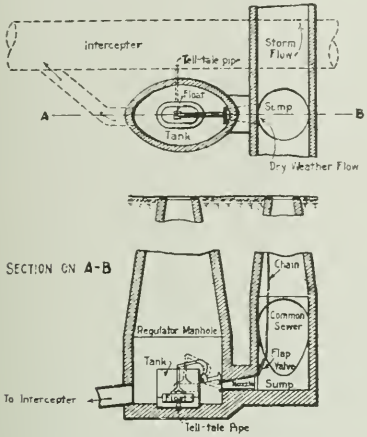

Fig. 1.—Typical Sewer Regulator.

The function of a storm water overflow is to supply a means of removing storm water in excess of a certain definite flow in the sewer to the nearest watercourse, or to a storm water channel provided for that purpose; in other words, to allow the escape from the sewer of all excess over a fixed quantity of sewage. A sewage flow regulator, conversely, is intended to prevent surcharging of an intercepting sewer by partly or wholly closing the inlet connections from the branch trunk sewers. The general object to be attained is the same in both cases, namely, to allow the admission of domestic sewage to the intercepting sewer and to divert the storm water to other channels; but an overflow provides an outlet for storm water from a trunk sewer, while a regulator prevents the admission of storm water to an intercepter.

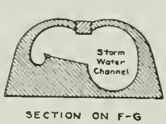
Overflows and regulators are frequently used in combination, the former allowing the excess above a certain flow to be discharged into storm water drains, the latter entirely cutting off inflow to the intercepter when the quantity of sewage in the latter has reached a certain point and when it is in danger of being surcharged.

Regulators.—A regulator is a mechanical appliance by which a gate is automatically closed by the rising of a float whose motion is controlled by the elevation of the sewage in the intercepter. A typical regulator is shown in Fig. 1.

The use of regulators of this type is open to the objection that frequent attendance is required in order to keep the apparatus in proper working condition. The regulators must be inspected and cleaned at short intervals, and after each storm must be carefully overhauled, if they are to be depended upon to perform their function.

Over-Fall Weirs.—There are two types of storm overflow, over-fall weirs and leaping weirs. An over-fall weir, as the name implies, is an outlet with a sill or crest arranged either across the sewer or longitudinally in one side of the structure, so designed that the excess flow, after the sewage reaches the height of the crest, is taken to a storm water channel, while the ordinary flow passes the weir and is discharged into the intercepter.

An excellent example of an overflow of this type is shown in Fig. 2, which illustrates the storm water overflow constructed in connection with the Walworth sewer in Cleveland, according to the designs of W. G. Parmley. In the case of large sewers, such as the one illustrated, an over-fall of considerable length is required. In this particular example the length of the crest was approximately 100 ft.



An overflow of this type, if properly designed, should be absolutely automatic in its action and should require no particular attention. The only objection to its use is that gravel and sand washes along the bottom of the sewer and the larger stones brought down by storm water do not pass over the weir, but follow the line of the intercepting sewer, which, therefore, receives practically all of the grit and is more likely to be obstructed by accumulations than if the heavy material brought down by storm water could be discharged with the overflow. This also involves undue wear upon the invert of the intercepter.

Leaping Weirs.—The leaping weir type of overflow is suitable only for comparatively small sewers. As the name implies, it consists of a weir or crest over which the ordinary or dry weather flow falls into a connection leading to the intercepting sewer, while the storm waters leap the opening and pass on through the storm water channel.

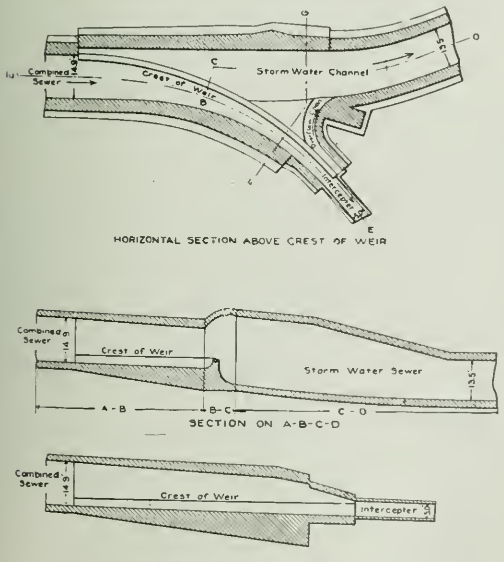


Fig. 2.—Overfall Weir for Storm Water Overflow.

A typical leaping weir is shown in Fig. 3, which illustrates an inlet constructed in connection with the Menomonie Intercepter at Milwaukee, Wis., from designs of George H. Benzenberg. Like the overflow weir, this type should require no attention, unless the opening becomes clogged by planks or other large substances which are not supposed to find their way into sewers, although they sometimes do. It is open to the same objection as the over-fall weir, that the gravel and sand are washed into the intercepter, although there is more likelihood with this type of overflow that a portion of the silt may be discharged with the storm water.

In view of the attention necessary to maintain regulators in proper working order, it is desirable to avoid their use as far as possible. Wherever found possible by studies of the details of design, the leaping weir type

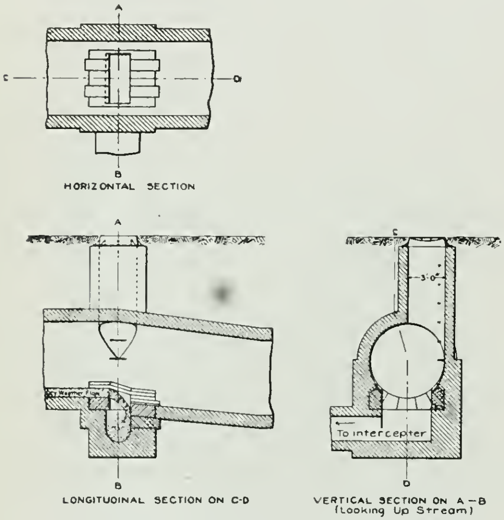

Fig. 3.—Typical "Leaping Weir" for Storm Water Overflow.

of overflow for the connections of the smaller trunk sewers and the over-fall weir for the larger sewers should be used rather than float-operated regulators.

It must not be forgotten that in the case of trunk sewer outlets which are below the level of high water in the river, so-called tide-gates must be provided, particularly in any project which involves pumping and treating the sewage collected by the intercepters; otherwise river water will at times enter the intercepter through the storm water overflows.

It is reported that timber limits extending over 115 square miles along the foreshore of Seymour Inlet and adjacent waters in British Columbia, including 3,000,000,000 feet of high-grade cedar, were recently transferred to a syndicate of capitalists from the United States. It is said to be the intention of the purchasers to begin logging operations on the limits in the near future, and the plans contemplate placing several sawmills on the property. The scarcity of cedar and the increasing price of high-grade timber in the United States have caused American millmen to turn their attention to British Columbia, which has the largest compact area of merchantable timber on the continent. The abolition of the duty on Canadian shingles and other forest products has encouraged and given impetus to the shingle industry, which has made great progress in the province recently.

OTTAWA WATER DISTRIBUTION.

A COMPREHENSIVE review of the present water system at Ottawa, tests made upon its efficiency, the requirements necessary to afford modern fire protection, a plan of the immediate and future improvements recommended, together with detailed estimates of the cost of these improvements, are presented to the City of Ottawa in a report by R. S. and W. S. Lea. A short digest has been made from this report and is given in the following paragraphs.

Ottawa's water system is operated by direct pumping at from 80 to 90 lbs. normal pressure and fire pressures up to 110 lbs. The supply is taken from the Ottawa River and almost all of it is pumped by water power. Over 40% of the system is 5-inch pipe; and, as a whole, the pipes are smaller than are usually found in cities of the size of Ottawa, even those having the oldest of systems. A comparison of the Ottawa system with those of five Massachusetts cities follows:

City.	Estimated population, (1913)	Average size of pipe. (Inches)	Relative capacity of system.
Ottawa, Ont.	100,000	6.4	1.00
Springfield, Mass.	100,400	10.5	3.66
Lynn, Mass.	97,500	8.0	1.80
Lowell, Mass.	110,100	9.2	2.59
Cambridge, Mass. ...	109,300	8.7	2.24
New Bedford, Mass. ..	112,500	9.0	2.45

In order to determine the normal capacity of the present system, a series of tests was made, using pressure gauges on the hydrants and a Curtis stream gauge at the nozzles, which were attached to 50 feet of hose. From these tests, the actual loss of head between the pumping station and any section of the city with ordinary domestic draft could be determined, as well as the additional loss resulting from a draft for fire purposes, not only at the hydrants from which water was drawn, but also both in their immediate vicinity and between this section and the pumping station. About 1,200 readings were taken in all.

It was found also that the friction losses in the system were, in many cases, three times what they would be with the usual permissible velocity of flow in the main pipes. Moreover, the hydrant pressures were below the commonly accepted standards.

The present population of Ottawa is about 100,000, and this population may be expected to at least double in the next twenty-five of thirty years. Rockliffe is the only section outside the city limits at present served by the Ottawa water system; but it is believed that provision should be made for supplying suburban districts in the future, since the city will probably be in a position to furnish water more cheaply than it can be obtained from a number of individual plants. More important still, the city cannot obtain the fullest advantages from its own proposed pure water supply if questionable supplies be continued in the suburbs.

The combined use and waste of water in Ottawa per capita is practically twice what it should be. Pitometer surveys and house-to-house inspections are in progress, with the object of finding the causes of the waste and reducing it.

The excessive normal draft per capita in Ottawa may be attributed to one or more of the following causes:

(1) The use of large quantities of water for power and manufacturing purposes;

(2) Carelessness in leaving taps running;
(3) Leakage from defective plumbing and fixtures;
(4) Leakage from the underground system.

The use of water for power and manufacturing purposes can be reduced to legitimate proportions by metering the supplies to such establishments. Education and inspection will probably reduce the losses due to (2). A long-continued extravagance in the use of water, however, becomes a habit, and no practicable method of effectively reducing it is known, except that of metering the domestic services. Leakage from defective plumbing and fixtures can be controlled by a systematic house-to-house inspection regularly maintained by a permanent corps, or by metering the services. The determination of underground leakage, the location of the leaks and their repair, is a work which may take much time, patience and money.

Obviously, the way to deal with the situation is, first, to determine for what proportion of the total waste each of the causes is responsible; after which remedial measures may be applied if their adoption is warranted by the waste it is practicable to prevent thereby.

Before permanently adopting any of the remedial measures referred to above, it is suggested that small sections of the system be chosen in typical residential, semi-commercial and business districts, and that their consumption be recorded for some time by means of a photo-pitometer or a Deacon meter. If there are any establishments in these sections using water for power or manufacturing purposes, these particular services should be metered. The number of domestic services and the number of consumers should be determined. After records from these small sections have been taken long enough to indicate the per capita domestic consumption, the house plumbing should be inspected and all defects repaired. Then tests could be carried out for underground leakage by the usual methods. Such a procedure as this would give some indication of the proportion which waste from the various causes bears to the total waste, and would serve as a basis for determining whether or not it would pay the city to adopt the available remedies.

An excessive use of water, it must be remembered, is responsible for a financial burden greater than is represented by the cost of pumping or filtering, as it may overtax the capacity of every part of the system. For instance, the per capita consumption is an important factor in the design of the improvements recommended; and the design is based on the assumptions that it will be sufficient to provide capacity in the distribution system for the maximum fire draft, and to maintain a domestic consumption at the rate of 125 gallons a day per capita. These assumptions presuppose the reduction of Ottawa's consumption to a normal figure, the steps for which are strongly recommended by the engineers.

An important question of policy is whether or not it is advisable to meter the domestic services. The larger services for power and manufacturing supplies should certainly be metered; and, moreover, no domestic connection should be permitted to any private fire service unless the service is equipped with a detector meter. Where the domestic services are not metered, a system of house-to-house inspection should be maintained to control the use of water for sprinkling purposes, and to insure that the plumbing is kept in a state of proper repair.

Unfortunately, there is a too general belief that the object of universal metering is to reduce the consumption of water by increasing the cost to the ordinary consumer. This view is entirely incorrect. It is true that the installation of meters has almost invariably reduced the water consumption to legitimate proportions; but this reduction in consumption is due to the restriction of waste on the part of careless consumers. With this waste eliminated, the total cost of providing a supply for a city cannot but be reduced. And, if there are sound reasons, based on carefully collected data, for believing that it would cost the city less to install and maintain meters on the domestic services than it would to supply the waste prevented by these meters, a city should not hesitate to adopt metering because of sentimental or imaginary objections.

The provision for fire draft is as follows:

For the principal business section, containing the risks of greatest value, 35 to 40 standard streams;

For the manufacturing districts, particularly the areas devoted to the lumber industry, 20 to 25 standard streams;

For the closely built semi-commercial section, 15 standard streams;

For the residential sections, depending on the character and proximity of the houses, 5 to 10 standard streams for the worst fires.

For direct pressure, it is desirable that with the usual hydrant spacing, running pressures of 65 to 70 lbs. be maintained in the residential sections under conditions of maximum draft, and 90 to 100 lbs. in closely built semi-commercial and manufacturing sections with no buildings over five stories in height. With a closer hydrant spacing than is generally adopted, fairly good protection is afforded with running pressures of 60 lbs. in residential sections, and 80 to 85 lbs. in semi-commercial and manufacturing sections.

In the scheme of improvements recommended, such capacities have been selected for the new feeders as will ensure satisfactory fire service with the available pressure direct from the hydrants over as large an area as possible. As the average static pressure on the Ottawa system is only 85 lbs., the friction loss from the point of supply to the centre of draft must necessarily be kept within close limits. In fact, it will never be possible to dispense with fire engines entirely for protecting districts with buildings over five stories in height, unless a high-pressure system is provided. And, since over 40% of the Ottawa system consists of 5-inch pipe or smaller, the only way that high local losses of head can be avoided and satisfactory hydrant pressures maintained, is to feed the general gridiron from relatively large mains crossing an area at intervals of from one-quarter to one-third of a mile.

Suitable fire pressures can be maintained for many years in the suburban districts without storage. When the suburban population is largely increased, it will probably be necessary to construct elevated tanks at three or more points to provide storage in the centres of these outlying districts for fire service. The construction of these tanks will maintain suitable pressures without any additions to the proposed feeders. Suitable sites for these tanks are available in Rockliffe for the southern district on the Buchan Road one mile from Billings Bridge, and for the western section somewhere south of Carling Avenue.

Cast iron pipe is recommended for the sizes under 16-inch, and riveted steel pipe for the 30-inch and 36-inch feeders. For the intermediate sizes, the choice between cast iron and steel should be determined by the prevailing prices when the pipe is purchased.

In general, valves are to be placed in the pipes immediately after they leave the main which feeds them, and also immediately after all branches of 12-inch diameter and over are taken off them. Where the branches are small, such as 6-inch and 8-inch, valves are to be placed at least as often as every sixth crossing; and where the

mains run parallel to the long sides of the blocks, valves are to be placed at every third crossing.

Where the new mains are in rock excavation, it will be desirable to replace the present small pipes by the new main in order to take advantage of the easy excavation. It is advisable to do so in any case where the old main is known to be subject to considerable leakage.

It is usually recommended to place hydrants at all street intersections, with a maximum spacing of 500 feet in residential areas and 200 to 250 feet in business districts. No general rule can be indiscriminately applied, however, owing to the difference in the friction losses in pipe of different sizes. For instance, the loss in a 5-inch pipe is about ten times the loss in an 8-inch pipe for the same discharge. Taking into consideration the combined effects of differences of elevation, pipe sizes and dimensions of blocks, the placing of hydrants is plainly a matter which cannot be settled by adhering to a general rule.

A reasonable hydrant spacing in the residential sections, dependent on the distance apart of the mains and the sizes of the smaller street pipes, will be about as follows:

Static pressure.	Distance between hydrants.
80 lbs.	500 to 550 feet
70 lbs.	400 to 450 feet
60 lbs.	300 to 350 feet

In the semi-commercial manufacturing districts, the spacing should be kept down to about 300 feet, and in the principal business districts with buildings up to eight and ten stories high, it will eventually be necessary to adopt a limit of about 200 feet.

The presence of large lumber yards in certain sections of the city constitutes a serious conflagration hazard. If a fire should get beyond control within the yards, the interior hydrants might not be accessible, while the fire might be beyond the range of the adjacent street hydrants. In such an emergency, one or more monitor nozzles mounted on stand pipes in towers at the sides of the yard would be of great service.

The principal business district in Ottawa is at present covered by the "Booster System" which has been lately put into service; and the improvements that have been recommended do not include this district.

It is advised that the city should proceed with the installation of a system of main pipes in sizes ranging from 12-inch to 36-inch. To carry this system to completion will eventually require 30 miles of pipe at an estimated cost, based on current prices for labor and material, of $947,500. Within the total amount recommended, about 13 miles are required for the improvement of the system in the present built-up sections, at an estimated cost of $420,000.

If the "Booster" pumping capacity is increased to meet the demand in the business section, four or five standard fire engines will be sufficient for many years to come; and these can be stationed where they will generally be needed.

The proposed scheme is, in fact, a very desirable one, but it calls for heavy expenditure. Estimates have therefore been prepared for an alternative scheme based on maintaining such hydrant pressures as will permit all streams being taken directly from the hydrants for the small fires, and relying on the use of fire engines in every part of the city for the control of the worst fires. The total estimated cost for this alternative scheme is $776,400 for 34 miles of pipe. The difference in the first cost is $180,100. Taking interest and depreciation at 5½%, this difference in first cost represents an annual charge of nearly $10,000. It is altogether likely, however, that the underwriters would specify eight or ten more fire engines with the alternative scheme than would be required under the original proposition. The annual cost of each fire engine and the incidental equipment has been estimated at $4,000. Therefore, on the basis of ultimate annual cost, including fire engines, the original proposition is, if anything, the cheaper scheme; and as it affords much superior fire protection, it is recommended without qualification.

Referring to the future protection of the principal business district, the "Booster System" should suffice until the end of the year. As an ultimate solution of the problem, this system, with motor-driven pumps, is not favored, as the power for its operation must be purchased at rather high rates. Moreover, the pressure is bound to be limited by what the existing pipes will stand; and this is not sufficient to supply the high-pressure fire streams necessary. Consequently fire engines will still have to be used; and there is also some danger in carrying high pressure on an old system to which connections of all kinds will continue to be made. The additional pressure is dependent upon the operation of a number of check valves, and if any one of these should fail, the pressure would be greatly reduced.

Finally, it is pointed out that no system will effect a reduction in the annual fire losses at all comparable to that which would ultimately result from removing the cause of serious fires by the enactment and enforcement of a good building code embodying the recommendations of the National Fire Protection Association. However, as an efficient fire protection scheme, no other proposition compares at all favorably with the independent high-pressure fire system. That can be made practically free from danger of broken connections to buildings, which records of all great fires have shown to be responsible for an enormous waste of water at the time it was most urgently needed. But, above all, the chief advantage of the system lies in the fact that it provides the means whereby water can be applied to the seat of a blaze in the shortest possible time.

The cost of a high-pressure system in the district covered by the present "Booster System" with pipes below the present system, a hydrant spacing limited to 200 feet, and a pumping plant capable of supplying nine standard pressure streams, each discharging 820 gallons per minute, is estimated at about $290,000.

WAR AND AMERICAN BUSINESS

Authorities are unanimous in the opinion that America will benefit in various ways as the result of the war. They admit that all nations will pay a share of the cost, but generally speaking, they think that the United States, and Canada to a lesser degree, will receive benefits.

Mr. Franklin K. Lane, secretary of the interior at Washington, predicts greater industrial expansion and especially greater mining activity in the United States as a result of the struggle. He says:—"Of importance second only to that of food supply is the supply of mineral products. We have cause for self-congratulation that we are able to feed ourselves. What we possibly have not realized, is that we are nearly as independent in the possession of essential mineral resources as in food products, and that interference with manufacturing caused by interruption of flow of importations of many necessary raw materials, because of the war, may be overcome almost wholly by development of neglected resources in our country."

He added that these resources will be developed if formative legislation be passed.

CLASSES OF PERMISSIBLE EXPLOSIVES.

In order that the users of explosives may know the nature and characteristic component of permissible explosives, and as an aid in the selection of an explosive to meet a specific requirement, the permissible explosives have been arranged in four classes by the United States Bureau of Mines, whose investigations of explosives and their use have been progressing steadily since 1908, with a view to lessening the accidents attending such use. Reports of tests of permissible explosives appear in Bulletin No. 66, from which the following useful information has been taken:—

It is divided into two subclasses. Subclass *a* includes every ammonium nitrate explosive that contains a sensitizer that is itself an explosive. Subclass *b* includes every ammonium nitrate explosive that contains a sensitizer that is not in itself an explosive. The ammonium nitrate explosives of subclass *a* consist principally of ammonium nitrate with small percentages of nitroglycerin, nitrocellulose, or nitrosubstitution compounds which are used as sensitizers. The ammonium nitrate explosives of subclass *b* consist principally of ammonium nitrate with small percentages of resinous matter or other non-explosive substances used as sensitizers.

All of the ammonium nitrate explosives readily absorb moisture from the atmosphere, and great care should be taken in storing them or in using them in damp places. They are not suitable for use in wet mines. If in such a mine a cartridge of an ammonium nitrate explosive is opened and its contents exposed for only a few hours to the damp atmosphere the explosive may deteriorate, and later fail to detonate completely. The ammonium nitrate explosives when stored in well-ventilated magazines for only a few months have shown signs of deterioration, and nearly all explosives of this class after six months' storage at the Pittsburgh experiment station have either failed to detonate or have detonated incompletely. For this reason ammonium nitrate explosives should be obtained in a fresh condition and should be used as soon as possible after their receipt. When fresh, these explosives, if properly detonated, have the advantage of producing only small quantities of poisonous and inflammable gases, and are adapted for mines that are not unusually wet, and also for mines and working-places that are not well ventilated.

Class 2, Hydrated Explosives.—To Class 2 belong all explosives in which salts containing water of crystallization are the characteristic materials. The explosives of this class are somewhat similar in composition to the ordinary low-grade dynamites, except that one or more salts containing water of crystallization are added to reduce the flame temperature. They are easily detonated, produce only small quantities of poisonous gases, and most of them can be used successfully in damp working-places.

Class 3, Organic Nitrate Explosives.—To Class 3 belong all the explosives in which the characteristic material is an organic nitrate other than nitroglycerin. The permissible explosives listed under Class 3 are nitrostarch explosives. They produce small quantities of poisonous gases on detonation.

Class 4, Nitroglycerin Explosives.—To Class 4 belong all the explosives in which the characteristic material is nitroglycerin. These explosives contain free water or an excess of carbon, which is added to reduce the flame temperature. A few explosives of this class contain salts that reduce the strength and shattering effect of the explosives on detonation. Nitroglycerin explosives have the advantages of detonating easily and of not being readily affected by moisture. On detonation some of them produce as large quantities of poisonous and inflammable gases as black blasting powder, and for this reason they should not be used in mines or working places that are not well ventilated.

Rate of Detonation of Permissible Explosives.—The energy developed by the detonation of permissible explosives, like that of other high explosives, depends on the change of the small solid and liquid particles of the explosive into large volumes of highly-heated gases and on the rate of detonation or the rapidity with which these gases are formed. The force exerted by these gases is the means of producing useful effects. The rate of detonation is the governing factor in judging the efficiency of an explosive, and it offers the best single means for selecting explosives suitable to meet the varying conditions of coal mining.

During the conversion of an explosive into solid, liquid, and gaseous products the cooling effect of the walls of the drill-hole tends to lower the temperature of the gases so that the maximum theoretical temperature or pressure is never reached. The more nearly instantaneous the explosive reaction, all other conditions being equal, the greater the volume of highly-heated gases produced, and the more violent the effect.

To meet the varying conditions of coal mining in this country the explosives manufacturers have devised explosives with rates of detonation that range from 4,750 to 14,560 feet (1,447 to 4,439 meters) per second.

Suggestions Useful in Selecting Explosives.—It is hoped that with few exceptions the classification given will serve as a useful guide for comparing the practical value of permissible explosives. It is evident that for certain work in which a shattering effect is desired, as in driving through or "brushing" rock, or in producing coal for coking purposes, the explosive reaction should be rapid. Hence, permissible explosives having a high rate of detonation should be selected. Similarly, for use in soft, friable coal to produce lump or steam coal, selection should be made of a permissible explosive that detonates slowly, and hence gives a more prolonged pressure. In medium hard coal an explosive having an intermediate rate of detonation would be expected to be most suitable, but is not always so. Coals vary in hardness and coal beds vary in the number and position of the joints, partings, shale bands, etc. These facts have to be considered in mining.

An explosive having a very low rate of detonation is not always best suited for mining soft, friable coal, because some of its energy may be lost by its gases escaping through cracks and fractures in the bed. Under such conditions an explosive having an intermediate rate produces the most economical results.

Another factor to be considered in connection with an explosive having a high rate of detonation or the use of a large charge of any explosive is the possible effect on the roof, or the strata overlying the coal bed. Large charges of explosives having a very high rate of detonation cause small fissures that may later necessitate extra timbering to prevent falls in rooms or entries, and thus make the operation of a mine more costly.

It is well known that the pressure developed by the detonation of explosives in a closed space is directly proportional to the charging density; in other words, a 1¾-inch drill-hole loaded with 1¼-inch cartridges will produce on the walls of the drill-hole about one-half as much pressure per square inch as it would if loaded with cartridges of 1¾-inch diameter. A limited experience indicates that explosives having a rapid rate of detonation will yield a larger proportion of lump coal if used

in a hole of larger diameter than the cartridge. Such air-spacing to reduce the shattering effect of an explosive is recommended by the Bureau of Mines, provided the charge is confined with moist clay stemming tamped to the mouth of the drill-hole.

Other less desirable means of reducing the shattering effect of an explosive are the use of an improper detonator, reducing the amount of stemming, using an explosive that is frozen or partly frozen, using an explosive in cartridges of less diameter than those originally tested, and introducing foreign substances between the cartridges of an explosive; but these methods are all dangerous. They not only eliminate the safety qualities of the explosive, but increase the chance of a resultant dust or gas explosion, and should not be adopted.

Results of Tests with Detonators.—Permissible explosives are detonated by means of detonators or electric detonators, which are graded by number according to the weight of fulminating charge. Different types of explosives require detonators of different strength. Detonators are usually fired with fuse. A detonator fitted with a means of firing it with an electric current is called an electric detonator. As an electric detonator is embedded in the explosives with which it is used and is isolated by the stemming, it is the safest means of igniting a charge of explosive in a gaseous mine.

One of the conditions prescribed by the Bureau of Mines for a permissible explosive is that it shall be fired by a detonator, preferably an electric detonator having a charge equivalent to that of the standard detonator used at the Pittsburgh experiment station. It is further required that this charge shall consist by weight of 90 parts of mercury fulminate and 10 parts of potassium chlorate (or their equivalents).

An investigation undertaken by the Bureau of Mines shows that the average percentage of failures of explosives to detonate is increased over 20 per cent. when the lower grades of electric detonators were used instead of No. 6 electric detonators, and over 50 per cent. when compared with No. 8 electric detonators. However, when sensitive explosives were tested under the conditions most favorable to detonation, the same energy was developed irrespective of the detonator used. When tests were made with insensitive explosives under conditions which similate their use in blasting, the energy increased with the grade of the detonator used. For example, the average explosive efficiency of four different explosives was increased 10.4 per cent. by using a No. 6 electric detonator instead of a No. 4 electric detonator, and 14.9 per cent. by using a No. 8 electric detonator. The tests emphasize the importance of using explosives in a fresh condition, and, since this is not always possible, the importance of strong detonators in blasting to offset any deterioration of the explosive through ageing.

The results substantiate these conclusions: (1) That the explosive efficiency of the detonators made by any one manufacturer increases with the grade; (2) that No. 6 electric detonators of four different makes have practically the same explosive efficiency; and (3) each is considered equivalent to the Pittsburgh experiment station standard No. 6 electric detonator for use with permissible explosives in coal mines when the No. 6 grade is prescribed.

Receivers have been appointed for the International Steam Pump Company, a $29,000,000 corporation, by United States Judge Mayer. The receivership was granted in an equity suit brought by bondholders and stockholders and a creditor. The corporation joined in the application. The receiver was authorized to continue the business.

MILD STEEL AND ITS TREATMENT.*

By Albert Sauveur,
Professor of Metallurgy and Metallography, Harvard University.

FOR the purpose of illustrating metallographic methods and their teaching we may select as a concrete example the treatment of mild steel, a metal so widely used in machine construction, as, for instance, in the manufacture of shafts, and extensively used, also, for a great variety of steel castings. Such steel may contain some 0.30 per cent. carbon, and should be of good commercial quality; i.e., should contain over 0.1 per cent. phosphorus—preferably not more than 0.05 per cent. of that element—nor over 0.05 per cent. sulphur. According to the treatment it has received it may have a tensile strength varying between 60,000 and 100,000 pounds per square inch, while its ductility, measured by its elongation, may fluctuate between 15 per cent. and 35 per cent. As cast into ingots or other forms this metal shares the shortcomings common to all steel castings—weakness, lack of ductility, and little resistance to shock. These unwelcome properties of steel in its cast condition are due primarily to the structure of cast steel, which is very coarsely crystalline.

It is well known that the properties of steel may be very greatly improved through properly conducted mechanical and thermal treatment, by which its structure

Fig. 1.

is modified or refined, and it is the purpose of this paper to describe briefly the various structures mild steel may be made to acquire as the result of work and of heat treatment, and to point out the relations existing between each structure and corresponding physical properties, such as hardness, strength, and ductility.

No explanation of the deep structural changes resulting from certain treatments can be given without reference to the thermal critical range of the steel considered. Fortunately, metallography has so diffused this fundamental knowledge that at the present time there is hardly a metallurgist or metallurgical student ignorant of it. A lengthy description of the occurrence of the critical range of mild steel and of its meaning will not be, therefore, necessary. It will be helpful, however, for the present purpose to illustrate graphically the relations existing between the critical range and the structural changes it is desired to describe.

In Fig. 1 the critical range is represented as covering a temperature zone extending from 700° to 800° C. It will not be necessary, for the aim in view, to take into consideration the existence of two critical points, A_{3-2}

* Lecture delivered before the Mechanical Engineering Society of the Worcester Polytechnic Institute, Worcester, Mass., and published in the Journal of the Franklin Institute.

and A_1, within that range, nor the fact that the points on heating, Ac_{3-2} and Ac_1, occur at temperatures some 25 to 50 degrees higher than the corresponding points on cooling, Ar_{3-2} and Ar_1.

Above its critical range the steel we are studying consists, like all steels, of a solid solution of iron and carbon. In this condition the two constituents are so completely merged that their independent existence cannot be recognized by any physical means; they form a chemically and physically homogeneous mass. Whether carbon in its elemental condition is dissolved in the iron, or whether it is the carbide of iron, Fe_3C, which the iron holds in solution, is here immaterial. We may likewise ignore the various allotropic conditions assumed by iron. The solid solution of iron and carbon stable above the critical range is called "austenite." Whenever it is possible to preserve austenite in the cold to the exclusion of other constituents and to microscopically examine its structure, it is found to be made up of crystalline polyhedra or gains exhibiting in a polished section the appearance of a network, the meshes representing sections through as many grains, and the net itself, junction lines between adjacent grains. The size of the austenite grains increases with (1) the maximum temperature from which cooling starts, (2) the length of time during which the metal was kept at that temperature, and (3) the slowness of its cooling to the critical range. It will not be necessary, nor is it desirable, to further discuss here the probable crystallography of austenite. As to its physical properties, austenite is hard, tenacious, and ductile, but has a low elastic limit.

On slow cooling through the critical range, as shown in Fig. 1, Diagram I., the solid solution of iron and carbon is converted into a mechanical mixture or aggregate of ferrite and pearlite, the latter constituent itself being an aggregate, in definite proportion, of "ferrite" and the carbide Fe_3C, or "cementite." Ferrite and pearlite may be considered as representing the proximate structural composition of the steel, while ferrite and cementite are its ultimate structural constituents. Ferrite, like austenite, and, for that matter, like pure metals and solid solutions in general, is made up of polyhedric crystalline grains, giving rise, on sectional polishing, to network structures. Pearlite is built up after the pattern so characteristic of eutectic and eutectoid alloys, of parallel, alternate plates of its two components, namely, ferrite and cementite. These plates are so thin, however, that a magnification exceeding 200 diameters is generally required for their resolution. Ferrite is very soft and very ductile, but relatively weak, while pearlite is very tenacious and much harder, but also much less ductile.

It is seen that in cooling through its critical range steel undergoes deep structural changes, being converted from the state of a solid solution to that of an aggregate of varying coarseness. So great a transformation must be accompanied by no less momentous alteration of properties, and, indeed, there is little in common between the physical properties of austenite and those pertaining to the ferrito-pearlitic structure existing below the critical range.

Steel with 0.30 per cent. carbon is composed, after slow cooling through its critical range, of 64 per cent. ferrite and 36 per cent. pearlite, as graphically shown in Fig. 1, Diagram I. Bearing in mind the physical properties of its two components, ferrite and pearlite, it will be obvious that mild steel in its ferrito-pearlitic condition, while more tenacious and less ductile than ferrite, will be considerably less tenacious and more ductile than pearlite. Its tenacity, as a matter of fact, should be in the vicinity of 70,000 pounds per square inch, and its elongation in 2 inches should be about 20 per cent. These properties, moreover, will vary considerably in accordance with the coarseness or fineness of the ferrito-pearlitic structure, the finer structure being generally the more ductile. The structure of the steel, after slow cooling through the critical range, will, as a rule, be the coarser, the coarser the austenite immediately before its transformation, and this in turn, as already noted, depends chiefly upon the maximum temperature from which cooling started, the time the metal was kept at that temperature, and the rate of cooling.

It should be borne in mind that the ferrito-pearlitic structure just mentioned, and which corresponds to the end products of the structural transformation taking place within the critical range, results from slow cooling through that range, as, for instance, by allowing the piece to cool within the furnace in which it was heated. On hastening the cooling, structural conditions may be produced corresponding to widely different properties, as will now be described.

The transformation of the austenitic solution into a ferrito-pearlitic aggregation is not sudden, but, on the

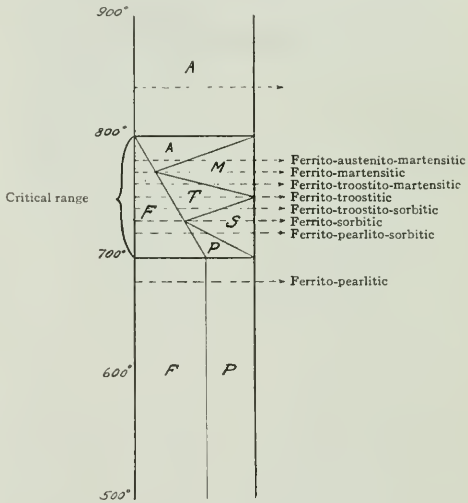

Fig. 2.

contrary, covers a notable range of temperature, while transition constituents are formed within the critical range, as depicted in Figs. 1 and 2. It is intended to show, by means of these diagrams, that, on entering the critical range, the austenite existing above that range is gradually converted into "martensite" with rejection of ferrite, a rejection which continues all through the range; that the martensite, on further cooling, is, in turn, transformed into troostite, which, at a still lower temperature, is itself converted into sorbite; while, finally, pearlite, the end product, forms as the steel emerges from its range. We thus recognize the existence of three so-called transition constituents—martensite, troostite, and sorbite—but it will be unnecessary to enter here into a discussion of their probable nature, a subject which is still, to a certain extent, a controversial matter. Martensite appears to be made up of needles, often forming equilateral triangles; troostite, which consists of irregular ragged or rounded masses; while sorbite exhibits a finely

granular and rather indistinct structure. In regard to physical properties, martensite is very hard and brittle, less hard and less brittle than martensite, while sorbite is less hard than troostite and more tenacious, but less ductile than pearlite.

By referring to Fig. 2 it will be seen that, theoretically at least, seven different structural conditions may be conceived to exist momentarily as the steel undergoes its critical transformation; namely, ferrito-austenito-martensitic, ferrito-martensitic, ferrito-troostito-martensitic, ferrito-troostitic, ferrito-troostito-sorbitic, ferrito-sorbitic, and ferrito-pearlito-sorbitic.

The mechanism of the structural changes depicted in Fig. 1, Diagram I., and in Fig. 2, refer to the changes taking place when the cooling is slow enough to permit

a complete transformation of the metal with final production of a ferrito-pearlitic structure. It will now be shown that through properly regulated cooling the transformation may be arrested at any desired stage in accordance with the physical properties wanted, which may vary from the hardness and brittleness of the quenched metal to the great softness and ductility resulting from very slow cooling. Between these two extreme types lies a great variety of combinations of hardness, strength, and ductility, each set corresponding to a well-defined treatment; hence the science and art of the heat treatment of steel, the importance of which steel-makers and users are only now beginning to fully appreciate.

In Fig. 1, Diagram II., the cooling has been so hastened that on reaching the bottom of the critical range the sorbite had been but partially converted into pearlite, the necessary time for its complete transformation having been denied. This quicker cooling has also prevented a full separation of the ferrite, as indicated in the diagram. The resulting structure may be described as ferrito-sorbito-pearlitic. Large pieces cooled in air often acquire it. Obviously, because of the properties of sorbite, steel in this condition is more tenacious, but less ductile, than the same metal in its ferrito-sorbitic state.
